This work is dedicated to Kenneth S. Norris,
great naturalist and first president of the
Society for Marine Mammalogy.
His passing in 1998 left a gap in all our lives.

CONTENTS

CONTENTS BY SUBJECT AREA xix
CONTRIBUTORS xxiii
PREFACE xxxv
GUIDE TO THE ENCYCLOPEDIA xxxvii

A

Abundance Estimation 1
Stephen T. Buckland, Anne E. York

Age Estimation 6
Aleta A. Hohn

Aggressive Behavior (Intraspecific) 13
Claudio Campagna

Albinism 16
Dagmar Fertl, Patricia E. Rosel

Amazon River Dolphin 18
(*Inia geoffrensis*)
Vera M. F. da Silva

Ambergris 20
Dale W. Rice

Anatomical Dissection: Thorax and Abdomen 21
John E. Reynolds III, Sentiel A. Rommel, Meghan E. Bolen

Antarctic Marine Mammals 30
Ian L. Boyd

Archaeocetes, Archaic 36
J. G. M. Thewissen

Arctic Marine Mammals 39
John J. Burns

Artiodactyla 45
Jessica M. Theodor

Atlantic Spotted Dolphin 47
(*Stenella frontalis*)
William F. Perrin

Atlantic White-Sided Dolphin 49
(*Lagenorhynchus acutus*)
Frank Cipriano

Australian Sea Lion 51
(*Neophoca cinerea*)
John K. Ling

B

Baculum 55
Edward H. Miller

Baiji 58
(*Lipotes vexillifer*)
Zhou Kaiya

Baleen 61
Dale W. Rice

Baleen Whales (Mysticetes) 62
John L. Bannister

Baleen Whales, Archaic 73
Nicholas C. Fraser, Alton C. Dooley, Jr.

Barnacles 75
Dagmar Fertl

Basilosaurids 78
Mark D. Uhen

Beaked Whales, Overview 81
James G. Mead

Bearded Seal 84
(*Erignathus barbatus*)
Kit M. Kovacs

Behavior, Overview 87
Peter L. Tyack

Beluga Whale 94
(*Delphinapterus leucas*)
Gregory M. O'Corry-Crowe

Biogeography 99
Rick LeDuc

Bioluminescence 102
Gregory K. Silber

Biomagnetism 104
Michael M. Walker

Blowing 105
James L. Sumich

Blubber 107
Sara J. Iverson

Blue Whale 112
(*Balaenoptera musculus*)
Richard Sears

Bones and Teeth, Histology of 116
Mary C. Maas

Bottlenose Dolphins 122
(*Tursiops truncatus* and *T. aduncus*)
Randall S. Wells, Michael D. Scott

Bottlenose Whales 128
(*Hyperoodon ampullatus* and
H. planifrons)
Shannon Gowans

Bowhead Whale 129
(*Balaena mysticetus*)
David J. Rugh, Kim E. W. Shelden

Bow-Riding 131
Bernd Würsig

Brain 133
Helmut H. A. Oelschläger, Jutta S.
Oelschläger

Brain Size Evolution 158
Lori Marino

Breaching 162
Hal Whitehead

Breathing 164
Douglas Wartzok

Breeding Sites 169
Mark A. Hindell

Bryde's Whales 171
(*Balaenoptera edeni* and *B. brydei*)
Hidehiro Kato

Burmeister's Porpoise 177
(*Phocoena spinipinnis*)
Julio C. Reyes

C

California, Galapagos, and Japanese Sea Lions 180
(*Zalophus californianus*, *Z. wollebaeki*, and *Z. japonicus*)
Carolyn B. Heath

Callosities 186
Mason T. Weinrich

Captive Breeding 188
Daniel K. Odell, Todd R. Robeck

Captivity 192
Peter Corkeron

Carnivora 197
Ronald E. Heinrich

***Cephalorhynchus* Dolphins** 200
(*Cephalorhynchus* spp.)
Stephen M. Dawson

Cetacea, Overview 204
Lawrence G. Barnes

Cetacean Ecology 208
Lisa T. Ballance

Cetacean Evolution 214
R. Ewan Fordyce

Cetacean Life History 221
Susan J. Chivers

Cetacean Physiology, Overview 225
Robert Elsner

Circulatory System 229
Paul J. Ponganis

Classification 231
Dale W. Rice

Clymene Dolphin 234
(*Stenella clymene*)
Thomas A. Jefferson

Coloration 236
William F. Perrin

Common Dolphins 245
(*Delphinus delphis*, *D. capensis*, and *D. tropicalis*)
William F. Perrin

Communication 248
Kathleen A. Dudzinski,
Jeanette A. Thomas, Etienne Douaze

Competition with Fisheries 268
Éva E. Plagányi,
Douglas S. Butterworth

Conservation Biology 273
Barbara L. Taylor

Conservation Efforts 276
Randall R. Reeves

Convergent Evolution 297
Emily A. Buchholtz

Courtship Behavior 299
Bernd Würsig

Crabeater Seal 302
(*Lobodon carcinophaga*)
John L. Bengtson

Culture in Whales and Dolphins 304
Hal Whitehead

Cuvier's Beaked Whale 305
(*Ziphius cavirostris*)
John E. Heyning

D

Dall's Porpoise 308
(*Phocoenoides dalli*)
Thomas A. Jefferson

Delphinids, Overview 310
Rick LeDuc

Delphinoids, Evolution of the Modern Families 314
Lawrence G. Barnes

Dental Morphology (Cetacean), Evolution of 316
Mark D. Uhen

Desmostylia 319
Daryl P. Domning

Dialects 322
John K. B. Ford

Diet 323
Nélio Barros, Malcolm R. Clarke

Distribution 327
Jaume Forcada

Diving Behavior 333
Brent S. Stewart

Diving Physiology 339
Gerald L. Kooyman

Dugong 344
(*Dugong dugon*)
Helene Marsh

E

Eared Seals (Otariidae) 348
Roger L. Gentry

Earless Seals (Phocidae) 352
Mike O. Hammill

Echolocation 358
Whitlow W. L. Au

Ecology, Overview 367
Bernd Würsig

Elephant Seals 370
(*Mirounga angustirostris* and *M. leonina*)
Mark A. Hindell

Endangered Species and Populations 373
John E. Reynolds III, Douglas P. DeMaster, Gregory K. Silber

Endocrine Systems 382
David J. St. Aubin

Energetics 387
Daniel P. Costa

Entrapment and Entanglement 394
Jon Lien

Estrus and Estrous Behavior 395
Daryl J. Boness

Ethics and Marine Mammals 398
Marc Bekoff

Evolutionary Biology, Overview 404
Frank Cipriano

Extinctions, Specific 408
Deborah A. Duffield

F

False Killer Whale 411
(*Pseudorca crassidens*)
Robin W. Baird

Feeding Strategies and Tactics 412
Michael R. Heithaus,
Lawrence M. Dill

Female Reproductive Systems 422
Robert E. A. Stewart,
Barbara E. Stewart

Filter Feeding 428
Donald A. Croll, Bernie R. Tershy

Finless Porpoise 432
(*Neophocaena phocaenoides*)
Masao Amano

Fin Whale 435
(*Balaenoptera physalus*)
Alex Aguilar

Fisheries, Interference with 438
Dagmar Fertl

Fishing Industry, Effects of 442

PREFACE

Marine mammals are awe inspiring, whether one is confronted with the underwater dash of a sea lion, a breaching humpback, or simply the sheer size of a beached sperm whale. It is no surprise that we are fascinated and intrigued by these creatures. Such fascination and curiosity brought us, the editors, to the study of marine mammals at the beginning of our careers, and they keep us excited now. To share the excitement and feed the curiosity of others, scientists or laypersons, we here attempt to summarize the field of marine mammalogy, in a very broad sense, including aspects of history and culture. This was the first reason to compile this encyclopedia.

The science of marine mammals goes back at least to Aristotle, who observed in 400 BC that dolphins gave birth to live young which were nursed with the mother's milk. Observations on the biology of marine mammals expanded throughout the Middle Ages, usually mixing freely with imagination and superstition. Konrad Gesner's *Historia Animalium* (1551), for instance, is a pictorial guide to the animals known in his time. Next to rhinos and seals, it also depicts the unicorn, the fabled mix of a horse and a narwhal. Interest greatly increased with the advent of hunting marine mammals on a large scale. Herman Melville's *Moby Dick* (1851) chronicles 19th century Western whaling and displays a curious mix of accurate natural history observations on whales with stubborn misconceptions (such as "whales are fish"). The great whaler/naturalist Charles Scammon accurately described the behavior and aspects of natural history of many species, albeit of necessity from his view behind gun and harpoon.

From these roots, marine mammal science has grown exponentially, especially since the Second World War. Unlike in earlier days, most contemporary research on marine mammals is carried out by observing living animals. Modern marine mammal studies combine aspects of mammalogy, ethology, ecology, animal conservation, molecular biology, oceanography, evolutionary biology, geology, and—in effect—all major branches of the physical and biological sciences, as well as some of the social sciences. This enormous breadth unfortunately necessitates that most marine mammalogists specialize, concentrating on one or a few aspects of marine mammal science and limiting the number of species that they study. Therein lies the second reason for compiling this encyclopedia: we aim to present a summary of the entire field for the scientist who needs information from an unfamiliar subfield.

As editors, we constrained what authors wrote as little as possible, applauding diversity and keeping to minimal guidelines. We consider modern marine mammals to include the mammalian order Cetacea (including whales, dolphins, and porpoises), the order Sirenia (dugongs and manatees), and many members of the order Carnivora: the polar bear, the sea otter and marine otter, and the pinnipeds (true seals, sea lions, fur seals, and walruses). We asked the authors to follow Rice (1998) for the species-level taxonomy and nomenclature of the modern marine mammals (with certain exceptions, as noted in the Marine Mammal Species list), as his work is an excellent, generally accepted listing of diversity.

There is some overlap among the articles. This is not an accident. As in every scientific field, different workers in marine mammalogy have different perspectives on many technical issues and disagree strongly on some of them. We urge the reader to use the cross-indexing to peruse different accounts relating to the same question; on some matters the jury is still very much out, and the range of views is interesting and important.

Ours is an encyclopedia, an alphabetically arranged compilation of articles that are independent and multi-authored, the only such work on marine mammals. However, some other recent books form excellent complements to our work. For example, *Handbook of Marine Mammals* (S. H. Ridgway and R. J. Harrison, Academic Press, 1985–1999) is a series of compendia presenting descriptions of the marine mammal species. *Biology of Marine Mammals* (J. E. Reynolds III and S. A. Rommel, Smithsonian Institution Press, 1999) presents an overview of marine mammals based on a number of long review chapters. *Marine Mammals: Evolutionary Biology* (A. Berta and J. L. Sumich, Academic Press, 1999)

presents a current review of the evolutionary aspects of marine mammal science in a textbook format. There are many other authored and edited books, monographs, and research papers, often on more specific topics or particular species. These are listed here in the bibliographies that follow each entry, and the interested reader is encouraged to make use of university libraries, major research libraries (such as in the Smithsonian Institution in Washington, DC, for example), and World Wide Web search engines to find out how to obtain specific reference works. In our modern computer-accessible information era, it is hardly ever appropriate to use the excuse "I cannot find the reference," and we hope that this encyclopedia serves as a text to help point the way.

We hesitated before agreeing to edit this encyclopedia. Marine mammalogy is an exceptionally broad field, ranging across many taxa and across disciplines from molecular genetics and microstructure to whaling history and ethics. We three are all cetologists: we study the evolution and biology of whales, dolphins, and porpoises, and we personally know relatively little about seals, sea cows, or whaling. But we rub shoulders with those who do know much about these things, in our laboratories and universities, in advisory bodies, and at conferences, so we were considered to be in a good position to elicit and edit articles from our colleagues. The project has been fatiguing and sometimes exasperating but elevating nonetheless. We have learned a lot along the way. We owe a great deal to many people. First we thank our editors at Academic Press: Chuck Crumly (the Encyclopedia was his concept and owes its existence to his drive), Gail Rice, and Chris Morris, who all put up bravely with our editing and publishing amateurism and endless missteps and interventions. A very large number of colleagues acted as anonymous peer reviewers for the articles. But the most credit must go to the authors, who gave so freely of their time and expertise. The Encyclopedia is appropriately an international project: articles were authored by scientists in Argentina, Australia, Brazil, Canada, China, Denmark, France, Georgia, Germany, Japan, Mexico, The Netherlands, New Zealand, Norway, Peru, Russia, South Africa, Spain, the United Kingdom, and the United States. The difficulties of such wide participation were eased by the Internet.

We and the authors have engaged in our tasks as a labor of love of our field. We hope that you find not only information in these pages, but also a sense of the excitement of the known and the mystery of the yet-to-be-explored. If this work so affects you, it will have been successful. We also hope that it will help stimulate our growing cadres of young colleagues, naturalists, conservationists, and citizens of earth to contribute to the efforts to save and protect these marvelous creatures of the seas.

GUIDE TO THE ENCYCLOPEDIA

The *Encyclopedia of Marine Mammals* is a complete source of information on the subject of marine mammals, contained within a single volume. Each article in the Encyclopedia provides an overview of the selected topic to inform a broad spectrum of readers, from researchers to students to the interested general public.

In order that you, the reader, will derive the maximum benefit from the *Encyclopedia of Marine Mammals*, we have provided this Guide. It explains how the book is organized and how the information within its pages can be located.

SUBJECT AREAS

The *Encyclopedia of Marine Mammals* presents 283 separate articles on the entire range of marine mammal study. Articles in the Encyclopedia fall within seven general subject areas, as follows:

- Anatomy and Physiology
- Behavior and Life History
- Ecology and Population Biology
- Evolution and Systematics
- Human Effects and Interactions
- Organisms and Faunas
- Research Methodology

ORGANIZATION

The *Encyclopedia of Marine Mammals* is organized to provide the maximum ease of use for its readers. All of the articles are arranged in a single alphabetical sequence by title. An alphabetical Table of Contents for the articles can be found beginning on p. vii of this introductory section.

As a reader of the Encyclopedia, you can use the alphabetical Table of Contents by itself to locate a topic. Or you can first identify the topic in the Contents by Subject Area and then go to the alphabetical Table to find the page location.

So that they can be more easily identified, article titles begin with the key word or phrase indicating the topic, with any descriptive terms following this. For example, "Noise, Effects of" is the title assigned to this article, rather than "Effects of Noise" because the specific term *Noise* is the key word.

ARTICLE FORMAT

Each article in the Encyclopedia begins with an introductory paragraph that defines the topic being discussed and summarizes the content of the article. For example, the article "Baculum" begins as follows:

> The baculum (os penis) is a bone in the penis of Insectivora, Chiroptera, Primates, Rodentia, and Carnivora; it is absent from Cetacea and Sirenia. The corresponding element in females is the os clitoridis. In marine mammals the baculum and os clitoridis have been studied mainly in pinnipeds.

Major headings highlight important subtopics that are discussed in the article. For example, the article "Intelligence and Cognition" includes the topics "Brain Size and Characteristics," "Learning," and "Behavioral Complexity in Nature."

CROSS-REFERENCES

The *Encyclopedia of Marine Mammals* has an extensive system of cross-referencing. References to other articles appear in three forms: as marginal headings within the A–Z article sequences; as designations within the running text of an article; and as indications of related topics at the end of an article.

As an example of the first type of reference cited above, the following marginal entry appears in the A–Z article list between the entries "Antarctic Marine Mammals" and "Archaeocetes, Archaic":

Aquariums
SEE *Marine Parks and Zoos*

This reference indicates that the topic of Aquariums is discussed elsewhere, under the article title "Marine Parks and Zoos."

An example of the second type, a cross-reference within the running text of an article, is this excerpt from the entry "Baleen Whales:"

> External parasites, particularly WHALE LICE (cyamid crustaceans) and BARNACLES (both acorn and stalked) are common on the slower swimming more coastal baleen whales, such as gray, humpback, and right whales.

This indicates that the items "whale lice" and "barnacles," which are set off in the text by small capital letters, appear as separate articles within the Encyclopedia.

An example of the third type, a cross-reference at the end of the article, can be found in the entry "Forensic Genetics." This article concludes with the statement:

See Also the Following Articles:

Classification Molecular Ecology Stock Identity

This reference indicates that these three related articles all provide some additional information about forensic genetics.

BIBLIOGRAPHY

The Bibliography section appears as the last element of an article, under the heading "References." This section lists recent secondary sources that will aid the reader in locating more detailed or technical information on the topic at hand. Review articles and research papers that are important to a more detailed understanding of the topic are also listed here.

The Bibliography entries in this Encyclopedia are for the benefit of the reader, to provide references for further reading or additional research on the given topic. Thus, they typically consist of a limited number of entries. They are not intended to represent a complete listing of all the materials consulted by the author or authors in preparing the article. The Bibliography is in effect an extension of the article itself, and it represents the author's choice of the best sources available for additional information.

RESOURCES

The final pages of the *Encyclopedia of Marine Mammals* contain three important resources for the reader.

- Species List. This section provides a complete list of living and extinct marine mammal species.
- Biographies. This section provides biographical information for more than 50 noted scientists who made important contributions to the field of marine mammal study.
- Comprehensive Glossary. This section provides definitions for more than 1,000 specialized terms that are used in the articles.

INDEX

Within the subject index entry for a given topic, references to general coverage of the topic appear first, such as a complete article on the subject. References to more specific aspects of the topic then appear below this in an indented list.

ENCYCLOPEDIA WEB SITE

The *Encyclopedia of Marine Mammals* maintains its own editorial Web Page on the Internet at:

http://www.apnet.com/narwhal/

This site gives information about the Encyclopedia project and features links to many related sites that provide information about the articles of the Encyclopedia. The site will continue to evolve as more information becomes available.

Abundance Estimation

STEPHEN T. BUCKLAND
University of St. Andrews, Scotland, United Kingdom

ANNE E. YORK
National Marine Mammal Laboratory, Seattle, Washington

Abundance estimation covers the range of techniques by which the size of a population of marine mammals can be estimated. Such population size estimates are often referred to as "absolute" abundance estimates. When it is difficult to estimate absolute abundance with an acceptably low bias, relative abundance indices are often used instead. These are indices that are believed to be proportional to population size, apart from stochastic variation, allowing trends in the population in space and/or time to be assessed. The main techniques for abundance estimation (relative or absolute) are distance sampling, mark-recapture, migration counts, and colony counts.

I. Distance Sampling

Distance sampling (Buckland *et al.*, 1993) is the most widely used technique for estimating the abundance of animal populations. Because it is particularly suited to populations of animals that are readily detectable (at least at close quarters) and sparsely distributed over a large area, it is unsurprising that the methods are widely used by marine mammalogists. Indeed, most of the innovative developments in distance sampling in the last two decades have arisen through applications of the methodology to cetaceans. Distance sampling has also been applied on several populations of ice seals.

The two primary methods of distance sampling are line transect sampling and point transect sampling. The latter method has never to our knowledge been applied to marine mammal populations, and we therefore concentrate mostly on line transect sampling. Another distance sampling method is cue counting, which was developed specifically for populations of large whales, and the theory for which is closely similar to that for point transects. Distance sampling data may be analyzed using software Distance (Thomas *et al.*, 1998).

A. Line Transect Sampling

1. Survey Design In line transect sampling, the survey design comprises a set of straight lines, spanning the full study area for which an abundance estimate is required. For marine mammal surveys, the lines are covered by a team of observers on a ship or boat or by one or more observers in an aircraft. The methodology requires that lines are randomly placed in the study area or that a grid of systematically spaced (i.e., equally spaced) lines is randomly located in the area. Because efficiency is improved if lines are placed perpendicular to density contours, a common design for inshore surveys is to have a series of parallel lines, randomly spaced or more usually systematically spaced, as far as possible perpendicular to the coastline. The study area is often divided into geographic blocks or strata, allowing different orientations of the grid of lines in different strata and allowing effort to be greater in high-density strata. For shipboard surveys especially, systematic zig-zag designs are often used because there is then no loss of expensive ship time in traversing off-effort (i.e., not searching for marine mammals) from one line to the next. The ship can then be continuously searching for marine mammals during daylight hours.

2. Assumptions The following three assumptions should hold:

1. Animals on or very close to the line are certain to be detected (but see later).
2. Animals are detected before they respond to the presence of the observer, and nonresponsive movement is slow relative to the speed of the observer.
3. Distances are measured accurately (for ungrouped distance data), or objects are correctly allocated to distance interval (for grouped data).

Bias from nonresponsive movement is generally negligible, provided that the average speed of the animals is less than one-half of the speed of the observer. A fourth assumption is made in

many derivations of estimators and variances: whether an object detected is independent of whether any other object is detected. Point estimates are robust to the assumption of independence, and robust variance estimates are obtained by taking the line to be the sampling unit, either by bootstrapping lines or by calculating a weighted sample variance of encounter rates by line.

We do not need to assume that animals are randomly distributed throughout the survey area, provided that lines are placed randomly with respect to the animals. This ensures that objects in the surveyed strip are uniformly distributed with distance from the line.

3. Estimation Perpendicular distances x are measured from the line to each detected animal. (We will consider the case that animals occur in groups later.) In practice, for shipboard surveys, detection distances r and detection angles θ are usually recorded, from which perpendicular distances are calculated as $x = r\sin(\theta)$ (Fig. 1). Suppose there are k lines of lengths $l_1, \ldots, l_k$ (with $\Sigma l_j = L$), and n animals are detected, at perpendicular distances $x_1, \ldots, x_n$. Suppose that animals further than some distance w from the line are not recorded. Then the surveyed area is $a = 2wL$, within which n animals are detected. However, not all animals within the surveyed area are detected. Let the effective half-width of the strip be $\mu < w$ (so that the proportion of animals within the surveyed strip that are detected is μ/w). Then animal density (number of animals per unit area) is estimated by

$$\hat{D} = \frac{n}{2\hat{\mu}L} \qquad (1)$$

Abundance is estimated as $\hat{N} = A\hat{D}$, where A is the size of the study area. We therefore need an estimate $\hat{\mu}$ of μ. The software Distance provides comprehensive options for these analyses.

4. Variance and Interval Estimation The variance of $\hat{D}$ may be approximated using the delta method, assuming no correlation between n and $\hat{\mu}$:

$$\hat{V}(\hat{D}) = \hat{D}^2\left[\frac{\hat{V}(n)}{n^2} + \frac{\hat{V}(\hat{\mu})}{\hat{\mu}^2}\right]$$

The variance of n is generally estimated from the sample variance in encounter rates, n_j/l_j, weighted by line lengths l_j. When $\hat{\mu}$ is estimated by maximum likelihood, its variance is estimated from the information matrix.

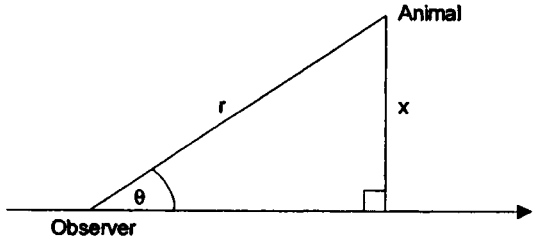

Figure 1 *The observer records an animal at detection distance r and detection angle θ, from which the perpendicular distance is calculated as x = r sin(θ).*

If we assume that $\hat{D}$ is log-normally distributed, approximate 95% confidence limits are given by $(\hat{D}/C, \hat{D}C)$ where

$$C = \exp\{1.96[\hat{V}(\log_e \hat{D})]^{0.5}\}$$

with $\hat{V}(\log_e \hat{D}) = \log_e [1 + \hat{V}(\hat{D})/\hat{D}^2]$.

Often, bootstrap variance and interval estimation are preferred. Resamples are usually generated by sampling with replacement from the lines so that independence between the lines is assumed, but independence between detections on the same line is not.

5. Estimation When Animals Occur in Clusters Animals often occur in groups, which we term "clusters." If one animal in a cluster is detected, it is assumed that the whole cluster is detected, and the position of the cluster is recorded. Equation (1) then gives an estimate of the density of clusters. To obtain the estimated density of individuals, we must multiply by an estimate of mean cluster size in the population, $E(s)$:

$$\hat{D} = \frac{n\hat{E}(s)}{2\hat{\mu}L}.$$

The corresponding variance estimate is

$$\hat{V}(\hat{D}) = \hat{D}^2\left[\frac{\hat{V}(n)}{n^2} + \frac{\hat{V}(\hat{\mu})}{\hat{\mu}^2} + \frac{\hat{V}\{\hat{E}(s)\}}{\{\hat{E}(s)\}^2}\right].$$

Because the probability of detection is often a function of cluster size, the sample of cluster sizes exhibits size bias. In the absence of size bias, we can take $\hat{E}(s) = \bar{s}$, the mean size of detected clusters. Several methods exist for estimating $E(s)$ in the presence of size bias (Buckland *et al.*, 1993).

The just-described methods assume that once a cluster of animals is detected, it is possible to record the size of that cluster accurately. For shipboard and aerial surveys, this often dictates that at least part of the survey is conducted in "closing mode." After detection, search effort ceases, and the vessel closes with the detected cluster, to allow more accurate estimation of cluster size. This strategy also eases the difficulties of species identification. If "passing mode" is adopted, then underestimation of the size of more distant clusters might be anticipated. Regression methods for correcting size bias also correct for this bias, provided that the sizes of clusters on or close to the transect line are estimated without bias. Where cluster size estimation is problematic, observer training is usually necessary to ensure that bias is not large.

6. Estimation When Detection on the Line Is Not Certain The standard line transect method assumes that animals on the line are certain to be detected. Double-platform methods in which observers search simultaneously from two platforms are therefore becoming commonplace. This allows extension of the standard methods to the case that animals on the line are not certain to be detected and also, given appropriate field methods, allows adjustment for responsive movement of animals prior to detection. Several researchers have made advances in developing methodology for analyzing such data, notably Borchers *et al.*

(1998). Their method uses Horvitz–Thompson-type estimators and also yields a unified approach to the analysis of line transect data in which animal density is estimated in a single step, which contrasts with the conventional strategy of independently estimating the three parameters: encounter rate, effective strip width, and mean cluster size. Double-platform surveys are used widely in cetacean surveys and have also been used for estimating the abundance of POLAR BEARS (*Ursus maritimus*).

7. Current Areas of Research Active research topics likely to become available shortly in software Distance include spatial modeling of line transect data; integrated analysis of double-platform data; general methods for incorporating covariates in analyses; automated survey design algorithms; and adaptive line transect sampling.

B. Strip Transect Sampling

Strip transect sampling is a special case of line transect sampling in which it is assumed that all animals out to the truncation distance w are detected. This simplifies analysis, and distances of detected animals from the line need not be measured, except to ensure that they are within distance w of the line. However, the method is seldom efficient for marine mammals; if the strip is narrow enough to ensure that all animals out to w are detected, then many animals are detected beyond w, and these observations must be ignored. Abundance of sirenian populations has traditionally been obtained by strip transect methods.

C. Cue Counting

In cue counting, observers on a ship or in an aircraft cover a sector ahead of their observation platform and record all cues detected within the sector and the distances of the cues from the platform. In principle, the method can be used for any marine mammal, but in practice, it has been used primarily for large whales, for which the cue is the blow. The same design considerations apply as for line transect sampling, although the analysis is essentially the same as for point transect sampling.

If cues are well defined (as blows of large whales are), then cue counting has the advantage over line transect sampling that the recording unit is the individual cue. Observers need not identify whether different cues are from different animals or how many animals are in a cluster. It also does not matter if some whales stay down so long that they will be undetectable even if they are on the transect line, provided that all cues within the recording sector and very close to the observation platform are detected. Another advantage is that the method requires observer-to-animal distances, which are easier to estimate than perpendicular distances of animals from the line. The main disadvantage is that the method yields estimates of cue density per unit time, which can only be converted into whale density by estimating the cue rate from additional costly surveys. The estimated cue rate is prone to bias, both because animals may behave differently when a survey ship is close by and because it is easier to monitor animals that cue frequently, thus biasing the cue rate upward. Additionally, if animals cue more frequently when a ship is bearing down on them, an excess of short distances will be observed in the distance data, biasing the estimation of cue density.

The number of cues per unit area per unit time is estimated by

$$\hat{D}_c = \frac{2n}{\phi \hat{\rho}^2 T},$$

where n is the number of cues detected in time T, ϕ is the angle of the sector in radians, and $\hat{\rho}$ is the estimated effective radius of detection. Estimated density is then

$$\hat{D} = \frac{\hat{D}_c}{\hat{\lambda}},$$

where $\hat{\lambda}$ is the estimated number of cues per animal per unit time (the cue rate). As before, abundance is estimated as $\hat{N} = A\hat{D}$, where A is the size of the study area.

Because cues may be from the same whale, or the same pod of whales, they cannot be assumed independent. However, this is not a problem given the robust variance estimation methods provided by software Distance.

If cues immediately ahead of the vessel might be missed, double-platform methods similar to those for line transect sampling may be used. This has the advantage over those analyses in that it is easier to identify whether a single cue is seen from both platforms, e.g., by recording exact times of cues, than to identify whether a single animal or animal cluster is seen by both platforms, as the two platforms may see different cues from the same animal.

II. Mark-Recapture

Mark-recapture tends to be more labor-intensive and more sensitive to failures of assumptions than distance sampling. However, it is applicable to some species that are not amenable to distance sampling methods and can yield estimates of survival and recruitment rates, which distance sampling cannot do. Mark-recapture methods can be useful for populations that aggregate at some location each year, whereas distance sampling methods are more effective on dispersed populations. They should therefore be seen as different tools for different purposes. Among marine mammals, mark-recapture has been used most often to estimate the abundance of pinnipeds, usually for the estimation of young of the year. Polar bears have also been the subject of mark-recapture studies. Perhaps the most comprehensive software currently available for analyzing mark-recapture data is MARK (White, 1999).

A. Estimation from a Tagged Subset of Animals

1. The Petersen Estimator In its simplest form, mark-recapture consists of marking a sample of M animals from a population of unknown size N, returning the animals to the population and then removing, capturing, or observing a sample of n animals. Suppose that, of these n animals, m were marked. We assume that the proportion of marked animals in the second sample is a valid estimate of the proportion of marked animals in the population, giving the following "Petersen" estimate of population size: $\hat{N} = nM/m$.

2. Chapman's Modified Estimator Inference for this model is complicated by the fact that the variance of $\hat{N}$ is infinite unless $n + M > N$, in which case m cannot be zero. Chapman's estimator $\hat{N}_c = (n + 1)(M + 1)/(m + 1) - 1$ has a lower bias (and no bias for $n + M > N$), provided that the assumptions of the estimator are satisfied. It has variance

$$\hat{V}(\hat{N}_c) = \frac{(n + 1)(M + 1)(n - m)(M - m)}{(m + 1)^2(m + 2)}.$$

Many variations on this theme have been developed, including extensions to multiple samples, extensions to open populations, "single release" methods, and "single recapture" methods (particularly suited for when the mark is recovered from a dead animal). We make no attempt to cover these methods here, but refer the reader to Seber (1982).

3. Assumptions The assumptions required for $\hat{N}$ to be a reasonable estimate of population size are that the population of interest is closed over the survey period and that animals are marked and resighted or recaptured at random. In using the ordinary Petersen estimate, it is also assumed that marks are not lost during the survey period and that marking does not affect the probability of resighting or recapturing the animal. Methods have been developed to circumvent these assumptions and the literature for this topic is rich (e.g., Otis *et al.*, 1978; Pollock, 1990). For most wildlife populations, probabilities of recapture or resighting tend to vary among animals for a variety of reasons. This heterogeneity can be problematic to model and can lead to a large bias in abundance estimates, so that the design of a mark-recapture survey should be carefully addressed to minimize heterogeneity.

4. Estimation of Pinniped Numbers by Mark-Recapture Mark-recapture techniques have been successfully used to estimate the abundance of young of the year for several species of fur seals. Chapman and Johnson (1968) described the first successful application of this technique for the population of northern fur seals (*Callorhinus ursinus*) on the Pribilof Islands. They marked seals by shearing some hair from their heads and later went back to the colony and counted numbers of marked and unmarked animals within groups of animals. They calculated a Petersen estimate of abundance, which they verified on small colonies where direct counts of young of the year could be made. Resighting was replicated on each colony and several procedures for estimating the variance of the total population size were investigated. These included (1) an empirical estimate calculated as the variance of the mean of replicated estimates for each colony, and the variance of the total calculated by summing the individual colony variances, and (2) a variance for each replicated colony estimate assuming the hypergeometric distribution, with the variance of the mean count for each colony estimated from the variances of the individual counts. They also discussed the use of interpenetrating subsamples to estimate the variance. This procedure is similar in flavor and intent to the bootstrap procedure.

5. Mark-Recovery Methods Before the development of line transect methods for estimating the size of populations of large baleen whales, mark-recovery studies were carried out in which "Discovery" marks were fired into whales, a proportion of which would later be recovered by whalers. Disadvantages of this approach included a requirement for very large sample sizes to ensure an adequate number of recaptures; a long delay before sufficient data accumulated to allow abundance to be estimated; and strong sensitivity of abundance estimates to failures of assumptions. The methods were largely unsuccessful. For a review of the mark-recapture models that are potentially relevant to such data, and of the numerous sources of potential bias in the abundance estimates, see Buckland and Duff (1989). Before the development of mark-recapture or mark-resight techniques for northern fur seal pups, there were many attempts to estimate the population size by tagging pups at birth and recovering the tags in a commercial harvest. This application failed for similar reasons that the use of Discovery tags failed to properly estimate the size of cetacean populations.

B. Use of Natural Markings

Studies that use natural markings to identify individual animals in a population have become widespread in recent years. These usually rely on photo identification of individuals. A significant milestone in the use of such methods was Hammond and colleagues (1990), which comprises an edited collection of papers from a workshop on the topic. While the technique is undoubtedly of great value, it is important to be aware of its limitations.

Natural markings data can be very effective for estimating survival rates of marine mammals. Abundance estimation is more problematic, as this involves extrapolation from the identified subpopulation. If a high proportion of the population (>80%) can be identified, then abundance estimates are likely to have small bias, especially as there is a tendency to underestimate population size. It is possible to achieve such high rates, e.g., for small coastal populations of bottlenose dolphins (*Tursiops truncatus*) and pinniped colonies, provided individuals have distinct markings. The method is then useful because it allows enumeration of almost the whole population without fear of double counting individuals or of seriously underestimating population size. When smaller proportions of animals are identified, estimates of population size can be badly compromised for a variety of reasons. Severe heterogeneity in the "capture" probabilities is common, e.g., because some natural markings are identified much more readily than others or because some individuals are more approachable than others. It is notoriously difficult to model such mark-recapture data reliably. Another problem is that the population being estimated is not always well defined, with some animals from elsewhere temporarily entering the population and others temporarily absent. A severe problem for large populations, in which only a small proportion can be identified, is that false positives in the matching procedure, even if they occur only rarely, can lead to a substantial underestimation of population size. Genetic fingerprinting, if feasible, can reduce this problem substantially.

Natural markings studies are invaluable for estimating survival and birth rates, for MIGRATION routes, and for detailed studies, including abundance estimation, of a small population. However, they are rarely a cost-effective or reliable method for

estimating the size of large populations of marine mammals. Given the current research interest in this topic, especially for estimating abundance of feeding or breeding aggregations of humpback (*Megaptera novaeangliae*), blue (*Balaenoptera musculus*), and right whales (*Eubalaena* spp.), further advances can be anticipated that will widen the applicability of the methods.

III. Migration Counts

Many populations of large whales conveniently file past coastal watch points on migration, allowing observers to count a large proportion of the population. This count can then be corrected for animals passing outside watch periods to estimate population size. In practice, further corrections are needed, e.g., to adjust for pods that pass undetected during watch periods, for biased estimation of pod size, for different rates of passage between day and night, and for a component of the population that fails to pass the watch point. Despite the need for various correction terms, migration count data yield very precise estimates of abundance with low bias, provided that the more significant correction factors are estimated reliably. This is unsurprising given that typically 30–40% of the population might be seen by the observers, a much higher fraction than is normal in a distance sampling survey.

The methods usually used for modeling migration counts were developed for the analysis of surveys of the California gray whale (*Eschrichtius robustus*). To estimate numbers of undetected pods passing during watch periods, two count stations operate independently, and these double-count data are modeled using logistic regression. A polynomial model is used to estimate the rate of passage as it varies through the season, from which numbers of whales passing outside watch periods are estimated. A Bayesian approach is used for analyzing similar data on bowhead whales (*Balaena mysticetus*).

IV. Colony Counts

Many populations of pinnipeds gather for breeding and pupping at certain times of the year. Researchers often make counts of these populations from cliffs above the colonies, from planes flying overhead, or sometimes from ships passing the colony. Often photographs are taken of the colonies. These are brought back to the laboratory for analysis and form a permanent record of the population. In most pinniped populations, it cannot be assumed that all the animals are on shore at any given time, although in fur seal populations, there is a time window in which almost all of the young of the year and breeding males are present, and in certain phocid populations all the young of the year and breeding females are present. Thus, colony counts alone cannot be used to determine absolute abundance of the population size, except for certain classes of animals, and this depends on the reproductive patterns of the population of interest, which must be taken into account when the survey is designed. Serial colony counts can be used to determine the rate of increase of the population if the same proportion of animals is present each year at the colony when the counts are made. This assumption is most likely valid for young of the year. For other segments of the population, this assumption fails if the timing of reproduction changes or if conditions at sea change so that animals need to spend a different amount of time at sea feeding and consequently a different amount of time at the colony.

The size of the harbor seal (*Phoca vitulina*) population in the state of Washington is estimated by combining colony counts made during aerial surveys and mark-recapture to account for animals not present during the aerial surveys. Transponder tags with unique frequencies are attached to animals before the surveys. During the flyovers, animals on shore are counted and radio searches are made to determine the proportion of animals that is ashore. The total population is estimated as $\hat{N}_{tot} = \overline{N}/\hat{p}$ where $\overline{N}$ is the average count of animals on shore and $\hat{p}$ is the estimated fraction of marked animals on shore. The variance of $\hat{N}_{tot}$ is estimated as

$$\hat{V}(\hat{N}_{tot}) = \frac{\hat{V}(\overline{N})}{\hat{p}^2} + \overline{N}^2\hat{V}\left(\frac{1}{\hat{p}}\right) - \hat{V}(\overline{N})\hat{V}\left(\frac{1}{\hat{p}}\right),$$

where $\hat{V}(\overline{N}) = s^2/n$, with s^2 equal to the sample variance of the n counts, and $\hat{V}(1/\hat{p}) = \hat{V}(\hat{p})/\hat{p}^4 = (1 - \hat{p})/M\hat{p}^3$, with M equal to the number of marked animals.

A corrected count method is also used to estimate numbers of southern elephant seal (*Mirounga leonina*) and fur seal pups (*Arctocephalus gazella*) on South Georgia. In those surveys, counts of adult females are made from shore or ship along the whole coastline during the pupping season. The counts made at any particular site are then used to estimate the total production for that site based on the adult female haul-out curves and pregnancy/pupping rate estimates from sites that are monitored regularly (twice daily in the case of fur seals) through the breeding season. Similarly, the abundance of northern fur seal pups on the Pribilof Islands is sometimes estimated from mark-recapture estimates on sample colonies coupled with counts of breeding males on all colonies (York and Kozloff, 1987). The ratio of pups to breeding males, estimated on the sampled rookeries, is multiplied by the total count of breeding males on all colonies.

The sizes of colonies of pinnipeds can also be determined using estimates of the area of all colonies coupled with estimates of the density of animals on those colonies. Although this method is often used to estimate the sizes of bird colonies, it has only been used occasionally to estimate pinniped population sizes. The estimates of the areas of the colonies were made from maps of the colonies. Counts or corrected counts, or mark-recapture estimates of the population of interest, are determined on a subsample of colonies. It is assumed that the density of animals in the sampled colonies is representative of the density on all colonies and that the total population is estimated by multiplying the total area by the estimated density. Researchers attempted to use this method to estimate the size of the Pribilof northern fur seal population in the late 1940s. At that time, it was thought that the variability of the estimates was too large and efforts were begun to design mark-recapture studies.

Counts, or more often corrected counts, are also sometimes attempted on other marine mammals. For example, because sea otters (*Enhydra lutris*) are difficult to survey by other means, they tend to be counted from a boat. Such counts typically underestimate population size, sometimes substantially so (Udevitz *et al.*, 1995).

Age Estimation

ALETA A. HOHN
National Marine Fisheries Service, Beaufort, North Carolina

Age estimation is a tool for obtaining a numerical value of age for animals for which actual age is not known. Currently, age is estimated primarily from counts of growth layers deposited in several persistent tissues, primarily TEETH, less often bone, and in some cases from other layered structures or from chemical signals. Growth layers in the persistent structures are similar in concept to growth rings in trees. Until use of growth layers became a feasible means of age estimation, relative measures of age, such as tooth wear, pelage or skin color, or fusion of cranial sutures, allowed individuals to be placed in age groups; these techniques largely have been replaced with methods that allow for estimation of absolute age by counting growth layers. Marine mammalogists pioneered age estimation from counting growth layers in teeth; this discovery was followed by widespread use for terrestrial mammals as well. Much of the development of this field has focused on how to ensure that age estimates are accurate and precise. That focus has been directed toward verifying the amount of time represented by a growth layer (i.e., calibration or validation), developing increasingly better ways to prepare samples for optimizing counts, and standardizing methods to ensure that growth layer counts are consistent among studies.

Age is fundamental to interpreting and understanding many aspects of the biology of marine mammals. The traditional and most obvious use of age is for estimating parameters used in population dynamics models. Age-specific estimates of fecundity or mortality can be used in these models to project population growth, for example. Estimates of age at sexual maturation are used in absolute terms in population models, whereas changes in this parameter have been interpreted to reflect changes in population abundance or resource availability and, therefore, indicate a density-compensatory response. Population age structure would also be a useful parameter, although it is rarely known. It is possible, however, to determine the age structure of individuals removed from a population intentionally, such as through directed fisheries, or incidentally, such as bycatch. This information then can be used to refine estimates of the impact of fisheries on those populations.

The need for accurate and precise estimates of age does not end with traditional population modeling. Of late, there has been increasing concern about the effects of contaminants on the health of marine mammals. Because many of these contaminants bioaccumulate, interpretation of the measured levels of organic or inorganic compounds must be taken as a function of the age, and reproductive condition, of the individual. Furthermore, because indices of health such as blood parameters change naturally with age, understanding the effects of contaminants or other factors on the health of individuals also requires knowing their age. With the recent epizootic events involving morbilliviruses (Tautenberger *et al.,* 1996), the ages of individuals infected as well as those with titers indicating previous infections become important in understanding the epidemiology of these outbreaks.

I. Growth Layer Terminology

In the context of age estimation, the term growth layer is ambiguous. That is because annual increments, as a rule, comprise more than the minimum two growth layers, e.g., a broad layer and a fine layer, needed to differentiate one annual increment from the next. Other layers are usually present; these layers are often referred to as accessory or incremental layers. These are all growth layers. It has been suggested that the existence of an annual layering pattern is controlled endoge-

nously whereas individual growth layers represent events that have a systemic effect on the animal and therefore influence the deposition of the collagen matrix or mineral in teeth or bone. Events that have been suggested include lunar cycles, maturation, pregnancy, lactation, weaning, and feeding bouts. In essence, the annual increments themselves, as well as any layers formed within the annual increments, are recording structures that reflect the physiology of an individual at the time of deposition (Klevezal, 1996). Interpreting these structures is an interesting pursuit itself and can serve as another tool for elucidating life history events for individuals. In the context of age estimation and identifying annual increments, however, they can cause errors and confusion and have resulted in semantic controversies with regard to the term "growth layer."

To help remedy confusion in terminology, a more descriptive phrase, growth layer group (GLG), was coined at a workshop held in 1977 on estimating age in toothed whales and sirenians (Perrin and Myrick, 1980), predominantly in reference to dentine. Its use has expanded, however, to other marine mammal species and to cement as well as dentine. A GLG is a group of layers that occur with cyclical and predictable repetition. Strictly speaking, a GLG is a generic term and does not automatically imply deposition that occurred over a 1-year period. It needs to be defined for each species and each use. For practical purposes, however, a GLG generally is defined by authors to represent 1-year's deposition, i.e., "annual" is implied. The term "annual layer" is equivalent to "annual GLG."

II. Calibration of Annual Layers

Verification that annual layers exist within the complement of visible layers derives from validation or calibration studies. Notably, the first confirmation of annual layers in pinniped teeth occurred soon after teeth were examined for the possibility of age estimation; Scheffer (1950) found external layers (ridges) in the canines of northern fur seals, *Callorhinus ursinus*, that corresponded to the known age of seals branded as pups and recovered up to 8 years later. Further studies to validate annual layering patterns and to show that patterns are consistent among individuals and species have involved three approaches: (1) examining teeth or bone from animals of known age or known history; (2) examining teeth or bone marked with tetracycline; and (3) comparing growth layers in teeth that have been removed at known intervals (multiple extractions).

For cetaceans, animals of known age or with a known history most often were captive for all or much of their lives. In the latter situation, support for annual layers then hinges on counts of the number of presumed annual layers corresponding to the known age or to the known approximate age of the animal given the length of time it spent in captivity and other data, such as its body length when removed from the wild. Initial encouragement that growth layers in dolphin teeth were annual was from three captive common bottlenose dolphins, *Tursiops truncatus* (Sergeant, 1959). Teeth obtained from free-ranging *Tursiops* of known age and known history were significant for confirming and identifying annual layering patterns and determining that annual layers in free-ranging bottlenose dolphins were similar to those in their captive conspecifics (Hohn *et al.*, 1989). Within pinnipeds, sirenians, and sea otters (*Enhydra lutris*), numerous studies of free-ranging tagged or individually identified animals have compared the number of growth layers in tooth sections to known ages (e.g., Bowen *et al.* 1983; Arnbom *et al.*, 1992). In many of these studies, as in cetacean studies, the actual age of individuals is greater than the "known age" because animals were captured or tagged some time after their birth. Thus, the number of growth layers counted is compared to that minimum age plus an additional number of years estimated as a function of the size of the animal at the time it was first tagged or identified. The most recent and rigorous studies counted growth layers without knowledge of the known ages of specimens in the sample, which eliminates a bias in counting. What is notable about all of these studies is that the authors concluded that they were able to identify annual growth layers (annual GLGs) that correspond to known ages or known approximate ages of the individuals in their samples at least up to some minimum age.

True calibration of growth layer deposition over extended periods of time relative to the life span of an animal has not been attempted. To do so would require direct marking of layers, such as through administration of tetracycline, preferably at the same time each year and ideally on the animal's birthday. Tetracycline binds permanently to actively growing mineralized tissue and fluoresces when a bone or tooth is viewed under ultraviolet light, hence its ability to serve as a marker. Two tetracycline treatments or one treatment followed by extraction have been used to unambiguously identify growth layer deposition over the period of time between the marks, providing a limited calibration; annual layers were determined from this method for several dolphin species, most extensively for spinner dolphins, *Stenella longirostris* (Myrick *et al.*, 1984) and common bottlenose dolphins (Myrick and Cornell, 1990). Alternatively, multiple extractions of teeth from an individual allow for calibration but with much restricted sampling opportunities. This method has been used with free-ranging bottlenose dolphins where two teeth were extracted and growth layer deposition between extractions compared (Hohn *et al.*, 1989). Limited opportunities exist for extensive direct calibration, although captive animals could be used for such studies as could free-ranging populations where individuals are resighted each year and could be caught, administered tetracycline, and released.

III. Tissues Commonly Used to Obtain Absolute Age Estimates

Given the importance of obtaining age estimates, various tissues and methods have been investigated for elucidating growth layers (Klevezal, 1996; McCann, 1993; Perrin and Myrick, 1980). The most commonly used tissue has been teeth, as for terrestrial mammals (Klevezal and Kleinenberg, 1967). Fortunately, odontocetes (Figs. 1–3), pinnipeds, sea otters (Fig. 4), and polar bears (*Ursus maritimus*) have teeth that are suitable for use in estimating age. In contrast, because teeth cannot be used for baleen whales and manatees, other tissues or methods have been investigated. As alternatives, incremental layers have been found in bone, baleen, and ear plugs. Teeth

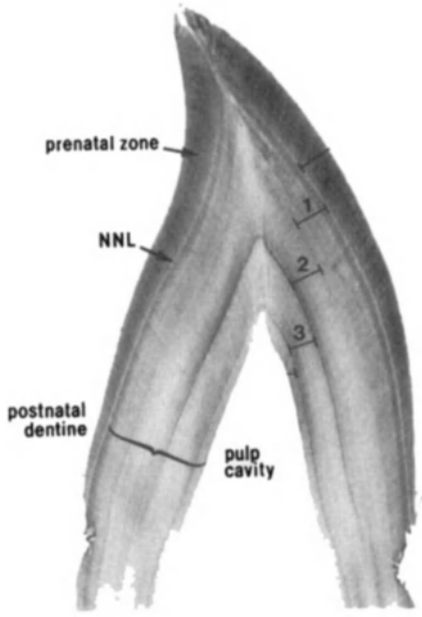

Figure 1 *Decalcified and stained midlongitudinal section in the buccal–lingual plane from a free-ranging bottlenose dolphin known to be 3 years of age. This view shows only the upper half of the section. The neonatal line (NNL) represents the time when the animal was born and, therefore, is age "0" for the purpose of estimating age. Dentine external to the neonatal line was deposited before birth and is known as prenatal dentine, whereas the neonatal line and dentine internal to it is postnatal dentine. A thin layer of enamel covered the prenatal dentine but was removed when the tooth was decalcified. The first three complete presumed annual growth layers or GLGs are marked in the sequence they were deposited. Teeth from young dolphins have very little cement and none can be seen in this photograph. Photograph from Hohn* et al. *(1989).*

have several advantages over these other tissues. The normal process of remodeling (resorption and reconstruction) in bone results in resorption of all but the most recent growth layers. For young animals, the number of bone layers may accurately reflect age; otherwise, the number of layers will be less than the age of the animal. The most useful bones are those that show negative allometry, i.e., growing more slowly than the skeleton as a whole (Klevezal, 1996). Growth layers have also been identified in baleen. Unfortunately, baleen abrades fairly quickly during normal use, and relatively few growth layers accumulate. Ear plugs are restricted to just a few species of whales and are challenging to collect.

In the normal course of events, teeth do not remodel, and growth layers continue to be deposited throughout the life of the individual. Teeth are easy to collect, store, and section and have become the preferred means of age estimation for most species with teeth. Within a tooth, two tissues have been used for aging: dentine and cement. New dentine is deposited on the internal surface, i.e., from the pulp cavity side, so that layers deposited when the animal was youngest are found on the outer edges of the tooth or at the crown (Figs. 1–3). Cement or cementum wraps around the outer dentine and functions in anchoring the tooth to its alveolus. In contrast to dentine, new cemental layers are deposited on the external surface (Fig. 3). In most species of cetaceans, the cemental layer is very thin and the resulting growth layers so fine that they can be difficult to differentiate. As a result, dentine is used primarily for estimating age. Notable exceptions include the franciscana, *Pontoporia blainvillei*, and the beaked whales, family Ziphiidae, where dentine is useful only for the first few years and then cement, which is extensive, must be used. In addition, for sperm whales (*Physeter macrocephalus*) and the beluga whale (*Delphinapterus leucas*), both cement and dentine are well developed and can be used. Because cetaceans have homodont dentition (the teeth are all the same), each tooth contains the same layering pattern except for the underdeveloped teeth found most anteriorly and posteriorly in the tooth rows.

For pinnipeds, sea otters, and polar bears cement is used most frequently for age estimation (Bodkin *et al.*, 1997; Garlich-Miller *et al.*, 1993) (Fig. 4), similar to most terrestrial mammals. For many species, dentine can give accurate age estimates for young animals, but the pulp cavity either becomes

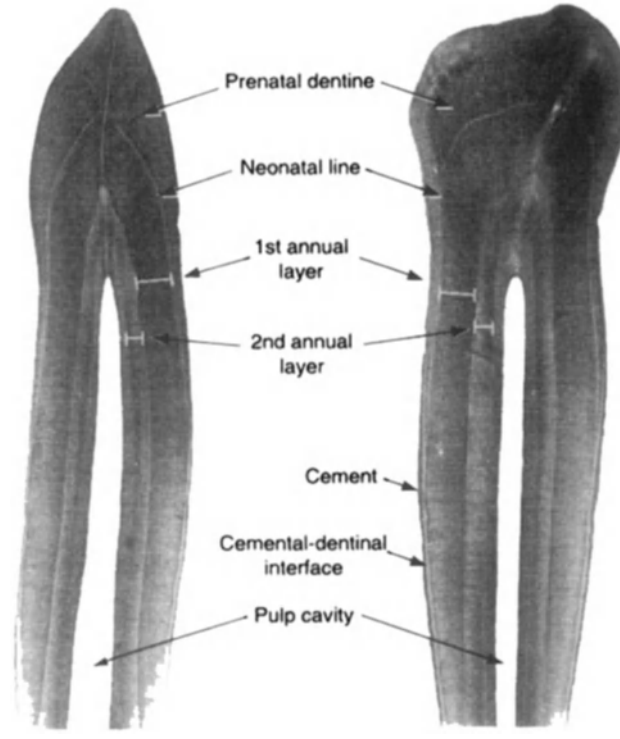

Figure 2 *Decalcified and stained midlongitudinal sections of teeth from a harbor porpoise* (Phocoena phocoena). *Porpoise teeth are spatulate. When sectioned along the buccal–lingual plane, they appear similar to dolphin tooth sections; when sectioned sagitally, the spatulate shape is apparent. The results are comparable in both orientations for this group. A narrow layer of cement occurs external to the dentine in the part of the tooth that was below the gum line.*

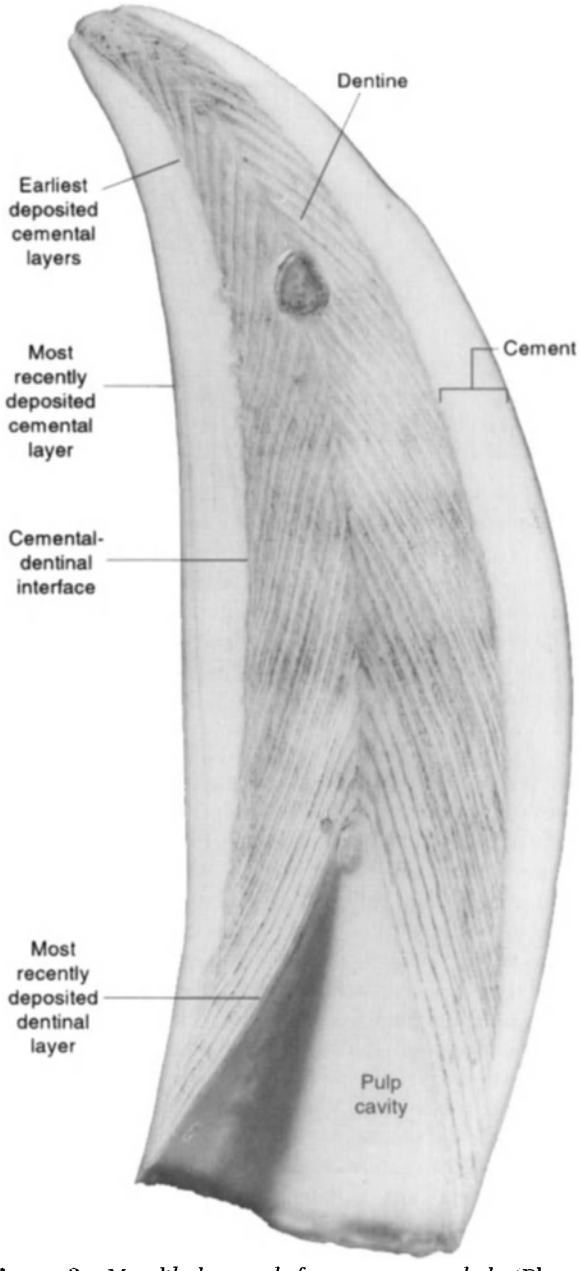

Figure 3 *Mandibular tooth from a sperm whale* (Physeter macrocephalus) *cut midlongitudinally in the buccal–lingual plane, etched in acid, and then rubbed with pencil to highlight growth layers in the dentine. Sperm whales have thick cement from which age can be estimated. In contrast to cement in the dolphin or porpoise tooth, here cement covers all of the dentine. In sperm whales and other species with continuously growing teeth, the tooth adds layers at the bottom (root end) and pushes upward. The cement was deposited when the dentine was still below the gum line. Erupted teeth wear continuously, and in older animals the earliest deposited layers are no longer present. The circular structures are pulp stones that form at the edge of the pulp cavity as globular masses of secondary dentine. Pulp stones are common in some species. Photograph courtesy of the International Whaling Commission.*

occluded or the dentine deposited is too irregular to resolve additional growth layers. Notable exceptions occur in some of the phocids, such as the ringed seal (*Pusa hispida*), Caspian seal (*Pusa caspica*), and the harbor seal (*Phoca vitulina*), where more than 15–20 dentinal layers can be found (Stewart *et al.*, 1996). For these species, which have heterodont dentition, canines are best for counting dentinal layers whereas postcanines are better for counting cement.

Although dentine and cement do not remodel like bone, teeth do wear down. When this occurs, it generally is not a problem for age estimation for species whose teeth show limited growth, i.e., do not continue to grow from the root but reach a maximum length when the animal is still relatively young. That is because an important marker for accurate age estimates is the neonatal line, which is deposited at birth and represents time zero for the purposes of counting growth layers (Figs. 1 and 2). As long as the neonatal line is visible, it is possible to obtain a complete count of growth layers. Initially, the neonatal line extends below the gum line. In species for which tooth growth is limited, even when the tooth wears down above the gum line, the neonatal line remains visible in the remaining tooth that was below the gum. In species with continuously growth teeth, such as the walrus (*Odobenus rosmarus*) (including mandibular teeth), bearded seal (*Erignathus barbatus*), narwhal (*Monodon monoceros*), members of the sperm whale family (Fig. 3), and the dugongs (*Dugong dugon*), wear continues as the tooth grows up from the root and eventually the neonatal line is worn away. When this occurs, the count of growth layers of dentine or cement is only a minimum. In some species, such as the beluga whale (*Delphinapterus leucas*), tooth wear is not equal and the best estimates of age are made from the least worn tooth.

Manatees (*Trichechus* spp.) present an unusual case for age estimation. In the related dugong, tusks (incisors) and other teeth provide a means for aging using techniques similar to those used for teeth from other species. Manatees lack tusks. Furthermore, they have an indeterminate number of molars that are constantly lost and replaced throughout life. Therefore, except in young animals, the number of growth layers in a tooth will reflect the age of the tooth but not the age of the individual manatee. As an alternative, it has been demonstrated in manatees that growth layers in tympano-periotic (auditory) bones are annual (Fig. 5) and that resorption occurs at a much slower rate than in other bones, meeting the requirement of a bone with negative allometry. More than 20 annual layers were found in many specimens and 59 found in a single animal (Marmontel *et al.*, 1996).

Baleen whales also present a special case for age estimation because they lack teeth. The rorquals (family Balaenopteridae) have ear plugs that are deposited in an annual layering pattern (Fig. 6) throughout life that are considered accurate for obtaining age estimates. These structures are more difficult to collect and are more fragile than teeth or bone. An advantage of ear plugs is that they do not resorb or wear. Other methods of aging have been investigated for balaenopterids, as well as other species of baleen whales. As in manatees, layers occur in the tympanic bullae (auditory) bone in bowhead (*Balaena mysticetus*), gray (*Eschrichtius robustus*), and common minke (*Balaenoptera acutorostrata*) whales (Christensen, 1995), often

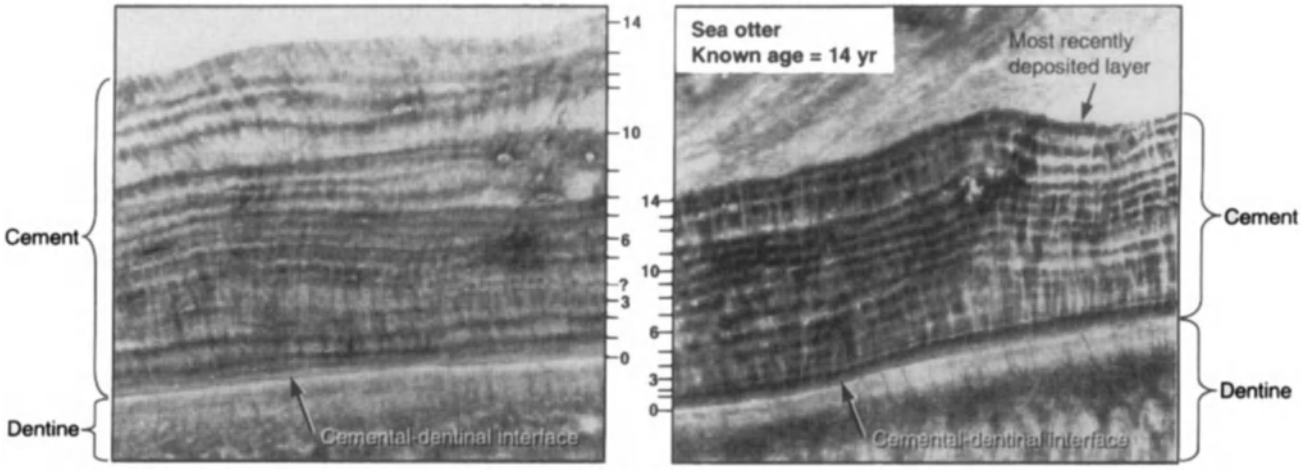

Figure 4 *Growth layer deposition in cement of a known-age sea otter (14 years). Images are from the same tooth section at different locations. In one location (right image), 14 well-defined, presumably annual layers are visible. These layers are exceptionally clear. In another location (left image), growth layers split and merge: on the right side there appear to be fewer layers, whereas on the left side there appear to be more layers. Presumed annuli are marked on the two images, with the marks on the left image before more subjective and a particularly uncertain layer marked with a dashed line. Counts begin at the interface where the dentine meets the cement, which represents time zero for counting growth layers. Positive identification of annual layers is made by carefully following layers along the tooth to watch for splitting and merging. Photographs of decalcified and stained thin sections courtesy of James Bodkin, USGS, and Gary Matson, Matson's laboratory. 250×.*

with no concomitant layers in other cranial or skeletal bones (Klevezal, 1996). Use of tympanic bullae is challenging because extensive effort is required to determine where exactly within the bullae the least amount of resorption and greatest resolution of growth layers will occur. When this region is located the maximal number of layers will be found. Otherwise, ages will be underestimated. Chemical signals, specifically amino acid racemization, have been used for dolphins and small and large species of whales (Bada *et al.* 1980), most recently fin (*B. physalus*) and bowhead whales (George *et al.*, 1999). Age is estimated as a function of the proportion of D and L isomers of aspartic acid in the lens of the eye.

IV. Collection and Preparation of Tissue for Age Estimation

When the primary tissue to be examined is dentine, especially for old animals, it is critical that a full midlongitudinal section be obtained. Otherwise, the very fine layers deposited in old animals will be missed. In toothed whales and dolphins (the odontocetes), the possibility of obtaining this midlongitudinal section is increased greatly if a tooth that is straight in the buccal–lingual plane (cheek to tongue) is used. Generally, the largest and straightest teeth occur near the center of the tooth row, and generally teeth are sectioned in the buccal–lingual plane. In some species, sections in the anterior–posterior plane are comparable (Fig. 2). It has become convention for studies on small odontocetes to use teeth from the center of the left ramus when possible (Perrin and Myrick, 1980). When using specimens from MUSEUM COLLECTIONS, often the teeth will have fallen out of the alveoli and so the straightest, largest (in that priority) teeth will be optimal. For studies using cemental layers, postcanines or molars generally are the preferred tissue. In terrestrial mammals, some differences in counts of cemental growth layers among tooth sections from the same individuals have demonstrated that the thickness of the cement influences the deposition pattern, either because the cement is so narrow that layers are not readily distinguishable or because the cement is so thick that other incremental layers are apparent and may appear as annual layers (Klevezal, 1996). Differences in cemental thickness can occur both within a molar and between molars (Fig. 4). Ideally, a full investigation of the best site for sectioning can be made to select the optimal tooth and location within that tooth. When that selection has been made, midlongitudinally sections are more likely than cross sections to show all of the cemental layers, although cross sections are commonly used (Klevezal, 1996). As noted earlier , there is also variability in compact bone thickness in tympanic bullae, resulting in variability in number of growth layers visible; an investigation of the optimal site for sectioning is required. The bone is then cross-sectioned at that site. Ear plugs are sectioned centrally along the long axis of the plug.

Because growth layers are integral to bone and tooth structure, growth layer counts are not sensitive to most of the common ways of storing bones and teeth: cleaned of soft tissue and stored dry, such as in museum bone collections, or in alcohol, formalin, or glycerin. It has been suggested that long-term storage in formalin will affect growth layer counts if formalin degrades to formic acid (Perrin and Myrick, 1980). Some teeth will crack at the tip when stored dry, making sectioning a bit more difficult but not affecting the growth layers. Earplugs are stored in 5–10% buffered formalin (Lockyer, 1984). For amino acid racemization, eye lenses must be collected fresh and frozen immediately (George *et al.*, 1999)

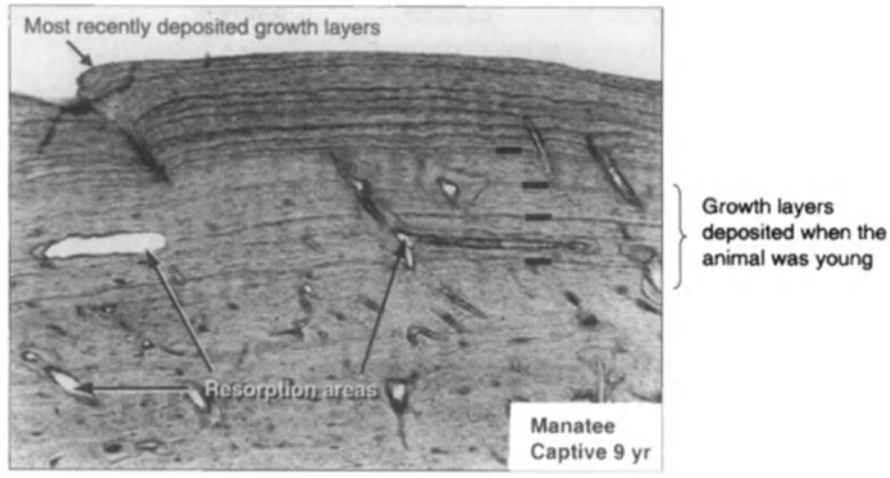

Figure 5 *Growth layer deposition in the tympano-periotic bone of a Caribbean manatee* (Trichechus manatus) *that was maintained in captivity for 9 years. Eleven to 12 growth layers can be seen. These layers are primarily on the outer surface of the bone. Even at this age, the bone tissue is being resorbed and is beginning the remodeling process. Photograph of decalcified and stained thin section courtesy of Miriam Marmontel and the USGS Sirenia Project.*

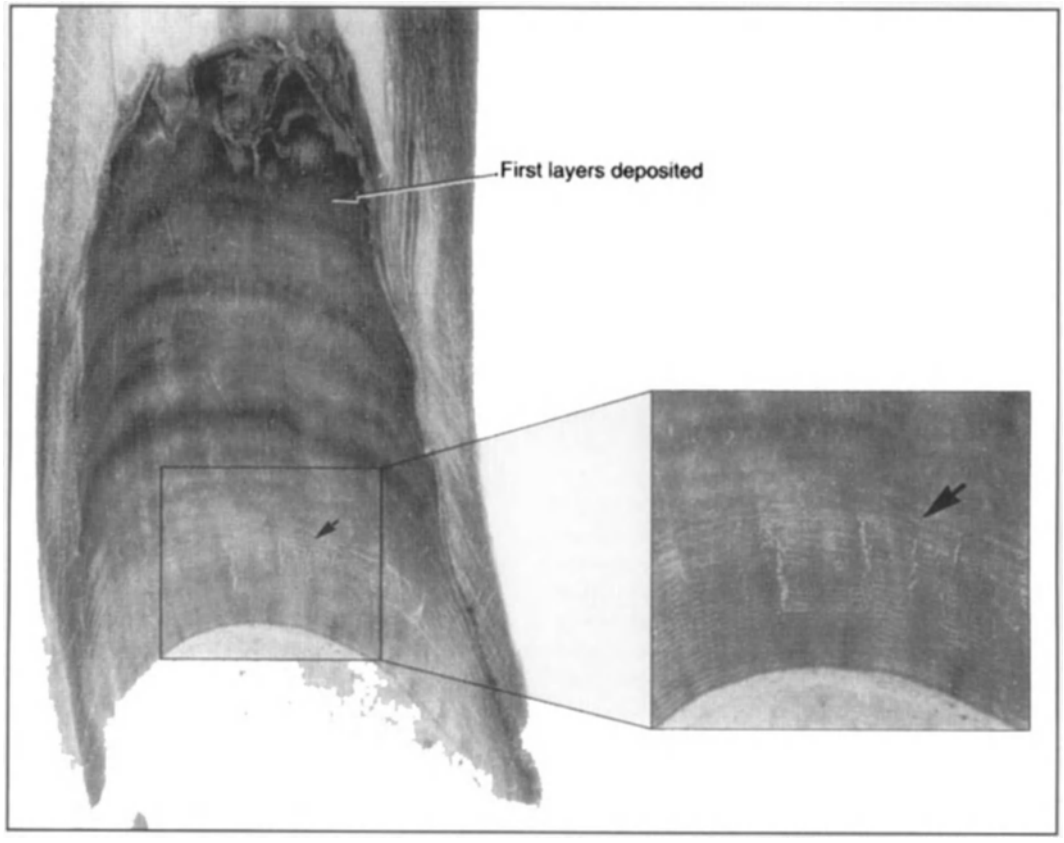

Figure 6 *Ear plug from a fin whale cut midlongitudinally to expose the growth layers. The arrow denotes a significant and abrupt change in growth layer characteristics that coincides with the transition of the animal from sexually immature to sexually mature. It is called the transition phase. Photograph from Lockyer (1984) and provided courtesy of C. Lockyer and the International Whaling Commission.*

Many creative methods have been tried to obtain the best resolution of growth layers (Perrin and Myrick, 1980). Two of these methods have persisted and become the most widely used: untreated sections (i.e, not decalcified and stained) and decalcified and stained thin sections. The former method generally involves using a low-speed saw with diamond blades to cut a section ranging from 50 to 200 μm thick, depending on the species and tissue, and counting layers directly from that section. The section may be mounted permanently on a microscope slide. This method was initially the most prevalent one for age estimation from teeth, a little less so for bone, and continues to be widely used because it is fast, easy, and requires little specialized equipment. The increasingly used alternative, decalcified and stained thin sections, requires additional preparation. For this method, whole teeth or thick sections from teeth or bone are decalcified in acid, sectioned on a microtome from 6 to 25 μm, depending on the species, tissue, and microtome used, and then stained in hematoxylin and sometimes counterstained with eosin, two routine histological stains. Sections are mounted on a microscope slide. It has become increasingly evident that using the easier method produces inaccurate results for both bone and tooth sections (Stewart *et al.*, 1996; Hohn and Fernandez, 1999). Stained thin sections allow for a much better resolution of growth layers in dentine, cement, and bone to the extent that many layers not apparent in untreated sections are visible and countable in stained sections. This difference is especially apparent in older animals where growth layers become increasingly thinner; staining is required to separate adjacent fine layers. As a result, many estimates of age using untreated sections are underestimates.

V. Consistency and Repeatability of Age Estimates

Because annual layers are not the only growth layers present, the interpretation of annual layers is often subjective. Misinterpretation of annual layers or differences in interpretation between investigators or studies lead to errors. Is one population but not another actually responding differently to exploitation or is an apparent difference simply caused by differences in age estimation? Is a population failing to recover because a growth model is incorrect or because the parameters used in that model were incorrect due to misinterpretation of annual layers?

Accuracy and precision are, in large part, influenced by the species being examined. For some species, growth layers are well defined and easily identified, whereas for other species growth layers are inherently indistinct. Annual layers in polar bear cement are notably difficult to interpret, at least during the first few years of life. Different areas in the cement have more or less distinct annual layers and accessory layers. Furthermore, different populations within a species may have different growth layer characteristics. For example, harbor porpoise from the Bay of Fundy have very distinctive growth layers, whereas those from California do not. Within studies it is common to conduct multiple readings of sections by one or more researchers to test for differences between readers or between readings for an individual reader. Measures of precision can be incorporated in models or can be used to evaluate the reliability of ages estimated for a sample.

Consistency and repeatability of age estimates can be increased if the tooth or bone sections are well prepared. Preparing these sections is a multistep process, and at each step the potential for error exists. If the end product is not well done, then the age estimate may be inaccurate or imprecise. For counts using dentine, a large source of error is using a section that is not midlongitudinal. For all sections, the incorrect stain or degree of staining (light or dark) and under- or overdecalcification also affect the final product in ways that prevent optimal resolution of all growth layers.

Even when sections are perfect, the subjective nature of counting growth layers still results in different age estimates. Descriptive models of the appearance, size, and complexity of annual layers have been developed to increase consistency, particularly between investigators. These models include photographs with the growth layers interpreted to be annual clearly marked (Hohn, 1990). Such photographs are equally valuable in individual studies to allow other investigators to determine whether the age estimates were obtained using comparable annual layering patterns. To date, such descriptive models have been prepared for bottlenose dolphins (Hohn *et al.*, 1989) and the franciscana (Pinedo and Hohn, 2000). Development of models for other species would increase the accuracy and precision of age estimates. Such models are particularly important and valuable when known-age specimens are available.

Aggressive Behavior (Intraspecific)

Claudio Campagna
Centro Nacional Patagónico, Puerto Madryn, Argentina

The heterogeneous phenomenon considered as intraspecific aggressive or agonistic behavior represents a conglomerate of social responses, including male disputes over territorial boundaries, female fights to protect an offspring, female harassment and forced copulations, and infant abuse and killing. Agonistic encounters:

1. Mediate competition for limited resources economically defendable and valuable to the fitness of an individual (Bartholomew, 1970). Finite resources that can be monopolized would lead to social conflict between individuals of different sexes and generations and of the same sex and similar age class and status. Most often, agonistic confrontation (at least the most conspicuous interactions) involves sexually mature males.
2. Are more common in some social contexts, such as breeding on land in a polygynous mating systems, in which competition for resources is typically solved via aggressive disputes. Size and strength (but also agility) correlate positively with winning a contest through exerting dominance over individuals subdued by the costs of rebellion.
3. Have a broad range of costs for actors and recipients, from simple rejection after a ritualized threat display to injury or even death after an overt physical encounter.

The form and frequency of agonistic behavior partially reflect the sophistication of a social system. Aquatic mammals vary widely in the complexity of their societies, thus in the manifestation of agonistic behaviors. The most openly competitive societies characterize the otariids, the walrus (*Odobenus rosmarus*), and phocids that live in crowded conditions (e.g., elephant seals, *Mirounga* spp., and gray seals, *Halichoerus grypus*), a fertile ground for aggressive social interactions (Riedman, 1990). Conversely, polar bears (*Ursus maritimus*), all the mysticetes and river dolphins, and some other phocids (e.g., Ross and leopard seals, *Ommatophoca rosii* and *Hydrurga leptonyx*) generally occur in smaller social groups, except for periods during reproduction in which breeding males engage in scramble competition over receptive females (Berta and Sumich, 1999). The most complex social systems in the aquatic mammals would characterize some of the odontocete cetaceans, such as killer whales, *Orcinus orca*, pilot whales, *Globicephala* spp., bottlenose dolphins, *Tursiops* spp., or sperm whales, *Physeter macrocephalus* (Connor *et al.*, 1998). These species live in stable social units and show coordinated, cooperative behaviors. The long-term shared history among individuals of the group would have ritualized many of the overt aggressive responses typical of the polygynus pinnipeds.

I. Male–Male Competition for Mates

Competition over limited resources to maximize reproductive success would be the most common origin of agonistic encounters. It is likely that in all aquatic mammals, males compete for access to reproductive females, by either direct or indirect monopolization, through achieving the best place for reproduction or the highest status in a dominance rank. Defense systems can set the stage for the evolution of sexually selected traits, such as dimorphism in size and in special morphological structures (e.g., tusks, manes, elongated snouts).

The behavioral manifestations of conflict directed to the intimidation of rivals is often referred to as agonistic display or agonistic social signaling. Behavioral displays include vocal signals, facial expressions, and stereotyped postures and movements, such as static open-mouth threats, open-mouth sparring, foreflipper raise or waving, and oblique staring. Overt fighting is commonly a last-resort solution to conflict.

A. Pinnipeds

The form of male agonistic encounters and their outcome has been described in detail for several pinnipeds. Within the highly polygynous otariids and phocids there are examples of resource-defense (territorial) and female-defense polygynous systems (Riedman, 1990). Both types of polygyny may occur in the same species, such as in the South American sea lion, *Otaria flavescens*, as a function of different ecological conditions (Campagna and Le Boeuf, 1988).

The establishment and defense of a territory involve vocal displays, stereotyped postures and movements, and fights. During territorial displays, male contenders may rush toward each other with the mouth open or vocalizing, weave the head from side to side, puff out the chest, or perform the "oblique stare" posture at one another, but physical contact is usually avoided. Much of the fighting between otariid males takes place early in the breeding season, when territorial boundaries are being established. When physical contact occurs, it typically lasts a few seconds but may be violent, particularly in the largest sea lions. Fights involve chest-to-chest pushing, vigorous biting of the neck and face, lunging, and slashing at the opponent's flippers, chest, and hindquarters.

In female-defense polygyny, females cannot be sequestered or attracted to a particular place. Males then compete to achieve a position among the females in the breeding colony and move with the shifting population of females [see Boness and James (1979) for gray seals and Campagna and Le Boeuf (1988) for South American sea lions]. Association to a particular group of females is loose and may change even during the same day due to female redistribution related to the physical environment (high temperatures, variable space due to tidal movements) or to social behaviors (e.g., group raids of ousted males into the colony; Campagna *et al.*, 1988).

In phocids such as elephant seals, males aggressively establish a dominance hierarchy rather than a resource or female defense system. Only the highest ranking individuals have undisturbed reproductive access to females (Le Boeuf and Laws, 1994). During the establishment of hierarchies, males attempt to intimidate each other with vocal displays. If none of the contestants retreats, then a chest-to-chest fight takes place. Fights in elephant seals are violent confrontations and may last half an hour. Each bull throws his weight against the other and slashes at his opponent's face, neck, and back with long canines. Most fights end with multiple lacerations and bloody wounds or even a broken canine tooth; even death may occur on rare occasions.

Vocal threats are a common component of agonistic encounters. Pinnipeds vocalize both in air and underwater (Riedman, 1990). Harp (*Pagophilus groenlandicus*), ringed (*Pusa hispida*), Weddell (*Leptonychotes weddellii*), and bearded (*Erignathus barbatus*) seals and the walrus have a rich underwater vocal repertoire. Males maintain underwater territories and vocalizations seem to be part of territorial displays. Vocal displays can be of a repetitive nature and are then termed songs. Otariid males, particularly among the fur seals (*Arctocephalus* spp.), have a rich variety of airborne threat vocalizations associated with boundary display postures. The California sea lion, *Zalophus californianus*, vocalizes both in air and underwater (several phocids also produce airborne and underwater sounds). The strong airborne calls or barks of *Zalophus* occur during breeding and nonbreeding seasons and may serve to advertise dominance. In elephant seals, airborne threat displays consist of loud and directional pulsed sounds that tend to precede fights.

B. Cetaceans

There is comparatively little description of agonistic encounters in the rest of the aquatic mammals. Agonistic behaviors to establish dominance relationships were described among dolphins in captivity. Observations of free-ranging cetaceans described a range of behaviors interpreted as agonistic, such as LOBTAILING, tail and flipper slaps to the body of other individuals, open-mouth postures, jaw claps, forceful exhalations, chases, body charges and leaps and body slaps, and vocal threat displays (Wells *et al.*, 1999). Escalated agonistic displays involve striking with flukes, biting, and jousting with tusks, the latter in narwhals (*Monodon monoceros*). Humpback whale (*Megaptera novaeangliae*) males fight vigorously in surface-active groups and receive not only scrapes and scratches but also deep gouges and bloody wounds as a result (Tyack and Whitehead, 1983).

The scar pattern of some odontocetes has been interpreted as the consequence of tooth marks and violent interactions. Several odontocetes have conspicuous scars. In Risso's dolphins, *Grampus griseus*, narwhals and several of the beaked whales, most of the body is covered with scars. At least for the narwhal, scars have been associated with intraspecific agonistic encounters (see later). Scrape marks are also common in baleen whales. It has been suggested for the southern right whales, *Eubalaena australis*, that males may use the thorny callosities during scramble competition over females.

Agonistic contests in cetaceans also involve vocal displays. Males of the humpback whale escort receptive females and vigorously rebuff other males by threatening displays such as thrashing of the flukes. The underwater songs of humpback whales in Hawaiian breeding grounds are performed by males and likely serve as communication signals in the context of male competition.

An example of male–male competition involves Australian bottlenose dolphins, *Tursiops aduncus* (Connor *et al.*, 1998). Males of this population form stable alliances of two or more individuals that cooperate to obtain and control reproductive females. Two alliances occasionally combine efforts to sequester or defend females from another alliance. Alliances in dolphins and group raids in sea lions (see later) represent special cases in which competition involves the participation of several individuals simultaneously.

C. Other Aquatic Mammals

Sea otters (*Enhydra lutris*), polar bears, and sirenians tend to be more solitary or live in low-density societies with little interaction among individuals (Berta and Sumich, 1999). Male sea otters are polygynous, establish breeding territories, and mate in the water. Females live in low-density areas chosen in relation to the distribution and abundance of food.

During the mating season, polar bear males rove to locate receptive females that are dispersed and solitary. Males access one female at a time. Competition involving physical interactions has been observed rarely but is indicated by broken teeth and scarring on the head and neck.

Manatees (*Trichechus* spp.) form mating groups in which several males compete for access to a receptive female by pushing and shoving each other. Physical competition for females also occurs in dugongs (*Dugong dugon*) with some males obtaining scars probably made by the tusks of other males.

II. Tusks as Special Structures for Aggression?

Two species of marine mammals have extraordinarily developed tusks: the walrus and the narwhal. The two upper canines in both male and female walrus are extraordinarily elongated (Riedman, 1990). The massive tusks of a male can weigh up to 10 pounds and be almost 1 m long. Both sexes use tusks in squabbles, to threaten one another, and, perhaps, to establish dominance. Males may force their way to selected places in crowded colonies by pushing and jabbing other walruses with their tusks.

The tusks of narwhals are even more exceptional morphological traits. As a general rule, the left canine in males extends anteriorly into a spiraled tusk to a length that may exceed 2.5 m. Some males have two tusks and a few females also develop one or even two shorter and less robust tusks. It has been suggested that narwhal tusks may be used to disturb or pierce prey, to open breathing holes in the ice, as defense weapons against predators, or as organs of sexual display. Although tusks may be used in more than one context, evidence shows that they serve in aggressive encounters (Silverman and Dunbar, 1980; Gerson and Hickie, 1985). Evidence includes direct observations of males crossing tusks and striking them against one another, scar patterns (with adult males having more and larger scars on the head after attaining sexual maturity), significantly higher incidences of broken tusks in mature males compared to immature individuals or females, and imbedded splinters and tusk tips found in the head of males. Tusks are also used to spear individuals of other species or, apparently, at times even female narwhals.

III. Sexual Selection and Special Morphological Traits

Pronounced SEXUAL DIMORPHISM in the direction of males being heavier and larger than females is common in all otariids, the walrus, and some phocids (e.g., elephant and gray seals). This kind of dimorphism often indicates direct physical confrontation among reproductive males involving pushing or strength contests. Dimorphism is not apparent, is slight, or is even reversed in most other phocids. A lack of or even reversed dimorphism is often accompanied by the defense of aquatic territories, aquatic mating, and serial monogamy. Females in these species are usually dispersed and breeding occurs over a protracted period. Social and ecological conditions do not favor frequent direct physical confrontations, but competition does occur, and may for more agile rather than larger individuals.

Among other aquatic mammals, males are much larger than females in some odontocetes, such as killer and sperm whales, whereas dimorphism is reversed in all the mysticetes. Mysticetes may have promiscuous MATING SYSTEMS in which competition for insemination takes place at the level of males displacing each other from the vicinity of a female and of sperm cells displacing or diluting sperm of other males. Gray (*Eschrichtius robustus*), right (*Eubalaena* spp.), and bowhead (*Balaena mysticetus*) whales have larger testes than expected based on their body weight, suggesting selection for sperm competition.

In addition to dimorphism in body size, males of some species evolved special secondary sexual features that may function in the context of competition for mates. Examples include the enlarged snouts of male elephant seals and gray seals and the inflatable nasal cavity of hooded seals (*Cystophora cristata*). Hooded seal males can blow a red, balloon-like sac from one nostril that is similar in shape to the long proboscis of elephant seals. These organs have visual or acoustic effects and may allow other males and females to judge the quality of a contender or a sexual partner. The developed neck and mane of sea lions with long and thick guard hairs also has visual effects and serves as a shield that protects internal organs from bites.

IV. Avoiding Fights

Competition for resources by direct aggression is a costly experience in species capable of inflicting serious injuries that could lower future fitness of the contestants. Thus, contenders with low chances of success should avoid physical confrontations. Theory predicts that the assessment of the fighting ability of competitors and of resource value prior to an escalation of violence may allow differential adaptive responses on the basis of the perceived asymmetries (Maynard Smith and Parker, 1974). Once a territory or social hierarchy is established, disputes tend to be asymmetric contests in which territory owners or high-ranking males almost always win. Threat displays may then serve as indicators of a quality and motivational state of a contender. Individual variation in vocal displays may help territorial males to recognize one another and to forgo direct competition if each knows its respective status.

In female-defense systems, the proportion of sexually receptive females accessible to a male is variable in space and time. Thus, the level of asymmetry can vary within the same day of a breeding season. This social context would favor behaviors that are unusual in strict territorial or hierarchical systems, such as group raids in South American sea lions.

V. Group Raids and Other Forms of Male Harassment of Reproductive Females

In the South American sea lion, losers in male–male competitions at times raid breeding colonies in groups of dozens of individuals (Campagna *et al.*, 1988). Raiders abduct females from the harems of established males and attempt to mate with them. A male seizes a female in his jaws and hurls her into the air to a spot where he can hold his ground against other males while aggressively keeping her in place. In the process, females are often wounded and can be killed. Perhaps group raids represent a primitive stage of a male alliance or coalition.

Violent behavior toward females is relatively common in pinnipeds. Harassed females are injured and sometimes killed by males during mating attempts. Le Boeuf and Mesnick (1990) suggested some social conditions that can increase mortality risks to a female during mating: (a) marked male sexual

dimorphism, (b) males outnumbering females, (c) use of force or potentially dangerous weapons in mating, and (d) monopolization of mating by a few individuals through direct or indirect control of resources (space, females, food, etc.) with forcible exclusion of the majority of the competitors. All of these traits are common in the most polygynous mating systems.

The majority of female deaths during the breeding season of elephant seals, the most sexually dimorphic of all the pinnipeds, occurs by traumatic injuries inflicted by males during mating attempts as the females depart the harems for the sea at the end of lactation. Male South American sea lions and elephant seals are three to five times heavier than females, have large canines, and often bite the neck of the female when copulating. Breeding colonies early and late in the season have a high number of males that intercept departing females and attempt to mate with them. Mating injuries inflicted by males to females have also been reported for several other species [e.g., gray seals, Boness *et al.* (1995), Hawaiian monk seals (*Monachus schauinslandi*), Hiruki *et al.* (1993)]. Male aggression toward females may be a selective force in shaping female behavior, female choice, maternal performance, and reproductive synchrony (Boness *et al.*, 1995).

VI. Female Agonistic Behavior

In polygynous pinnipeds, females are aggressive toward one another and rarely tolerate neighbors close by, which helps to regulate density of a site. A common context of female agonistic encounters is that of protection of a pup in a crowded breeding colony. Alien pups are often bitten by females. Aggressive mothers react rapidly and intensively to the threat to their pup by a neighbor, which enhances chances of pup survival by decreasing the risks of mother–pup separation and pup injury (Christenson and Le Boeuf, 1978).

At times, females threaten transient males when the latter approach or protest vocally when males mount them. As a result, a harassing male will then be more likely challenged by another male who hears the female vocalizing. These challenges generally interrupt a male's approach or mount, and hence a potential copulation. By resisting male copulatory attempts, females increase their likelihood of mating with a dominant individual, which may be viewed as an indirect form of mate choice.

VII. Abuse and Killing of Young

Infanticide is the killing by conspecifics of young still dependent on their mothers. Infant abuse implies injury of a young either via active violent behaviors or via passive neglect. Violent abuse of pups by males (most often young individuals but also adults) occurs in several pinniped species, particularly in sea lions and elephant seals. The killing of young is most often the by-product of abuse, although it may also occur as a directed behavior. In addition to pinnipeds, infanticide has been described in polar bears and is inferred in at least one odontocete, the common bottlenose dolphin.

Albinism

Dagmar Fertl
Minerals Management Service, U.S. Department of the Interior, New Orleans, Louisiana

Patricia E. Rosel
National Marine Fisheries Service, Charleston, South Carolina

Albinism refers to a group of inherited conditions resulting in little or no pigment (hypopigmentation) in the eyes alone or in the eyes, skin, and hair. In humans, all types of albinism exhibit abnormalities in the optic system, including

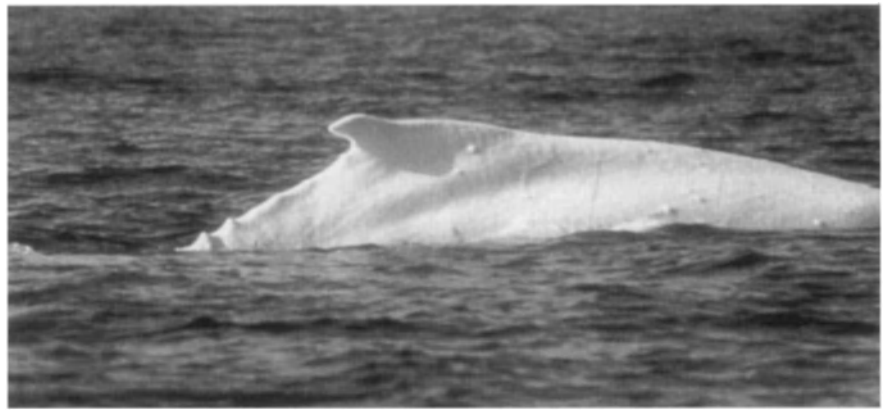

Figure 1 *Anomalously white humpback whale sighted off Australia. Photo by Paul Forestell, Pacific Whale Foundation.*

misrouting of the optic fibers between the retina and the brain, and incomplete development of the fovea, the area of the retina where the sharpest vision is located. Thus, these characteristics can provide useful diagnostic criteria for identifying albinism. Inheritance of an altered copy of a gene that does not function correctly is the cause of most types of albinism. Albinos have white or light skin and hair, and often pink eyes, although the eye color can vary from dull gray to brown. The "pink" eyes are due to the reflection from choroid capillaries behind the retina. Albinism is differentiated from piebaldism (body pigmentation missing in only some areas) and leucism (dark-eyed anomalously white animals). Pigmentation patterns should not be the only criterion used to define albinism, as some mutant phenotypes (pseudoalbinism) may be due to the action of genes at other loci.

I. Pigmentation

Mammalian color is almost entirely dependent on presence (or absence) of the pigment melanin in the skin, hair, and eyes. Melanin is produced through a stepwise biochemical pathway in which the amino acid tyrosine is converted to melanin. The enzyme tyrosinase plays a critical role in this pathway, and alterations or mutations in the tyrosinase gene can result in a defective enzyme that is unable to produce melanin, or does so at a reduced rate. Mutations in five other genes have also been identified in different types of albinism in humans.

II. Problems Associated with Albinism

Humans with albinism often are photophobic and have other vision impairments, such as extreme far-sightedness, near-sightedness, and astigmatism. There are unpublished reports of apparent vision problems for albino seals, when they are on shore. Costs of this aberrant pigmentation for marine mammals may include reduced heat absorption in colder waters, increased conspicuousness to predators, and impaired visual communication.

III. Albinism and Marine Mammals

Anomalously white individuals have been reported for 20 cetacean species (Fertl *et al.*, 1999) (Fig. 1); they have also been reported for pinnipeds (e.g., Rodriguez and Bastida, 1993). No reports are known of anomalously white sea otters (*Enhydra lutris*) or sirenians. Anomalously white individuals are often

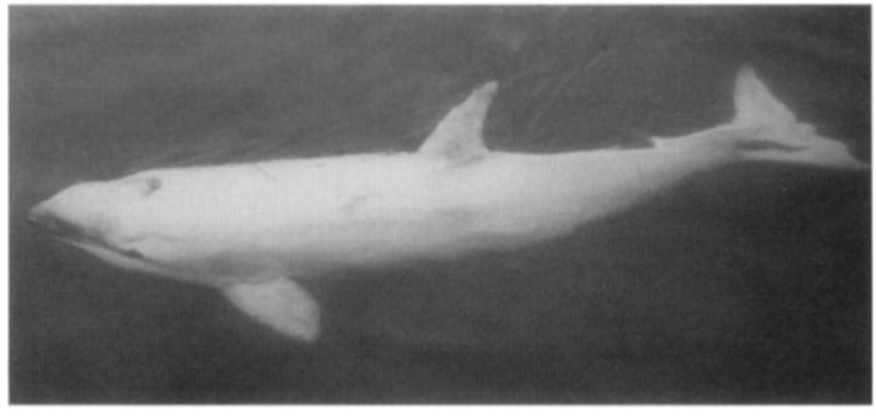

Figure 2 *An albino killer whale ("Chimo") postmortem diagnosed with Chédiak–Higashi syndrome. Photo by Peter Thomas.*

presumed to be true albinos. Some of those individuals match the description of true albinism [e.g., there are well-documented reports of albino sperm whales (*Physeter macrocephalus*) and bottlenose dolphins (*Tursiops truncatus*)], but many do not. "Chimo," an anomalously white killer (*Orcinus orca*) captured for display in Canada, was diagnosed postmortem with Chédiak-Higashi Syndrome, (Fig. 2), a type of albinism. This inherited disorder is characterized by diluted pigmentation patterns that appear pale gray, white blood cell abnormalities, and a shortened life span. Whales and dolphins also may appear white if extensively scarred, or covered with a fungus, such as Lobo's disease.

Amazon River Dolphin

Inia geoffrensis

VERA M. F. DA SILVA
Instituto Nacional de Pesquisas da Amazônia, Manaus, Brazil

I. Genus and Species: Common Names and Taxonomy

The Amazon River dolphin, *Inia geoffrensis*, is known by different names throughout its distribution: boto in Brazil; bufeo and bufeo colorado in Colombia, Ecuador, and Peru; and tonina and delfin rosado in Venezuela. It is also known in English as pink dolphin, although the Brazilian name "boto" is considered the international common name.

The boto belongs to the superfamily Platanistoidea. The genus *Inia* is monospecific, with three currently recognized subspecies: *Inia geoffrensis geoffrensis, I. g. boliviensis,* and *I. G. humoldtiana.*

II. Distribution, Abundance, and Density

The boto has an extraordinarily wide distribution, occurring almost everywhere it can physically reach without venturing into marine waters. It occurs in six countries of South America—Bolivia, Brazil, Colombia, Ecuador, Peru, and Venezuela—in a total area of about 7 million km^2 (Fig. 1). It can be found along the entire Amazon River and its principal tributaries, smaller rivers and lakes, from the delta near Belém to its headwaters in the Ucayali and Marañon Rivers in Peru. Its principal limits are impassable falls such as those of the upper Xingú and Tapajós Rivers, and the Teotônio falls in the upper Madeira River in the southern part of the Amazon basin. The boto is also found throughout the Orinoco river basin, with the exception of the Caroni River and upper Caura River above Para falls in Venezuela. An isolated population occurs above Teotônio and Abuña falls in the upper Madeira River and in the Beni/Mamoré basin of Bolivia.

The boto is the most common river dolphin. Its current distribution and abundance apparently do not differ from in the past, although relative abundance and density are highly seasonal and appear to vary among rivers. During the dry season the dolphins are concentrated in the main channels of the rivers, whereas during the flooded season they dispense into the flooded forest (igapó) and river floodplains (várzea).

No quantitative estimation of the relative abundance of the boto between rivers or basins exists. Differences in survey methodology used by different authors and lack of effort make the comparison between the results of the different surveys available in the literature very difficult. The only long-distance surveys of the species were carried out on the Solimões-Amazon River, from Manaus to Santo Antônio do Içá-Tabatinga over a total of ca. 1200 km. The number of sightings per unit effort gave an average number of 332 ± 55 botos per survey (n = 9), and the estimated density was of 0.08–0.33 botos/km in the main river and 0.49–0.98 botos/km in the smaller channels. Another boat survey along ca. 120 km of the Amazon River bordering Colombia, Peru, and Brazil carried out by Vidal and collaborators (1997) estimated 345 (CV = 0.12) botos in the study area with a density per square kilometer of 4.8 in tributaries, 2.7 around islands, and 2.0 along the main banks. These figures suggest that the boto shows the highest densities among any cetacean.

III. External Characteristics

The boto (Fig. 2) is the largest of the river dolphins, with a maximum recorded body length of 255 cm and mass of 185 kg for males and 215 cm and ca. 150 kg for females. The body is corpulent and heavy but extremely flexible. Nonfused cervical vertebrae allow the movement of the head in all directions. The flukes are broad and triangular: the dorsal fin is long, low, and keel-shaped, extending from the midbody to the strong laterally flattened caudal peduncle. The flippers are large, broad, and paddle-like and are capable of circular movements. Although most of these characteristics restrict speed during swim-

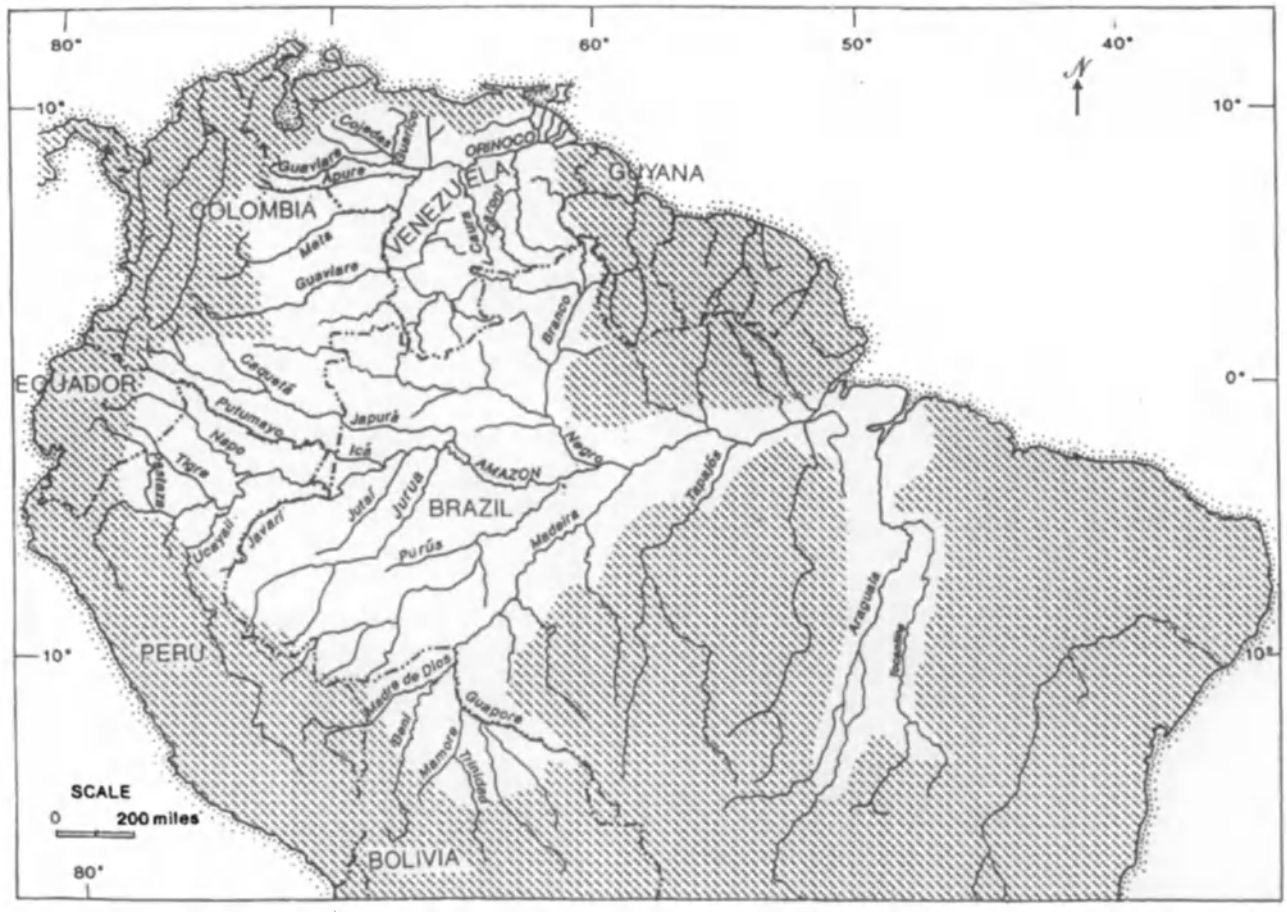

Figure 1 *Map showing the general distribution of the boto* (Inia geoffrensis) *in South America.*

ming, they allow this dolphin to maneuver between trees and submerged vegetation to search for food in the flooded forest. The rostrum and mandible are prominent, long, and robust. Short bristles on the top of the rostrum persist during adulthood. The melon is small and flaccid, but the shape can be altered by muscular control. The small, round eyes are functional and the vision is good, both under and above water.

Body color varies with age. Fetuses, neonates, and young animals are dark gray. Juveniles and subadults are uniform medium gray to pinkish, and older botos are completely pink or blotched pink. When adult botos are dark on the dorsum, the flanks and underside are pinkish. One albino was captured and maintained in captivity for more than 1 year in an aquarium in Germany.

IV. Behavior and Life History

The boto is at times solitary and is not often seen in cohesive groups of more than three individuals; most groups of two are mother–calf pairs. Loose aggregations may be seen at the mouth or in bends of rivers and canals due to the large concentrations

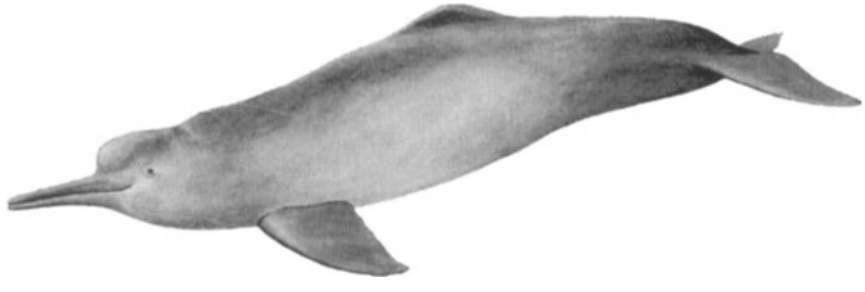

Figure 2 *Often characterized by pink body color, Amazon River dolphins* (Inia geoffrensis) *are the largest of the platanistoid dolphins. Pieter A. Folkens/Higher Porpoise DG.*

of fish or for purposes of courtship and mating. The boto is known to react protectively to injured or captured individuals.

The boto is a slow swimmer with a normal speed of 1.5–3.2 km/hr, but bursts of >14–22 km/hr have been recorded. The boto is capable of strong swimming for some length of time. When surfacing, the melon, tip of the rostrum, and long dorsal keel are out of the water simultaneously in a very conspicuous way. The boto does a high-arching roll in which these parts appear sequentially thrust well out of the water. The tail is rarely raised out of the water prior to a dive. Botos also wave a flipper, show the head or tail above the surface, lob-tail, and rarely jump clear of the water.

Studies in captivity indicated that botos are less timid and show less social contact, aggressive behavior, play, and aerial behavior than bottlenose dolphins (*Tursiops truncatus*). However, botos in captivity may not show their true range of behaviors. The boto is very curious and playful, rarely showing fear of strange objects. Wild botos grasp fishermen's paddles, rub against canoes, pull grass under water, throw sticks, and play with logs, clay, turtles, and fish. Several observers have reportedly seen botos in a stationary position, often upside down with the eyes closed.

The boto is active day and night. The greatest fishing activity occurs at 0600–0900 and 1500–1600 hrs. It feeds on over 43 species of fish belonging to 19 families. Stomach content analysis has revealed up to 11 fish species in one animal. The mean size of consumed fish is 20 cm (range 5–80 cm), with larger fish torn to pieces. In captivity, food sharing has been recorded. Daily consumption is about 2.5% of the body weight. The boto's diet is unique among cetaceans in that its heterodont dentition allows it to tackle and crush armored prey.

Males attain sexual maturity much later than females at about 200 cm in length. In females, sexual maturity occurs at around 5 years of age at body lengths between 160 and 175 cm. Reproductive events are seasonal. Gestation time has been estimated at about 11 months, and the calving season is apparently long, with most births occurring at the peak of the river's flood level. Length at birth is about 80 cm. Lactation lasts more than 1 year and the birth interval is 2 to 3 years. Studies of marking and recaptures carried out by da Silva and Martin in Central Brazil have shown that some individuals are resident in a particular area during the entire year.

V. Human Effects and Interactions

The boto is part of the FOLKLORE and culture of Amazonian people, and several legends and myths are commonly known throughout its distribution. Because of these legends, often giving the boto supernatural powers, the boto was protected and respected in the past, although body parts of incidentally captured animals have been used by local people for medical purposes and as love charms. With increased use of nylon gill nets, machine-made lampara seines, and other new fishing techniques, the incidental catching of botos has become more common. With greater demand for fish due to rapid increases in human populations, the boto's food sources are being reduced. Other threats to the species are the construction of hydroelectric dams on major tributaries affecting the abundance and presence of some species of fish. Dams separate and isolate populations and may reduce the gene pool, and thereby increase chances of extinction. Analysis of milk from botos from the upper Amazon River (Letícia) and Central Amazon (Manaus) revealed that chemical pollution of the river systems by pesticides and mercury poses serious threats to the species.

VI. Status and Conservation

Inia geoffrensis is listed in Appendix II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) and is classified by the IUCN as Vulnerable because of serious threats throughout its range.

Ambergris

DALE W. RICE
National Marine Mammal Laboratory, Seattle, Washington

Ambergris is a substance that forms only in the intestines of the sperm whale (*Physeter macrocephalus*). The word comes from the Old French *ambre gris* or "gray amber," as opposed to *ambre jaune*, "yellow amber," which refers to the true, resinous amber. Most ambergris is found in the large intestine, but smaller pieces have been found in the small intestine, and it may be that it initially forms in the small intestine and subsequently passes into the large intestine. Probably most lumps of ambergris are eventually voided during defecation,

unless they grow too large to pass through the anus. Ambergris occurs in only 1 to 5% of whales of both sexes and all ages, but the circumstances that induce its production remain unknown.

Ambergris forms as concretions that usually weigh 0.1 to 10.0 kg, but rarely much bigger pieces have been recovered; the largest on record, weighing 420 kg., was removed from a 14.9-m bull sperm whale killed in the Southern Ocean on December 21, 1953 (Clarke, 1954). Such huge masses greatly distend the whale's large intestine. Most pieces of ambergris are in the form of an irregular roundish lump, somewhat resembling a potato. Their specific gravity is 0.73 to 0.95. In consistency they are solid and friable, similar to nearly dry clay. Internally they usually show no laminations, but when broken apart they tend to fracture along concentric cleavage surfaces. In color they are pale yellowish to light gray on the inside, whereas the outer surface is dark brown with a varnished appearance. The chitinous beaks of cephalopods are almost invariably found imbedded in the lumps. Fresh ambergris has the highly distinctive pungent odor of sperm whale feces, but aged pieces have an almost pleasant musty or even musky smell.

Chemically, ambergris is a nonvolatile solid consisting mainly of a mixture of waxy, unsaturated, high molecular weight alcohols. The principal component is an ester of ambrein ($C_{23}H_{39}OH$), which gives it its peculiar properties and odor (Gilmore, 1951). One analysis gave the following chemical composition: ambrein, 25–45%; epicoprosterol, 30–40%; coprosterol, 1–5%; coprostanone, 3–4%; cholesterol, 0.1%; pristane, 2–4%; ketone, 3–4%; free acids, 5–8%; and residues insoluble in ether, 10–16% (Berzin, 1971; this analysis was mistranslated in the 1972 English edition of Berzin's book).

Contrary to the prevalent notion, ambergris is hardly ever found on beaches; most is recovered directly from whale carcasses. Through the years many people have brought me malodorous globs that they picked up on the seashore in hopes that it was ambergris; none of it ever was. If a suspected specimen of ambergris fits the physical description, the simplest way to confirm its identity is to heat a wire or needle in a flame and thrust it into the sample to a depth of about a centimeter; if the substance is really ambergris it will instantly melt into an opaque fluid the color of dark chocolate. When the needle is withdrawn, the ambergris will leave a tacky residue on it.

Ambergris was known throughout the Moslem world as early as the 9th century. There it was highly valued as an incense, an aphrodisiac, a laxative, a spice, an ingredient in candles and cosmetics, and as a medication for treating a diversity of ailments. Its reputation soon spread around the globe. In those days, ambergris was picked up on beaches or found floating on the sea, and its origin remained a complete mystery, thus giving rise to many fanciful and hotly debated theories. In 1574 the Flemish botanist Carolus Clusius was the first author to deduce from the inclusions of squid beaks in ambergris that it was the product of the digestive tract of whales. It was not until after the commencement of the American sperm whale fishery in 1712 that it became generally recognized that ambergris was produced solely by the sperm whale (Beale, 1839; Dannenfeldt, 1982). In the ensuing years, ambergris was prized mainly as a fixative for fragrances in perfumes. In the 20th century, synthetic chemicals replaced it so it no longer has much value.

Anatomical Dissection: Thorax and Abdomen

John E. Reynolds III
Eckerd College, St. Petersburg, Florida

Sentiel A. Rommel and Meghan E. Bolen
Florida Marine Research Institute, St. Petersburg

The general organization of the postcranial soft tissues does not vary appreciably among mammals. Factors that may influence the relative proportions or positions of organs and organ systems include phylogeny and adaptations to a particular environment or trophic level.

The structure and function of specific postcranial organs or organ systems are described in other articles of this encyclopedia. This article provides a "road map" that orients a prosector to the organs and organ systems of marine mammals. For comparative purposes, we focus on the California sea lion (*Zalophus californianus*), Florida manatee (*Trichechus manatus latirostris*), harbor seal (*Phoca vitulina*), and common bottlenose dolphin (*Tursiops truncatus*). Our descriptions are at the gross anatomical level.

To recognize variations on a theme, one must first recognize the theme. Although there is no "typical" mammal, we shall use our own species and the domestic dog as the norms against which to make comparisons. To appreciate human and dog anatomy, we suggest Hollinshead and Rosse (1985) and Evans (1993), respectively. Anatomy of internal organs of domestic mammals is covered by Schummer *et al.* (1979). For discussions of the anatomy of various types of marine mammals, consult Fraser (1952), Green (1972), Herbert (1987), Howell (1930), King (1983), Murie (1872, 1874), Pabst *et al.* (1999), von Schulte (1916), Slijper (1962), and St. Pierre (1974).

Wherever possible, anatomical terms follow the Nomina Anatomica Veterinaria as illustrated by Schaller (1992).

I. Mammalian Postcranial Landmarks

Marine mammals are generally dissected either ventrally or laterally, but some large, stranded animals must be examined in whatever position they are found. For consistency, we provide figures that describe anatomy in terms of a lateral view, and we discuss organs and organ systems in the order in which they are revealed during necropsy. Although this approach may take some getting used to if one is accustomed simply to the ventral approach, the lateral orientation approximates the living condition more closely.

A. The Diaphragm

The diaphragm of most marine mammals is generally similar in orientation to that of the diaphragm in both the human and the dog. It lies in a transverse plane and provides a musculotendinous sheet to separate the heart and its major vessels, the lungs and their associated vessels and airways, the thyroid, thymus, and a variety of lymph nodes (all located cranial to the diaphragm) from the major organs of the digestive, excretory, and urogenital systems (all typically caudal to the diaphragm). The diaphragm is generally confluent with the transverse septum (a connective tissue separator between the heart and liver) and, thus, attaches medially at its ventral extremity to the sternum.

Although the diaphragm separates the heart and lungs from the other organs of the body, the diaphragm is traversed by nerves and other structures, such as the aorta (crossing in a dorsal and medial position), the vena cava (crossing more ventrally than the aorta, and often slightly right of the midline, although appearing to approximate the center of the liver), and the esophagus (crossing slightly right of the midline, at roughly a mid-horizontal level). This approximately transverse orientation exists in most marine mammals, although the orientation of the diaphragm may be more or less diagonal, with the ventral portion being more cranial than the dorsal portion (Fig. 1A).

The West Indian manatee's diaphragm differs from this general pattern of orientation and attachment. The diaphragm and the transverse septum are separate, with the septum occupying approximately the "typical" position of the diaphragm and the diaphragm itself occupying a horizontal plane extending virtually the entire length of the body cavity (Fig. 1B). This apparently unique orientation contributes to buoyancy control (Rommel and Reynolds, 2000). Additionally, there are two separate hemidiaphragms in the manatee (Figs. 2B and 2C). The central tendons attach firmly to the ventral aspects of the thoracic vertebrae, producing two isolated pleural cavities. The position of the manatee

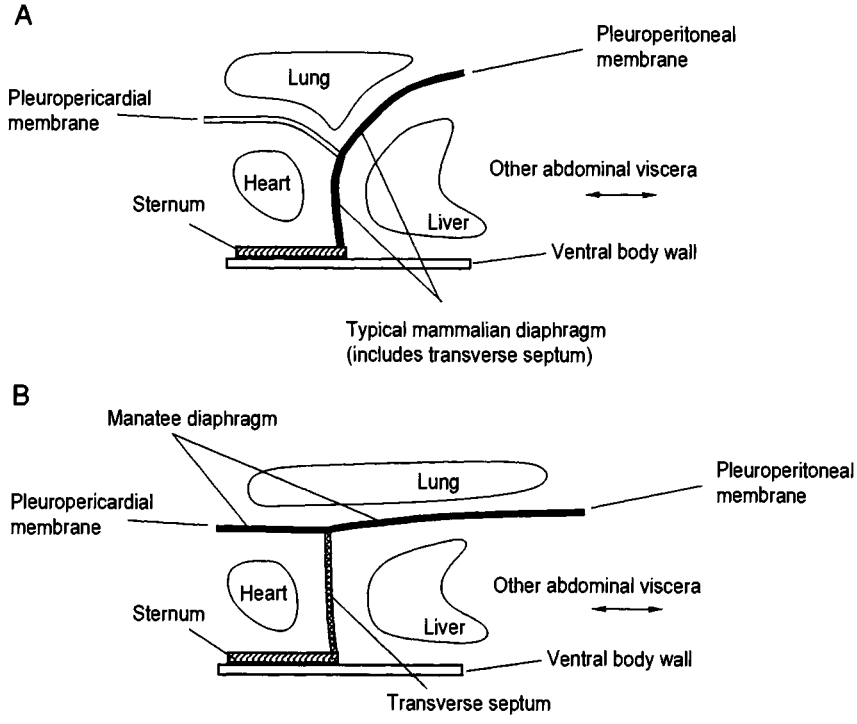

Figure 1 *Schematic arrangements of mammalian diaphragms. Modified after Rommel and Reynolds (2000). (A) The typical mammalian diaphragm extends ventrally from the dorsal midline to attach to the sternum. The typical diaphragm is a separator between the heart and lungs in the front and the liver and other abdominal organs in the back. (B) The manatee diaphragm extends dorsally to the heart and does not touch the sternum. There is a mechanical barrier between the heart and the liver and other abdominal organs, but it is a relatively weak barrier called the transverse septum.*

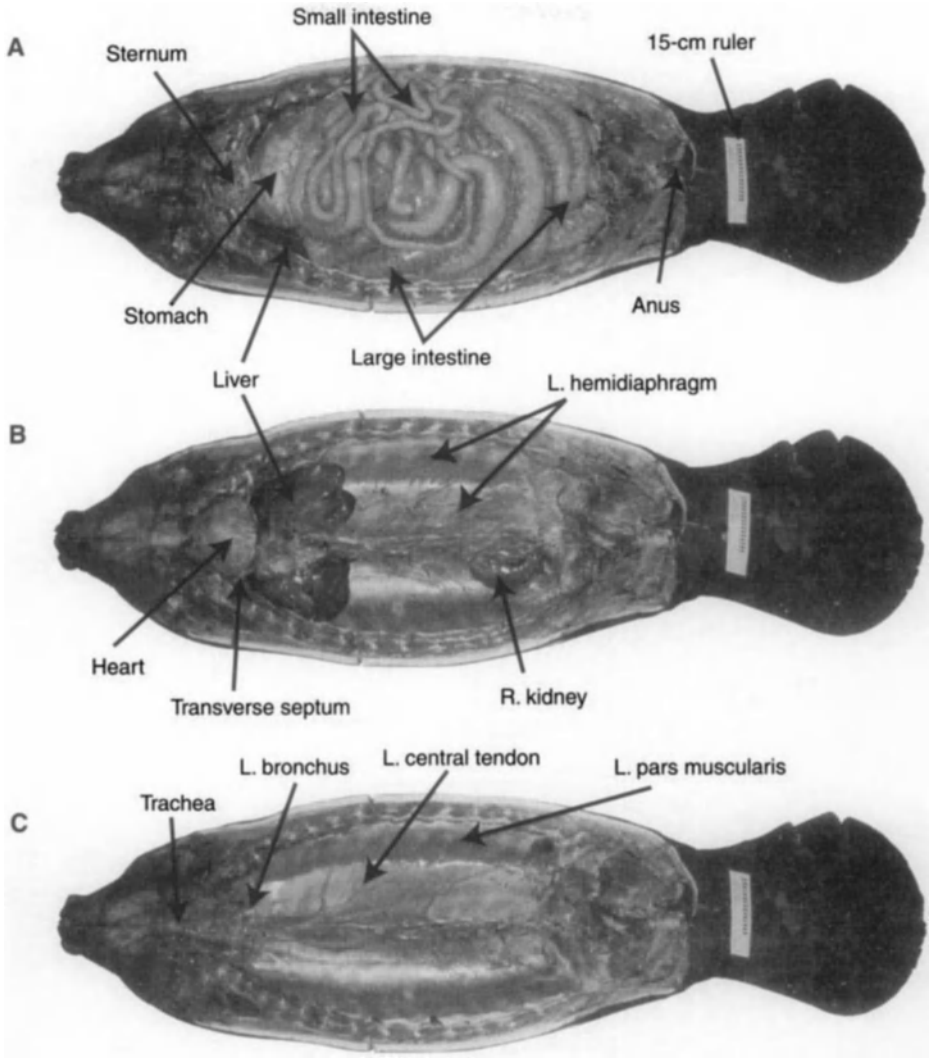

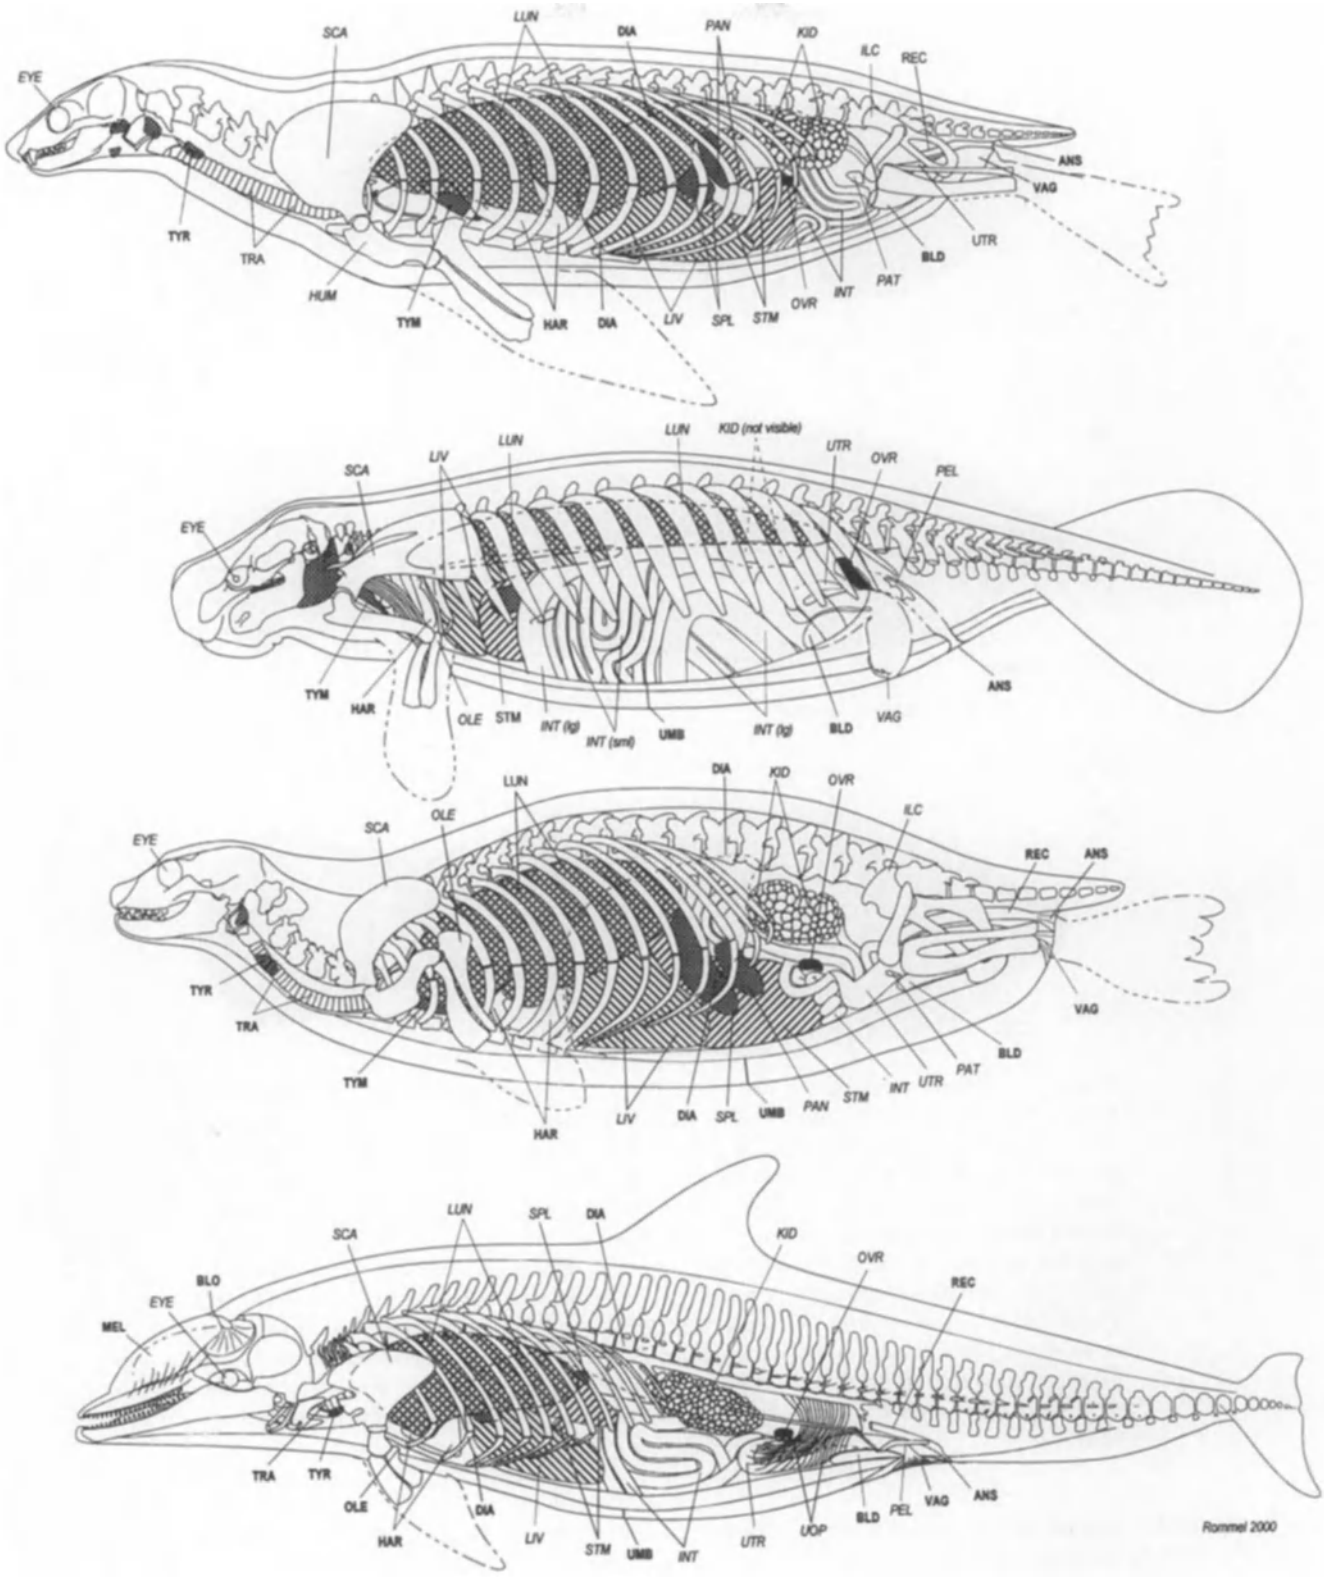

Figure 2 *Ventral views of the Florida manatee. Modified after Rommel and Reynolds (2000). The ruler is 15 cm long. (A) After removal of the ventral skin, fat, and musculature, the small and large intestines are exposed; the large intestine (with contents) may account for 10% of the total body weight and can measure 20 m long. Portions of the stomach and ventral margins of the liver are visible caudal to the sternum. (B) Removal of the GI tract reveals the heart, transverse septum, liver, hemidiaphragms, and right kidney (the left kidney was removed to expose that portion of the hemidiaphragm). (C) The two central tendons of the hemidiaphragms attach medially to the ventral aspects of the vertebral column. The diaphragm muscles attach laterally to the ribs. The lungs are flattened, elongate structures dorsal to the hemidiaphragms; when fully inflated, the lungs extend almost the entire length of the region dorsal to the hemidiaphragms. Note the junctions of the central tendon and the pars muscularis of each hemidiaphragm; this approximates the lateral margin of each lung.*

diaphragm stands in contrast with the curved, oblique diaphragms (DIA, Fig. 3) of the sea lion, seal, and dolphin.

B. Regions and Structures Cranial to the Diaphragm

The region cranial to the diaphragm is typically compartmentalized into three sections: (1) the pericardium (containing the heart), (2) the pleural cavities (containing the lungs), and (3) the mediastinum (Figs. 3 and 4).

The pericardium is a fluid-filled sac surrounding the heart (HAR, Fig. 3); in manatees, it often contains more fluid than is found in the pericardia of the typical mammal or in those of other marine mammals. The heart occupies a ventral position in the thorax (immediately dorsal to the sternum), making it easy

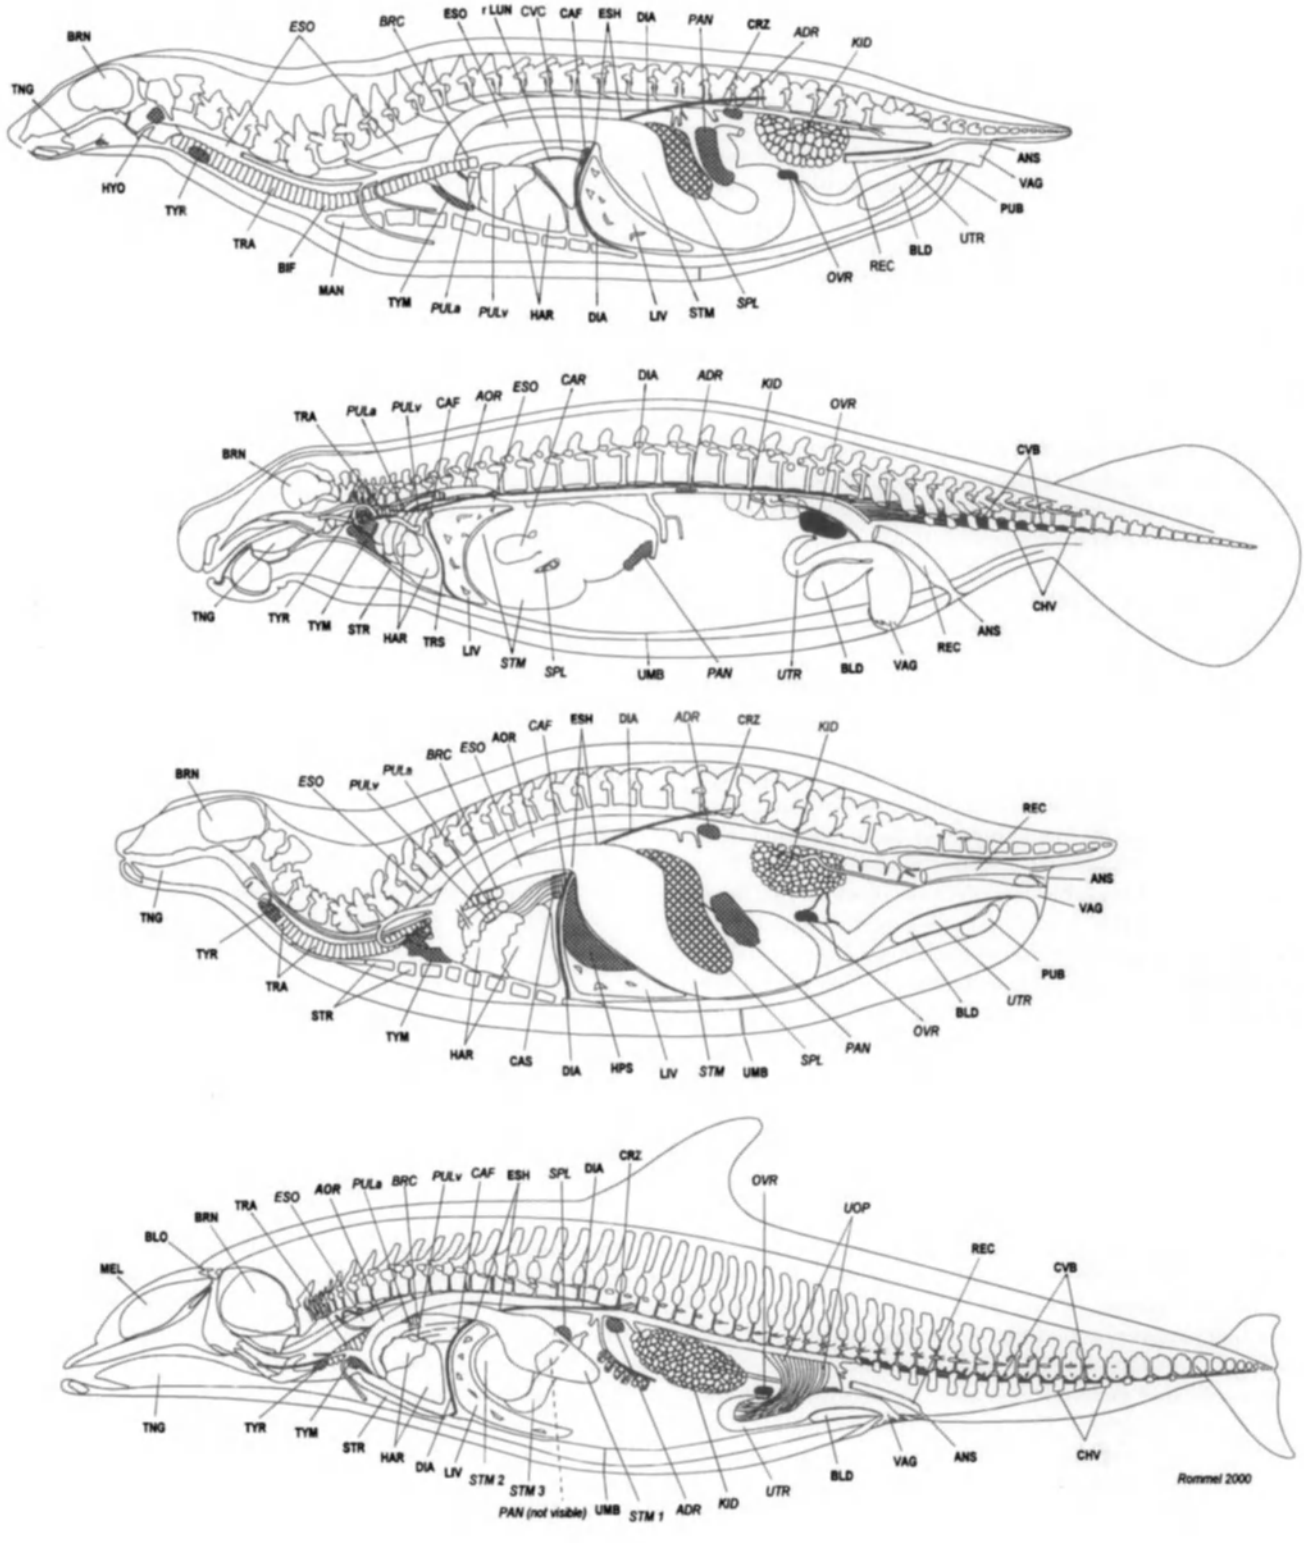
to see when the overlying muscles, ribs, and sternum are removed. The heart lies immediately cranial to the central portion of the diaphragm (or just the transverse septum in the manatee). Some lungs may embrace the caudal aspect of the heart, separating the heart from the diaphragm. As do the hearts of all other mammals, marine mammal hearts have four chambers, separate routes for pulmonary and systemic circulation, and the usual arrangements of great vessels (venae cavae, aorta, coronary arteries, pulmonary vessels). Cardiac fat is commonly found in manatees but is typically absent in pinnipeds and cetaceans.

The pleural cavities and lungs of mammals are generally found dorsally and laterally to the heart and are separated along the midline by the heart and mediastinum (see later). In the manatee, the lungs are unusual in that they extend virtually the length of the body cavity and remain dorsal to the heart (Rommel and Reynolds, 2000). Lungs of some marine mammals (cetaceans and sirenians) tend to be unlobed. The size of the lungs of marine mammals varies according to each species' diving proficiency. Marine mammals that make deep and prolonged dives (e.g., elephant seals, *Mirounga* spp) tend to have smaller lungs than expected (based on allometric relationships), whereas shallow divers (e.g., sea otters, *Enhydra lutris*) tend to have larger than expected lungs.

The mediastinum is typically considered to be the area between the lungs, excluding the heart and pericardium. The mediastinum contains the major vessels leading to and emanating from the heart, nerves (e.g., the phrenic nerve to the diaphragm), and lymph nodes. The thymus, which is larger in younger individuals, is found on the cranial aspect of the pericardium (sometimes extending caudally to embrace almost the entire heart) and may extend into the neck in some species. The thyroid gland is located in the cranial part of the mediastinum along either side of the distal part of the trachea, cranial to its bifurcation into the bronchi (in sea lions, but not in other marine mammals, the bifurcation is cranial to the thoracic inlet).[1] In most marine mammals, the mediastinum is generally not remarkable; in the manatee, however, the unusual placement of the lungs and the unique diaphragm change how one must define the mediastinum (Rommel and Reynolds, 2000).

One additional structure, located on the cranial aspect of the diaphragm in seals and sea lions, is an atypical mammalian muscular feature associated with the heart. This is the caval sphincter (CAS, Fig. 3), which can regulate the flow of oxygenated[2] blood in the large venous hepatic sinus to the heart during dives (Elsner, 1969).

C. Structures Caudal to the Diaphragm



Easy to find landmarks caudal to the diaphragm include a massive liver and the various components of the gastrointestinal (GI) tract. The urogenital organs are generally found only after removal of the GI tract (note that the exception is the uterus of a pregnant female).

1. The Liver Typically, the liver is located immediately caudal to the diaphragm. It is a large, brownish, multilobed organ positioned so that most of its volume/mass is to the right of the midline of the body. Although marine mammal livers are generally similar to the livers of other mammals, in manatees, the organ is displaced somewhat to the left and dorsal relative to its location in most other mammals. The size, color, and "sharpness" of the liver margins can be used to assess the nutritive state and health of individual animals. Bile may be stored in a gallbladder (often greenish in color) located ventrally between the lobes of the liver, although some species (e.g., cetaceans, horses, and rats) lack a gallbladder. Bile enters the duodenum to facilitate the chemical digestion of fats.

[1]The thoracic inlet is the cranial opening of the thoracic cavity and is bounded by the vertebral and sternal ribs and sternum.

[2]Diving mammals with abundant arteriovenous anastomoses (shunts between arteries and veins before capillary beds) can have high blood pressure and highly oxygenated blood in their veins. One such venous reservoir of oxygenated venous blood is the hepatic sinus of seals (King, 1983).

Figure 3 *Left lateral illustrations of the superficial internal structures and "anatomical landmarks" of the California sea lion, Florida manatee, harbor seal, and common bottlenose dolphin with the skeleton (minus the distal appendicular elements) superimposed for reference. Our view is a left lateral view, focused on relatively superficial internal structures (labeled in bold) visible from that perspective; the other important bony or soft "landmarks" are not necessarily visible from a left lateral view but they are useful for orientation and are labeled in italics. Skeletal elements are included for reference, but not all are labeled. Each drawing is scaled so that there are equivalent distances between the shoulder and the hip; thus, the thoracic and abdominal cavities are roughly equal in length. The shoulder joints are aligned. The left kidney (not visible from this vantage in the manatee) is illustrated. The relative sizes of the lungs represent partial inflation—full inflation would extend margins to distal tips of ribs (except in the manatee). The following abbreviations are used as labels (structures on the midline are in* **bold,** *those off-midline are not):* **ANS,** *anus;* **BLD,** *urinary bladder;* **BLO,** *blowhole of dolphin;* **DIA,** *diaphragm, midline extent (except manatee); EYE, eye (note small size in manatee);* **HAR,** *heart; ILC, iliac crest of the pelvis; INT, intestines, note the large diameter of the large intestines in the manatee; KID, left kidney (not visible from this vantage in the manatee); LIV, liver; LUN, lung (note that in this illustration, the lung extends under the scapula except in the seal);* **MEL,** *melon, dolphin only; OLE, olecranon; OVR, left ovary; PAN, pancreas (in this view visible only in seal and sea lion); PAT, patella; PEL, pelvic vestige;* **REC,** *rectum; SCA, scapula; SPL, spleen; STM, stomach;* **TRA,** *trachea (not visible in this view of the manatee);* **TYM,** *thymus gland;* **TYR,** *thyroid gland;* **UMB,** *umbilical scar; UOP, uterovarian plexus in dolphins; UTR, uterine horn;* **VAG,** *vagina. 2. The GI Tract Most of the volume of the cavity caudal to the diaphragm (the abdominal cavity) is occupied by the various components of the GI tract: the stomach, the small intestine (duodenum, jejunum, and ileum), and the large intestine (cecum, colon, and rectum). The proportions and functions of these components reflect the feeding habits and trophic levels of the different marine mammals. Therefore, the gastrointestinal tracts of marine mammals vary considerably.

Food and water travel from the mouth, through a muscular pharynx, and into the esophagus. As noted earlier, the latter pierces the diaphragm to join the stomach, which is typically a single, distensible sac. The distal end of the stomach (the pylorus) is marked by a strong sphincter before it connects with the small intestine (duodenal ampulla in cetaceans). The separation between jejunum and ilium of the small intestine is difficult to distinguish grossly, although the two sections are different microscopically. The junction of the small and large intestines is often (but not in cetaceans) marked by the presence of a cecum (homologous to the human appendix). In manatees, the midgut cecum has two blind pouches called cecal horns. In some marine mammals, the large intestine, as its name implies, has a larger diameter than the small intestine.

The gastrointestinal tracts of pinnipeds and other marine mammal carnivores follow the general patterns outlined earlier, although the intestines can be remarkably long in some species. Cetaceans, however, have some unique specializations (Gaskin, 1978). Cetaceans can have two or three stomachs (usually three), depending on the species being examined. The multiple stomachs of cetaceans function in much the same way as the single stomach found in most other mammals. The first stomach of cetaceans, called the forestomach (essentially an enlargement of the esophagus), is muscular and very distensible, and it acts much like a bird crop, i.e., as a receiving chamber. The second or glandular stomach is the primary site of chemical breakdown among the stomach compartments; it contains the same types of enzymes and hydrochloric acid that characterize a "typical" stomach. Finally, the "U-shaped" third or pyloric stomach ends in a strong sphincteric muscle that regulates the flow of digesta into the duodenum (the duodenal ampulla is sometimes mistakenly called a fourth stomach) of the small intestine. The cetacean duodenum is expanded into a sac-like ampulla. The only other remarkable feature at the gross level is the lack of a cecum, which makes it difficult to tell where the small intestine ends and the large intestine begins. The intestines of some cetaceans may be extremely long (especially in the sperm whale, *Physeter macrocephalus*; Slijper, 1962), but they are not especially long in many other marine mammal species.[3]

Among marine mammals, sirenians have the most remarkably developed gastrointestinal tract. Sirenians are herbivores and hindgut digesters (similar to horses and elephants) so the large intestine (specifically the colon) is extremely enlarged, enabling it to act as a fermentation vat (see Marsh *et al.*, 1977; Reynolds and Rommel, 1996). In horses, the cecum is the region of the large intestine that is enlarged, but in sirenians, the cecum is relatively small and has two "horns." The sirenian stomach is single chambered and has a prominent accessory secretory gland (the cardiac gland) extending from the greater curvature. The duodenum is capacious and has two obvious diverticulae projecting from it. The GI tract and its contents can account for more than 20% of a manatee's weight.

The length and mass of the gastrointestinal tract are impressive and create three-dimensional relationships that can be complex. Simplifying the organization is the fact that tough sheets of connective tissue called mesenteries suspend the organs from the dorsal part of the abdominal cavity and shorter bands of connective tissue (ligaments)[4] hold organs close to one another in predictable arrangements (e.g., the proximal spleen is always found

[3]Assessing the length of intestines is fraught with potential bias because it is extremely difficult not to stretch the intestines to unnatural lengths after they are freed from the mesenteries and straightened. Linear measurements of gastrointestinal tract are, therefore, highly subjective.

[4]Ligament has several meanings in anatomy: a musculoskeletal element (e.g., the anterior [cranial] cruciate ligament), a vestige of a fetal artery or vein (e.g., the round ligament of the bladder), the margin of a fold in a mesentery (e.g., broad ligament), and a serosal fold between organs (e.g., the gastrolienal ligament).

Figure 4 *A view slightly to the left of the midsagittal plane illustrates the circulation, body cavities, and selected organs of the California sea lion, Florida manatee, harbor seal, and common bottlenose dolphin, with the skeleton for reference. The left lung is removed. Note that the diaphragm separates the heart and lungs from the liver and other abdominal organs. Each drawing is scaled so that there are equivalent distances between the shoulder and the hip; thus, the thoracic and abdominal cavities are roughly equal in length. The shoulder joints are aligned. Note that the manatee's diaphragm is unique and that the distribution of organs and the separation of thoracic structures from abdominal structures require special consideration in these beasts. The following abbreviations are used as labels (structures on the midline are in* **bold**, *those off midline are not): ADR, adrenal gland;* **ANS,** *anus;* **AOR,** *aorta;* **BLD,** *urinary bladder;* **BLO,** *blowhole;* BRC, *bronchus;* **BRN,** *brain;* **CAF,** *caval foramen;* CAR, *cardiac gland, in manatee only;* **CAS,** *caval sphincter, surrounding the vena cava in the seal and sea lion;* **CHV,** *chevron bones;* CRZ, *crus (plural crura) of the diaphragm;* **CVB,** *caudal vascular bundle, in manatee and dolphin;* **DIA,** *diaphragm, cut at midline, extends from crura dorsally to sternum ventrally (except in manatees);* ESH, *esophageal hiatus;* **ESO,** *esophagus (to the left of the midline cranially, on the midline caudally);* **HAR,** *heart;* **HPS,** *hepatic sinus within liver, in seals only;* KID, *right kidney;* **LIV,** *liver, cut at midline;* **LUN,** *lung, right lung between heart and diaphragm:* **MEL,** *melon, dolphin only;* PAN, *pancreas;* **PUB,** *pubic symphysis (seals and sea lions only);* PULa, *pulmonary artery, cut at hilus of lung;* PULv, *pulmonary vein, cut at hilus of lung;* **REC,** *rectum, straight part of terminal colon;* SPL, *spleen;* STM1, *forestomach;* STM2, *main stomach (STM in noncetaceans);* STM3, *pyloric stomach;* **STR,** *sternum, sternabrae;* **TNG,** *tongue;* **TRA,** *trachea;* **TRS,** *transverse septum;* **TYM,** *thymus gland;* **TYR,** *thyroid gland;* **UMB,** *umbilicus;* UOP, *right uterovarian vascular plexus in dolphin;* UTR, *uterus;* **VAG,** *vagina. Copyright S. A. Rommel.*

along the greater curvature of the stomach and is connected to the stomach by the gastroliental, or gastrosplenic, ligament). Also suspended in the mesenteries are numerous lymph nodes and fat.

Accessory organs of digestion include the salivary glands (small in most marine mammals but very large in the manatee), pancreas, and liver (where bile is produced and then stored in the gall bladder). The pancreas is sometimes a little difficult to locate because it can be a rather diffuse organ and it decomposes rapidly; however, a clue to its location is its proximity to the initial part of the duodenum, into which pancreatic enzymes flow. Another organ that is structurally, but not functionally, associated with the GI tract is the spleen, which is suspended by a ligament, generally from the greater curvature of the stomach (the first stomach in cetaceans) on the left side of the body. The spleen may be a single organ accompanied by accessory spleens in some species. The spleen is bluish in color and varies considerably in size among species; in manatees and cetaceans it is relatively small, but is more massive in some deep-diving pinnipeds (Zapol *et al.*, 1979) and acts as a storage region for red blood cells.

3. Urogenital Anatomy The kidneys lie in a retroperitoneal position, typically against the musculature of the back (epaxial muscles) at or near the dorsal midline attachment of the diaphragm (crura). In the manatee, the unusual placement of the diaphragm means that the kidneys lie against the diaphragm, not against the epaxial muscles. All mammals have metanephric kidneys (i.e., containing cortex, medulla, calyces). In many marine mammals, the kidneys are specialized as reniculate (multilobed) kidneys, where each lobe (renule) has all the components of a complete metanephric kidney. Why marine mammals have reniculate kidneys is uncertain, but the fact that some large terrestrial mammals also have reniculate kidneys has led to speculation that they are an adaptation associated simply with large body size (Vardy and Bryden, 1981).

The renal arteries of cetaceans enter the cranial poles of the kidneys, whereas in other marine mammals, they enter the hilus (typical of most mammals). Additionally, in manatees, there are accessory arteries on the surface of the kidney. The kidneys are drained by separate ureters, which carry urine to a medially and relatively ventrally positioned urinary bladder. The urinary bladder lies on the floor of the caudal abdominal cavity and, when distended, may extend as far forward as the umbilicus in some species. The pelvic landmarks are less prominent in fully aquatic mammals. In the manatee, the bladder can be obscured by abdominal fat.

Pabst *et al.* (1999) noted that the reproductive organs tend to reflect phylogeny more than adaptations to a particular niche. If one were to examine the ventral side of cetaceans and sirenians before removing the skin and other layers, one would discover that positions of male and female genital openings are different, permitting rather easy determination of sex without dissection. In all marine mammals, the female urogenital opening is more caudal than the opening for the penis in males. One way to approach dissection of the reproductive tracts is to follow structures into the abdomen from their external openings.

The position and general form of the female reproductive tract in marine mammals are generally similar to those of the female reproductive tracts in terrestrial mammals. The vagina opens cranial to the anus and leads to the uterus, which is bicornuate in marine mammal species. The body of the uterus is found on the midline and is located dorsally to the urinary bladder (the ventral aspect of the uterus rests against the bladder). Although the body of the uterus lies along the midline, it has bilaterally paired, relatively large diameter projections called uterine horns (cornua), which extend laterally. The relatively small-diameter oviducts conduct eggs from the ovaries to the uterine horns where implantation of the fertilized egg and subsequent placental development occur. The dimensions of the uterine horns vary with reproductive history and age. Often the fetus may expand the pregnant horn to the point that it fills a substantial portion of the abdominal cavity. The horns terminate abruptly, narrowing and extending as uterine tubes (fallopian tubes) to paired ovaries. The uterus and the uterine horns are held in place in the abdominal cavity by the broad ligaments. Uterine and ovarian scarring may provide information about the reproductive history of the individual.

The ovaries of mature females may have one or more white or yellow-brown scars, called corpora albicantia and corpora lutea, respectively. Although ovaries are usually solid organs, in sirenians they are relatively diffuse.

Mammary glands are ventral, medial, and relatively caudal in most marine mammals, but they are axillary in sirenians. Many marine mammals have a single pair of nipples, sea lions and polar bears, *Ursus maritimus*, (DeMaster and Sterling, 1981), have two pairs of nipples, and cetaceans have mammary slits (note that some male cetaceans have distinct mammary slits).

The male reproductive tracts of marine mammals have the same fundamental components as the tracts in "typical" mammals, but positional relationships are significantly different. This difference is due to the testicond (ascrotal) position of the testes in most marine mammal species [sea otters are scrotal (J. Bodkin personal communication); polar bears are seasonally scrotal (I. Stirling personal communication); sea lion testes become scrotal when temperatures are elevated]. The testes of some marine mammals are intraabdominal, but in phocids, for example, they lie outside the abdomen, partially covered by the oblique muscles and BLUBBER. The position of marine mammal testes creates certain thermal problems because spermatozoa do not survive well at body (core) temperatures; in some species, these problems are solved by the circulatory adaptations mentioned later.

The penis of marine mammals is retractable and it normally lies within the body wall. The general structure of the penis relates to phylogeny (see Pabst *et al.*, 1999).

4. Adrenal Glands The term "suprarenal gland" is often used interchangeably with "adrenal gland." Although the suprarenals often lie immediately atop or very close to the kidneys of terrestrial mammals, adrenals of marine mammals may lie several centimeters cranial to the kidneys, along either side of the median. Adrenal glands can be confused with lymph nodes, but if one slices the organ in half, an adrenal gland is easy to distinguish grossly by its distinct cortex and medulla.

5. Circulatory Structures Basically, blood vessels are named for the regions they feed or drain. Thus, the fully aquatic marine mammals (cetaceans and sirenians) lack femoral arteries that supply the pelvic appendage. However, most organs in

marine mammals are similar to those of terrestrial mammals so their blood supply is also similar. Therefore, readers who want to learn details of typical circulatory anatomy should consult one of the anatomy references cited earlier. The thoracic aorta leaves the heart and lies ventral to the vertebral column, giving off segmental arteries to the vertebrae and epaxial muscles (and in the case of cetaceans and manatees to the thoracic retia). The aorta continues through the aortic hiatus of the diaphragm (between the crura) and into the abdomen as the abdominal aorta and lumbar aorta, which give off several paired (e.g., renal, gonadal) and unpaired (e.g., celiac, mesenteric) arteries. The caudal aorta follows the ventral aspect of the tail vertebrae. In the permanently aquatic marine mammals, there are robust ventral chevron bones that form a canal in which the caudal aorta, its branches, and some veins are protected.

Some of the diving mammals (e.g., seals, cetaceans, and sirenians) have few or no valves in their veins (Rommel *et al.*, 1995); this adaptation simplifies blood collection.[5] Other exceptions to the general pattern of mammalian circulation are associated with thermoregulation and diving. Countercurrent heat exchangers abound, and extensive arteriovenous anastomoses exist to permit two general objectives to be fulfilled: (1) regulating loss of heat to the external environment, while keeping core temperatures high; and (2) permitting cool blood to reach specific organs (e.g., testes, uteri, spinal cord) that cannot sustain exposure to high body temperatures (see reviews by Rommel *et al.*, 1998; Pabst *et al.*, 1999).

In mammals, several paths for supplying blood to the brain exist; via the internal carotid, the external carotid, and the vertebral/basilar arteries. Some species use only one, others use two, and manatees use all three pathways. In cetaceans, the path for supplying blood to the brain is unique. The blood destined for the brain first enters the thoracic rete, a plexus of convoluted, small diameter arteries in the dorsal thorax. Blood leaves the thoracic rete and enters the spinal rete where it surrounds the spinal cord and enters the base of the skull (McFarland *et al.*, 1979). There are two working explanations for this convoluted path of blood to the brain: (1) the elasticity of the retial system allows mechanical damping of the blood pulse pressure wave (McFarland *et al.*, 1979) and (2) the juxtaposition of the thoracic retia to the dorsal aspect of the lungs may provide thermal control of the blood entering the spinal retia. Combined with cooled blood in the epidural veins, the spinal retia may provide some temperature control of the central nervous system (Rommel *et al.* 1993, paper presented at the Tenth Biennial Conference on the Biology of Marine Mammals).

II. Overview

Marine mammal postcranial soft tissue anatomy is, in many regards, similar to that of "typical" mammals. However, the relative proportions of and, to some extent, the positions of organs may be somewhat different from the norm.

We close with a reminder about orientation: namely the orientation of the prosector relative to the orientation of the specimen and the orientation of the specimen to the orientation of that animal when it was alive. The position of animals during necropsy may be belly-up, obviously not the usual position of the living animals. Thus, gravitational forces make the positional relationships we may observe during necropsy somewhat artificial; we assess "dead anatomy" rather than "living anatomy." We suggest that people examining marine mammal postcranial anatomy bear this fact in mind and try to constantly picture how the structures being observed during necropsy might be arranged in a free-ranging animal. The more the latter perspective can be maintained, the easier it will be to envision dynamic relationships among organs and systems and to relate function (physiology) to structure (anatomy).

Acknowledgments

We thank Ian Stirling and Jim Bodkin for providing information on the polar bear and sea otter, respectively. We thank Derek Fagone, Judy Leiby, Tom Pitchford, and James Quinn at the Florida Marine Research Institute for reviewing the manuscript. We thank Llyn French for help with Fig. 2. Anatomical illustrations were created with FastCAD (Evolution Computing, Tempe, AZ).

Antarctic Marine Mammals

Ian L. Boyd
University of St. Andrews, Scotland, United Kingdom

The Southern Ocean is the oceanic region surrounding the continent of Antarctica. Its southern boundary is defined by the narrow coastal continental shelf of Antarctica itself. To the north the boundary is defined by an oceanic frontal feature known as the Antarctic convergence or southern polar frontal zone. This zone marks the boundary between cold southern polar waters and northern temperate waters. The ocean temperature can change by as much as 10°C across the front, which may be only a few miles across. The polar front is an important physical feature that determines marine mammal distributions. It defines the normal southern extent of the distributions of most tropical and temperate marine mammals (Fig. 1).

A second feature that is important to marine mammals in the Antarctic is the annual sea ice. The seasonal changes in sea ice cover can lead to up to 50% of the Southern Ocean being covered in ice during late winter, but by late summer this can have contracted to 10% of the winter maximum. These large seasonal fluctuations in the sea ice have profound implications for the ecology of the Southern Ocean, including that of marine mammals. Many marine mammals, including most cetaceans, migrate north across the polar front in winter.

I. Antarctic Species

This section deals with true Antarctic species defined as those species whose populations rely on the Southern Ocean as a habitat, i.e., critical to a part of their life history, either through the provision of habitat for breeding or through the provision of the major source of food. Species that inhabit the sub-Antarctic, which is generally seen as including the islands that circle Antarctica in the region of the polar front or the polar frontal zone itself, are not included.

The Southern Ocean accounts for about 10% of the world's oceans but it probably supports >50% of the world's marine mammal biomass, including six species of pinnipeds, eight species of baleen whales, and at least seven species of odontocete whales. Therefore, in terms of the diversity of species, the Antarctic is host to only one-fifth of the world's pinniped and a little less than one-fifth of the world's cetacean species. This low diversity may be attributed partly to the lack of land masses to cause isolation and speciation and also because, although large in its total area, the Southern Ocean does not have the diversity of habitats and prey species seen in other ocean basins.

Among the pinnipeds, there is one species from the family Otariidae (eared seals, which include fur seals and sea lions) and there are five species from the family Phocidae (earless or "true" seals), but all of these come from a single subfamily, the Monachinae (see Table I). This list is as notable as much by its absences as it is for those that are present. For example, there is no representative of the phocid subfamily Phocinae, which contains a diverse collection of species of Northern Hemisphere seals. There are also no representatives of the subfamily Otariinae, which includes all of the sea lions, and there is only one representative of the diverse Southern Hemisphere subfamily Arctocephalinae, which includes the southern fur seals.

Where pinnipeds are concerned, historically it would appear that there have been only two or three species immigrating into the Antarctic. The main immigration was of an ancestral phocid, possibly related to the nearly extinct tropical phocids of today known as monk seals, which gave rise to the four most closely related Antarctic phocids: the crabeater, Weddell, Ross, and leopard seals. At some later date it is likely that elephant seals arrived. Although they extend their distribution into south temperate latitudes, as much as 90% of the world population relies on the Southern Ocean as a critical habitat.

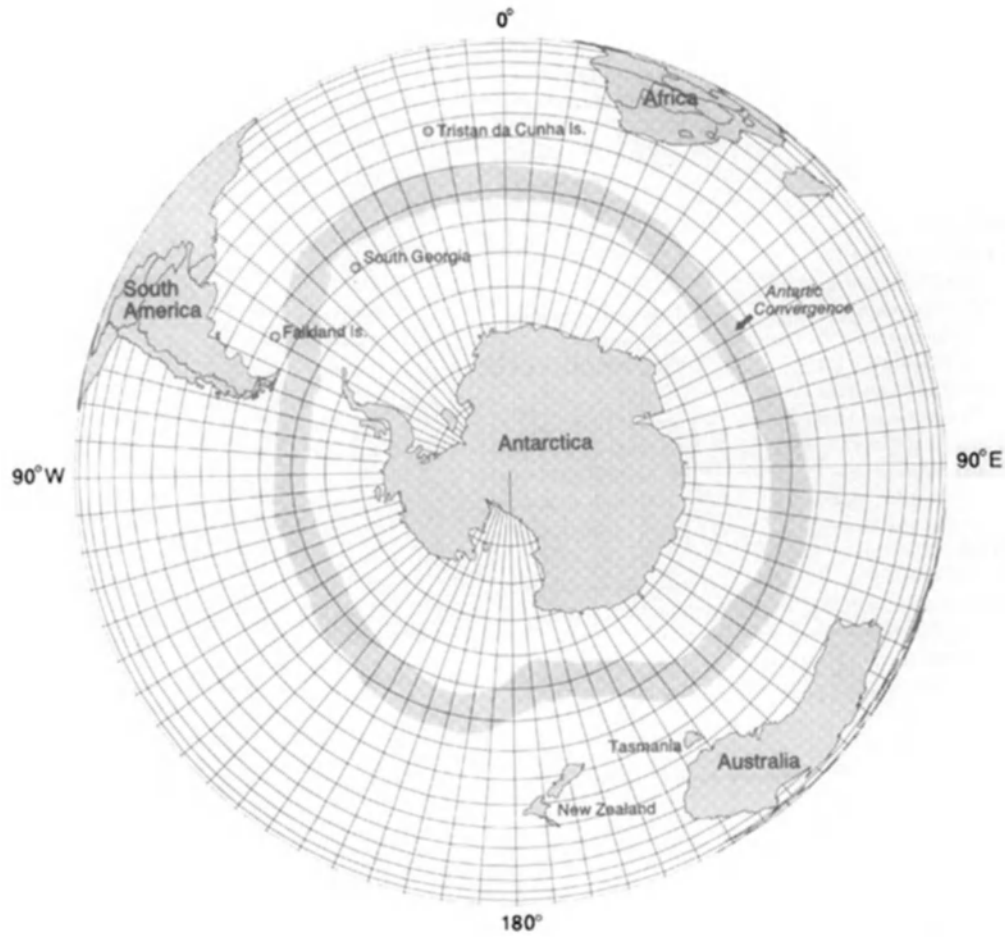

Figure 1 *Waters of warmer northern seas meet the perpetually colder waters around Antarctica to create the Antarctic Convergence. This confluence of relatively warm and frigidly cold waters occurs in some of the roughest seas known.*

These were likely to have been followed, or perhaps even preceded, by Antarctic fur seals. The taxonomic status of Southern Hemisphere fur seals, a group within which eight species are currently recognized, is uncertain and it seems probable that many of these are not true species but are instead subspecies. Therefore, the Antarctic fur seal may simply be an Antarctic race or subspecies of the southern fur seal.

Among cetaceans, there are only three Antarctic species within the highly diverse family Delphinidae, which includes all of the dolphins and porpoises. These three are the hourglass dolphin, long-finned pilot whale, and killer whale. The beaked whales are represented by only three species, but because these species are very difficult to identify in the field, it is possible that among the very large number of these individuals that are found in the Southern Ocean, several other species could be present.

II. Ecology of Antarctic Marine Mammals

The presence of a large biomass of marine mammals in the Antarctic is probably a result of the unusual food chain structure of the Southern Ocean. The marine mammals of the Antarctic with large numbers, such as crabeater seals and Antarctic fur seals, rely on krill as their main food source (see Section IV). This is in contrast to marine mammal communities elsewhere that rely mainly on a fish-based diet. Energy enters the food chain through photosynthesis and carbon sequestration by phytoplankton. The relative efficiency with which this energy is passed up the food chain to predators with a krill- or fish-based diet is illustrated in Fig. 2. The efficiency of energy transfer at each step in the food chain can be as low as only a few percent. The fewer steps there are between phytoplankton and marine mammals, the more efficiently will energy be transferred to marine mammals. In the Antarctic, there is on average one less step than there is in other oceanic ecosystems, which has led to the very large biomasses of marine mammals found in the Southern Ocean.

III. Distribution and Abundance

Antarctic marine mammals can be divided ecologically among those associated with fast ice, pack ice, or found in the open ocean. Weddell seals are most associated with fast ice, Ross seals with open water or pack ice. Leopard seals are

TABLE I
Species and Common Names, Abundances, Trends in Abundance, and Conservation Status of Antarctic Marine Mammals

Taxonomic classification	*Common name*	*Abundance*[a]	*Trend in abundance*	*Conservation status*
Order Cetacea				
Suborder Odontoceti				
Family Delphinidae				
Lagenorhynchus cruciger	Hourglass dolphin	150,000	—	Unknown
Orcinus orca	Killer whale	80,000	—	No threat
Globicephala melas	Long-finned pilot whale	200,000	—	No threat
Family Physeteridae				
Physeter macrocephalus	Sperm whale	30,000	—	No threat
Family Ziphiidae	Beaked whales	600,000	—	No threat
Berardius arnuxii	Arnoux's beaked whale	—	—	Unknown
Hyperoodon planifrons	Southern bottlenose whale	—	—	No threat
Mesoplodon layardii	Strap-toothed whale	—	—	Unknown
Suborder Mysticeti

[a]Cetacean abundances are from most recent estimates, but are not known as precisely as shown here. The number of asterisks denotes the range in the size of the populations: °, 0 to 1000; °°, 1000 to 10,000; °°°, 10,000 to 100,000; °°°°, 100,000 to 1,000,000; °°°°°, 1,000,000 to 10,000,000; and °°°°°°, 7,000,000 to 14,000,000.
[b]Minke whale abundance is for the two species combined.

animals mainly of the pack ice zone, but they may also be found feeding at penguin and seal colonies north of the pack ice zone. Crabeater seals travel extensively within the pack ice zone and individuals may have a potential range that extends to the total area of the Antarctic pack. The same may be true for Ross seals, although relatively little is known about the biology of these animals. They have been recorded to migrate north of the pack ice zone. Weddell seals appear to be relatively sedentary, forming more or less isolated populations around the coast of Antarctica.

Elephant seals are known to feed within the pack ice zone on occasion, but they are mainly animals of the open oceans north of the pack ice zone. Antarctic fur seals are sometimes found along the boundary between the pack ice and the open ocean but, again, they are mainly animals of the open ocean. Perhaps up to half of both the Antarctic fur seal and southern elephant seal populations migrate north of the polar front during the winter.

Toothed whales have a stratified distribution within the Southern Ocean relative to the polar front and the edge of the pack ice (Fig. 3). Some species, such as long-finned pilot whales and hourglass dolphins, are more closely associated with the polar front, whereas others, such as killer whales, are more often present close to the pack ice. Bottlenose and killer whales

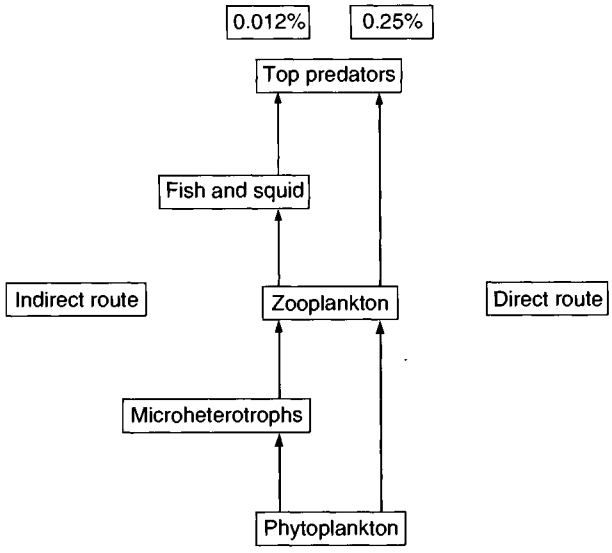

Figure 2 *Simplified diagram of energy flow to marine mammals as top food chain predators in marine food chains. This shows the contrast in efficiency of transfer when energy mainly takes a direct route, as in the case of marine mammals in the Southern Ocean, compared with the more indirect route involving more steps in the food chain. The percentage of the energy taken in by phytoplankton that subsequently reaches the top predators is shown at the top of the diagram.*

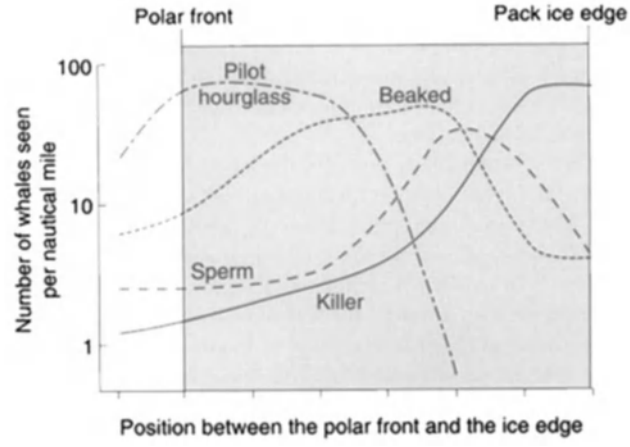

Figure 3 *Distribution of odontocete whales in the Southern Ocean relative to the southern polar front and the edge of the pack ice. Reprinted from Kasamatsu and Joyce (1995) with permission of Cambridge University Press.*

are the only cetaceans regularly associated with a distribution within the pack ice zone, but they are also present within the open ocean. Bottlenose whales appear to be able to survive comfortably among almost continuous sea ice cover. Killer whales have been recorded in pack ice in winter, but the only baleen whale found regularly in the pack ice zone is the minke whale. Other larger species, including the sperm whale, are restricted to the open ocean, but during the summer they may feed along the boundary between the pack ice and the open ocean. In general, these species are absent from the Southern Ocean during the winter. In the case of the sperm whale, only males are found within the Southern Ocean as females remain north of the polar front throughout the year.

Marine mammal distributions are also affected by bathymetric and oceanographic conditions. Southern right whales, which are possibly from the same population that winters at Peninsula Valdés, Argentina, and along the coast of South Africa, spend the summer foraging over the continental shelf of South Georgia within the Southern Ocean. Baleen whale and Antarctic fur seal abundance around south Georgia is also influenced by the local oceanography so that there are regions of predictably high abundance of these marine mammals at specific points along the edge of the continental shelf. Southern elephant seals also appear to migrate from breeding and

Figure 4 *Populations of blue whales* (Balaenoptera musculus) *have declined around the world and especially in Antarctica. (Photo by K. C. Balcomb.)*

molting grounds on sub-Antarctic islands to shallow regions along the coast of Antarctica. Most of these types of preferences for different locations are assumed to reflect the distribution of food so that marine mammals migrate to the areas of greatest food abundance.

The crabeater seal is probably the most abundant seal in the world, with a population of somewhere between 7 and 14 million. There are considerably fewer Weddell seals and leopard seals (Table I). Ross seals are rarely seen and the total number is very uncertain, but it is probably the least abundant Antarctic pinniped. The Antarctic fur seal population is >3 million and is increasing at about 10% each year. In contrast, the southern elephant seal population within the Antarctic appears to have been relatively stable since the early-1960s, even though the number of elephant seals breeding at sites outside the Antarctic has declined steadily over the same period. The elephant seal population at South Georgia is estimated at 470,000, which probably represents 58% of the world population of the species.

In general, whale populations are in a highly depleted state (Table I). Blue whales are numbered in the hundreds for the whole of the Antarctic, and the sighting of a blue whale is a rare event. The number of fin whales appears to be increasing, as are humpback whales and southern right whales.

Within the Antarctic, there are no significant threats to pinniped species. However, some cetacean populations have been depleted to such a high degree that several are endangered. In particular, blue whales are so rare in the Antarctic that they are possibly close to extinction from the area (Fig. 4). Similarly, severely depleted southern right whale and humpback whale populations have very specific migratory routes between summering grounds in the Antarctic and winter grounds in temperate and tropical regions, which make them more vulnerable to threats such as disturbance, habitat loss, and reduced genetic diversity.

IV. Diet

Among seals, there is a progression of dietary specialization from those that mainly eat krill to those that mainly eat fish (Fig. 5). The leopard seal has seabirds and other seals as a major component of its diet, and it is probable that some individuals specialize in feeding on other seals or penguins instead of krill, fish, or squid. Among whales, dietary specializations are divided along taxonomic lines between odontocetes that mainly eat squid and mysticetes that forage primarily on zooplankton.

The crabeater seal is one of the most ecologically specialized of all seals because it feeds almost entirely on Antarctic krill that it gathers from the underside of ice floes where the krill themselves feed on the single-celled algae that grow within the brine channels in the ice. Antarctic fur seals also feed on krill to the north of the Antarctic pack ice edge, and many of the other Antarctic seals rely, to varying degrees, on krill as a source of food. Antarctic krill probably sustains more than half of the world's biomass of seals and also sustains a substantial proportion of the biomass of the world's seabirds and whales.

Although the dentition of crabeater seals is modified to help strain krill from the water, the feeding apparatus of the baleen whales is the most highly modified for a DIET of plankton. Krill

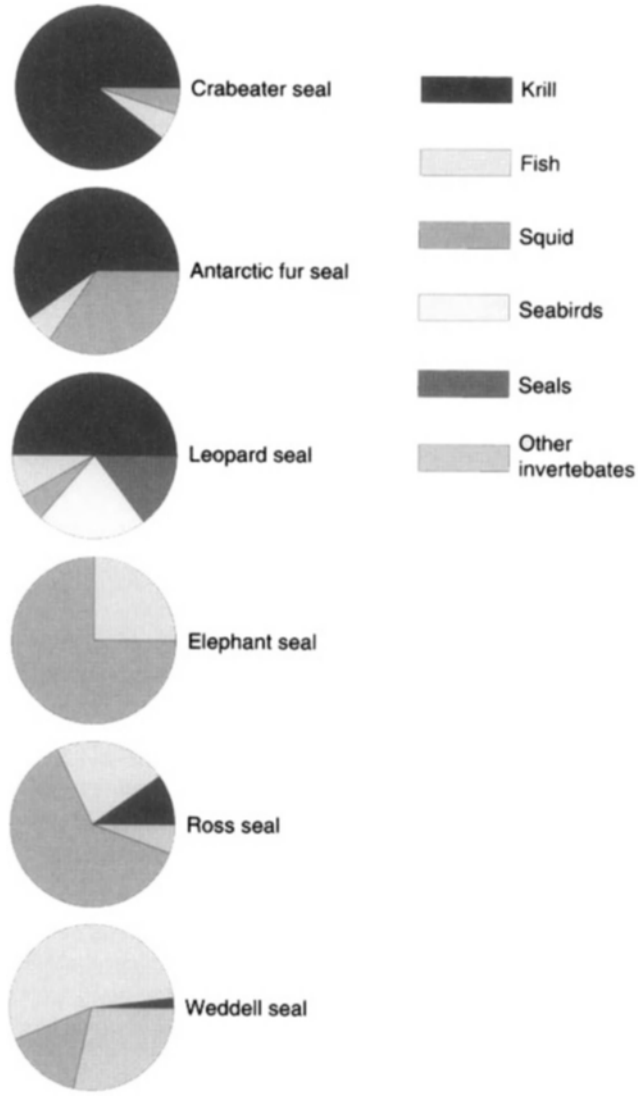

Figure 5 *Pie charts showing the composition of diets of Antarctic seals. The charts are arranged with those species that depend most on krill at the top and those that depend most on fish at the bottom; Between these are those species that have squid as a major component of the diet.*

is the major component in the diet of most of the Antarctic baleen whales, although copepods may also be strained from the water, especially by right whales. The Antarctic KRILL, *Euphausia superba,* often occurs in dense swarms in the open ocean, and the baleen whales have probably evolved to exploit these dense patches of food. Baleen whales eat 30–50 million tons of krill in the Antarctic each year and seals probably eat a similar or slightly lower total amount as whales. Consumption of squid by beaked whales and sperm whales is estimated to be about 14 million tons each year. Killer whales prey on fish and squid but also hunt seals and penguins. Pods of killer whales have been observed tipping over ice floes to push crabeater seals into the water in an effort to catch them.

V. Exploitation

Throughout the 19th and early 20th centuries, the Antarctic was viewed as an almost limitless source of marine mammals to be hunted for skins, oil, and other products that found expanding markets in Europe and North America. However, industrialization of whale and seal HUNTING brought both greater efficiency and the inevitability that the resources would be exhausted, much to the detriment of the ecology of the Antarctic and its populations of marine mammals.

There were three phases of exploitation: exploratory sealing (late 18th and early 19th centuries), preindustrial sealing and whaling (19th century), and industrial whaling (20th century). There are very few records of the exploratory sealing and the preindustrial era. During the exploratory era, exploitation was mainly targeted at fur seals to supply skins for the Chinese market, where they were turned into felt to supply the European market. By about 1830, fur seals in the Antarctic and elsewhere in the Southern Hemisphere had been all but extinguished. In 1825, James Weddell, himself the captain of a sealing vessel, noted that "the number of skins brought from off Georgia cannot be estimated at fewer than 1,200,000." He was referring to South Georgia, where >95% of the current world population of Antarctic fur seals resides. This species was considered to be extinct until the early 1920s when whalers saw several individuals at South Georgia. Since then, the numbers have increased rapidly and the population is conservatively estimated to now be on the order of 3 million. The preindustrial era was mainly targeted at whaling and the larger seals, particularly elephant seals, for their oil. This activity was mainly undertaken from sailing vessels. The introduction of steam power to the Antarctic was largely responsible for the transition to industrial whaling.

Industrial whaling began in the early years of the 20th century. This industry operated for more than 60 years and in that time it removed about 71 million tons of whale biomass involving 1.4 million individual whales from the Antarctic; about 10% of these were taken at South Georgia. Antarctic fur seals feed on krill (Fig. 5), and may have benefitted by the reduction in numbers of krill-feeding baleen whales and therefore had less competition for their food.

The industry was selective about which species of whales it targeted. The largest and most profitable were selected first, followed by progressively smaller species (Fig. 6). Eventually, the industry became unprofitable because only minke whales were left to exploit and these were too small to be profitable.

VI. Conservation Measures

Concerns about the effects of industrial whaling on the populations of whales began early in the industrial era. By the early 1920s, the "Discovery Investigations" had been established to determine whale populations mainly around South Georgia. These were funded by a levy on the industry, but they were free from control of the industry. They are one of the first examples of the fledgling field of ecology being used to solve a wildlife management problem. Even though the "Discovery Investigations" made ground-breaking scientific progress and were influential in the introduction of some conservation measures, they came too late to influence the power of the industry and the fate of the populations of whales in the Southern Ocean.

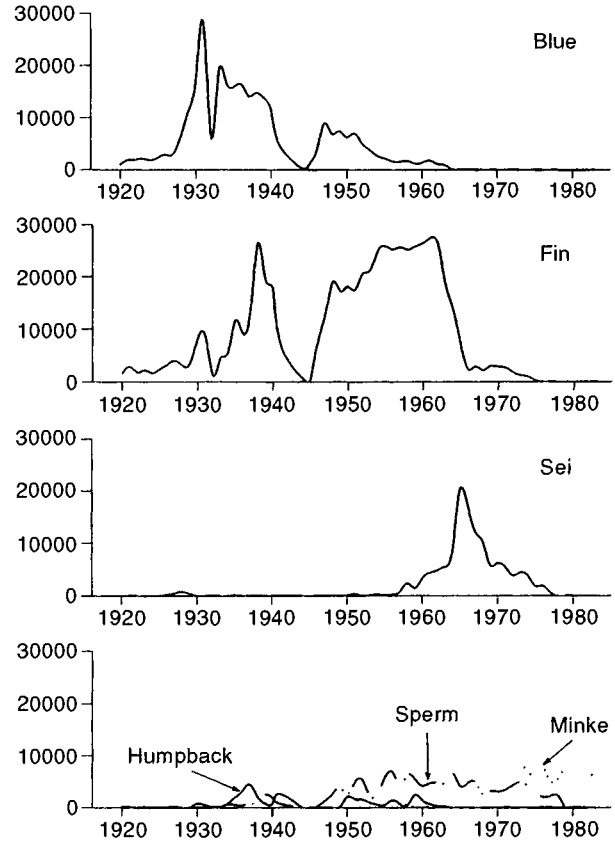

Figure 6 *Changes in the number of each species of whale caught in the industrial whale harvest in the Southern Ocean.*

The story of overexploitation of a marine resource in the Southern Ocean repeated itself in the 1960s and 1970s when industrial fisheries targeted fin fish populations and reduced them to uneconomic levels. This stimulated a renewed effort to ensure that there was proactive conservation of marine living resources in the Southern Ocean. The result was the Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR) and the Convention for the Conservation of Antarctic Seals (CCAS), which came into effect in 1982 and 1978, respectively. One of the unique features of the CCAMLR convention is that it accepts that exploitation has effects on components of the ecosystem far beyond those that are being targeted for exploitation. This means that any proposals for the exploitation of living resources in the Antarctic must consider the effects that such exploitation is likely to have on marine mammals, whether or not they are the target species. Therefore, even though marine mammals enjoy legal protection in the Antarctic from unregulated exploitation under the environmental protocol within the Antarctic Treaty, they are also protected from other activities within the Southern Ocean ecosystem. Only time will tell if this is sufficient to ensure their long-term survival.

Archaeocetes, Archaic

J. G. M. THEWISSEN
Northeastern Ohio Universities College of Medicine, Rootstown

Archaeocetes is the common name for a group of primitive whales that lived in the Eocene Period (approximately 55–34 million years ago). Archaeocetes are important because they represent the earliest radiation of cetaceans and because they include the ancestors of the two modern suborders of cetaceans (Mysticeti and Odontoceti). Archaeocetes are also the main source of information about the great morphological changes that were associated with the acquisition of aquatic features in cetaceans; archaeocetes document the initial amphibious stages in cetacean evolution [for a semipopular account, see Zimmer (1998)]. Six families of cetaceans are commonly included in archaeocetes (Thewissen, 1998; Fig. 1): Pakicetidae, Ambulocetidae, Remingtonocetidae, Protocetidae, Basilosauridae, and Dorudontidae. Basilosaurids and dorudontids are discussed separately, and the remaining four families are treated here. Williams (1998) discussed the taxonomy of these archaeocetes.

I. Pakicetidae

Pakicetidae are only known from the early-to-middle Eocene and lived approximately 50 million years ago in India and Pakistan. Dozens of fossils of pakicetids are known, but none consist of complete skeletons. Known skeletal elements of pakicetids include mainly SKULLS, teeth, and jaw fragments. The smallest pakicetids were as small as a fox, with the largest as large as a wolf. The dentition of pakicetids varied greatly: the smaller species had TEETH that resemble those of modern fish eaters, and teeth of the largest pakicetids resemble those of hyenas in some respects. Pakicetids may have been predators or carrion feeders. The nasal opening of pakicetids was near the front of the head, and the eyes faced dorsally, similar to crocodiles (Fig. 2). Pakicetids had small BRAINS flanked by enormous chewing muscles. The skull and dentition of pakicetids do not resemble those of modern whales and dolphins, but the ear of pakicetids clearly shows that they were cetaceans: there is a sigmoid process, an involucrum, and ear ossicles that

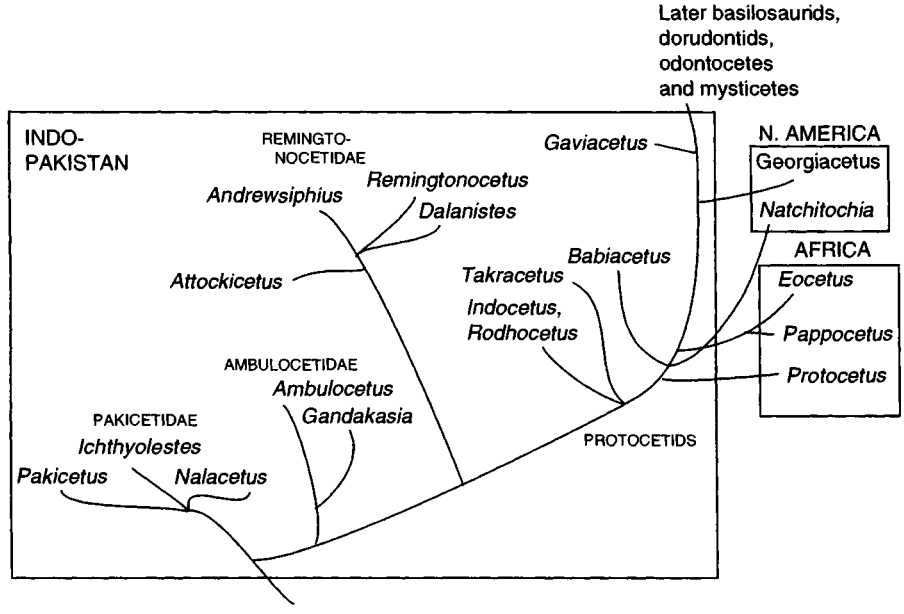

Figure 1 *Phylogeny of early and middle Eocene cetaceans, indicating on which continent each of the families occurred. Protocetids is considered a paraphyletic group, and Gaviacetus is not considered a protocetid.*

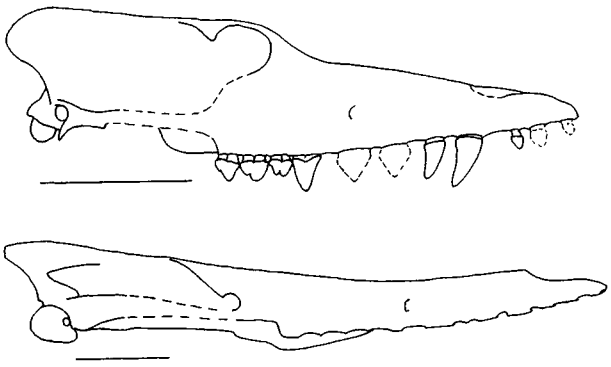

Figure 2 *Reconstructed skulls of* Pakicetus *and* Remingtonocetus. *No teeth are indicated for* Remingtonocetus, *as their morphology is poorly known. Scale bars are 10 cm.*

are pachyostotic and rotated (Thewissen and Hussain, 1993). Pakicetid fossils are only found in freshwater deposits and most are known from deposits that represent shallow ephemeral streams in an arid climate, which makes it unlikely that pakicetids were good swimmers. Three genera are included in Pakicetidae: *Pakicetus*, *Ichthyolestes*, and *Nalacetus*.

II. Ambulocetidae

Ambulocetids are known from middle Eocene rocks in northern India and Pakistan. There are fewer than 10 described ambulocetid fossils, but one of these consists of a nearly complete skeleton of a single individual of *Ambulocetus natans* (Thewissen *et al.*, 1994, 1996; Fig. 3). This skeleton is a prime source of information about early cetacean biology. *Ambulocetus* was similar in size to a large male sea lion. It had a large head, with a long snout and eyes that were dorsal on the skull, but faced laterally. The teeth are robust and strongly worn. Skull and vertebrae indicate that the muscles of the head and neck were strong, indicating that *Ambulocetus* was a powerful animal. The shape of the lower jaw of *Ambulocetus*, unlike that of the pakicetids, shows that there was an unusual soft tissue connection between the back of the jaw and the middle ear. In modern odontocetes, this connection consists of a large fat pad that functions as part of the sound-receiving system. This connection is small in *Ambulocetus* and was probably not as important functionally as it is in modern cetaceans. It does show that hearing adaptation arose early in cetacean phylogeny. *Ambulocetus* had a back that was strong and muscular, and the tail was long and lacked flukes. The hindlimbs were relatively short, but the feet were long, and there were four toes. The long paddle-shaped feet indicate that it swam like a modern otter, by swinging its hindlimbs through the water and creating additional propulsive force with its tail (Thewissen and Fish, 1997). The forelimbs were short, with five fingers that each terminated in a short hoof. The hands were much shorter than the feet. The skeleton of *Ambulocetus* indicates that it was probably slow on land. *Ambulocetus* was probably an ambush hunter, attacking prey in or near shallow water. This method of hunting is used by modern crocodiles.

Ambulocetus is only known from nearshore marine environments, including estuaries or bays. Geochemical analyses of ambulocetid bones indicate that it drank a mixture of fresh and seawater and that different individuals may have inhabited different microenvironments (Roe *et al.*, 1998). Genera included in Ambulocetidae are *Ambulocetus*, *Gandakasia*, and *Himalayacetus*.

III. Remingtonocetidae

Remingtonocetids are only known from India and Pakistan, from sediments approximately 46 to 43 million years old (middle Eocene; Bajpai and Thewissen, 1998). Dozens of remingtonocetid fossils have been described, but most of these document only the morphology of skull and lower jaw (Fig. 2). Dental and postcranial remains are scarce. The smallest remingtonocetids may have been as small as *Pakicetus*, and the largest may have been close in size to *Ambulocetus*. All early cetaceans had long snouts, but those of remingtonocetids are proportionally even longer than those of other archaeocetes. Skull shape varied between different remingtonocetid genera and possibly reflected different dietary specializations. In *Andrewsiphius* the snout is very narrow and high, and the chewing muscles are weak, suggesting that it may have eaten small, slippery fish. In *Remingtonocetus*, the snout is rounded and robust, and the chewing muscles are large, as would be expected in an animal that attacks larger, struggling prey. No remingtonocetid displays the robust masticatory morphology of *Ambulocetus*. The nasal opening of remingtonocetids is near the front of the skull, similar to pakicetids. The eyes are small, unlike ambulocetids and protocetids. The ear of remingtonocetids is larger than that of pakicetids and ambulocetids, and the connection between the lower jaw and the ear is larger than in ambulocetids. The ears are also set far part, possibly to increase directional hearing. These features are consistent with an increased emphasis on underwater hearing in remingtonocetids.

The postcranial morphology of remingtonocetids is only known from fragmentary specimens. These indicate that the neck was long and mobile and that the hindlimbs were large and that remingtonocetids were certainly able to support their body weight with their limbs, similar to ambulocetids (Gingerich *et al.*, 1995).

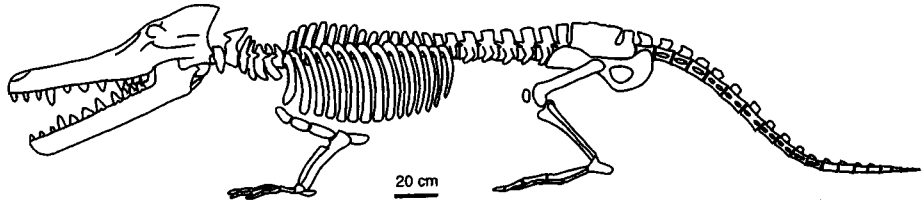

Figure 3 *Skeleton of* Ambulocetus. *Scale bar is 20 cm.*

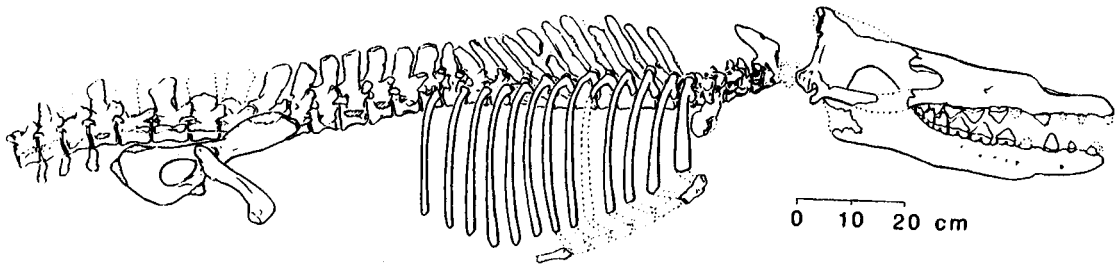

Figure 4 *Skeleton of the protocetid* Rodhocetus. *Reprinted by permission from* Nature *368, 845 (1994).* © *Macmillan Magazines Ltd.*

The most primitive and oldest remingtonocetid (*Attockicetus*) is found in the same deposits as *Ambulocetus*. The other remingtonocetids are known from marine, nearshore deposits and may have lived in bays and saltwater swamps. Stable isotope geochemistry indicates that remingtonocetids ingested seawater (Roe *et al.*, 1998). Remingtonocetid genera include *Remingtonocetus, Andrewsiphius, Attockicetus,* and *Dalanistes.*

IV. Protocetidae

Protocetids are found in middle Eocene rocks in Indo-Pakistan, Africa, Europe, and North America. They are the oldest whales to disperse across the oceans, although they probably only inhabited the warm seas near the tropics. Many protocetid genera are known, and several of these include several partial skeletons (Fig. 4) (Hulbert *et al.*, 1998). Protocetids are diverse; their average size was somewhat smaller than *Ambulocetus.*

Protocetids had long snouts, large eyes, and their nasal opening was farther caudally than in earlier archaeocetes. This suggests that protocetids could breathe while holding much of their head horizontally, similar to modern cetaceans. It foreshadows the origin of the cetacean blowhole. The teeth of protocetids vary between genera, but there is trend toward the reduction of occlusal basins on the teeth. Basins on the teeth of primitive mammals, including pakicetids and ambulocetids, are an essential part of chewing morphology. Modern cetaceans do not chew and lack basins, and protocetids show an early stage in the reduction of masticatory function of the teeth. It is likely that protocetids were active hunters of marine animals, possibly similar to modern pinnipeds. Protocetid locomotor morphology was varied. In general, the tail is well developed and was probably involved in creating propulsive forces (Buchholtz, 1998). The hindlimbs are reduced, and in some species the innominate is not connected by bone to the vertebral column, suggesting that the hindlimb did not support the body weight. There are no fossils that document all of protocetid hindlimb morphology, but some preserved elements suggest that the hindlimbs were short. Indo-Pakistani protocetids inhabited the same environments as the remingtonocetids, and protocetids from other continents are known from shallow marine environments. Known genera of protocetids are *Protocetus, Babiacetus, Eocetus, Georgiacetus, Indocetus, Natchitochia, Pappocetus, Rodhocetus,* and *Takracetus.*

These archaeocete families document that the Eocene cetacean evolution is characterized by increasing aquatic adaptations, starting at amphibious early whales (pakicetids, ambulocetids) to more marine protocetids. Late Eocene whales (Dorudontids, basilosaurids) were probably obligate marine mammals.

Arctic Marine Mammals

JOHN J. BURNS
Fairbanks, Alaska

There is a popular tendency to speak in rather nebulous terms about arctic marine mammals without defining the Arctic, the role and diversity of sea ice as a major component in high-latitude ecosystems, or the diversity of marine mammals adapted to live in various ice-dominated habitats. There are, in fact, few truly arctic marine mammals. This introductory discussion is about those that occur in ice-covered seas, at least during winter and spring, and in most cases give birth when ice is present. They include one ursid, eight pinnipeds, and three cetaceans. Only three species have a continuous circumpolar distribution. A few species (or stocks thereof) maintain a mostly year-round association with sea ice whereas most do not. The different marine mammals show various degrees of adaptation to ice. There is a continuum of ice-influenced habitats, and of mammalian adaptations to those habitats.

I. Northern Ice-Covered Marine Environments

Traditionally the Arctic is viewed as an ill-defined region around the North Pole that is further subdivided into the high arctic and the low arctic. We are here concerned with much broader, although still poorly defined, areas within which ice-associated bears, pinnipeds, and cetaceans occur. Some freshwater seals are included. It is useful to think in terms of regional climate, oceanography, annual ice dynamics, and life history strategies. For most marine environments the definitions advanced by Dunbar (1953) are particularly useful. The arctic seas are those in which unmixed polar water from the upper layers of the Arctic Ocean occurs in the upper 200–300 m. A large portion of this zone is ice covered throughout the year. The maritime subarctic includes those seas contiguous with the Arctic Ocean in which the upper water layers are of mixed polar and nonpolar origin. There are, however, some noncontiguous subarctic seas (no water of polar origin) adjacent to terrestrial ecosystems that lie in the subarctic zone. Examples include the Okhotsk Sea, the northern part of the Sea of Japan (Tartar Strait), Lake Baikal in Siberia, and Cook Inlet in Alaska (Fig. 1). In the subarctic there is a complete annual ice cycle, from formation in autumn to disappearance in summer. Finally, there are areas in the temperate zone where unique climate conditions produce a winter ice cover of relatively short duration. Such areas include the Baltic Sea, the northern Yellow Sea, and the western Sea of Japan.

In late summer the average annual minimum extent of sea ice is 5.2 million km^2, restricted mainly to the Arctic Ocean. The average maximum extent in late winter–early spring is 11.7 million km^2, including all of the subarctic seas (or parts thereof), and parts of some in the temperate zone. Most species of the so-called arctic marine mammals are associated with the seasonal ice during the breeding period. They cope with the annual expansion and contraction of the ice cover in a variety of different species-specific ways. Clearly there are many kinds of ice-dominated habitats formed in response to factors such as regional climate, weather, latitude, currents, tides, winds, land masses, proximity of open seas, and others.

II. Sea Ice Habitats

Sea ice in the Arctic and subarctic occurs in more complex forms than ice in the Antarctic. This is because of the central location of the Arctic Ocean with its perennial drifting ice, its partially landlocked nature, and the complexity of the subarctic seas encircling it. The annual expansion and contraction of the ice cover provides conditions ranging from the thick and relatively stable multiyear ice of the high latitudes to the transient and highly labile southern pack ice margins that border the open sea. Marine mammals must have regular access to air above the ice, as well as to their food in the ocean below it. During the breeding season the ice on which pinnipeds haul out must be thick enough and persist long enough for completion of the critical stages of birth, nurture of their young, and, in many cases, completion of the annual molt. Additionally, by virtue of location, behavior, reproductive strategies, and/or physical capabilities, they must be able to avoid excessive predation on dependent and often nonaquatic young. All of the marine mammals must also cope with the great reduction or complete absence of ice during the open water seasons.

There are many different features of the varied types of ice cover that provide marine mammals access to air and allow the pinnipeds to haul out. There are also some features, characteristics, or types of ice that exclude most marine mammals. Important ice features or types include stable land-fast ice (excludes most marine mammals); annually recurring persistent polynyas (irregular shaped areas of open water surrounded by ice); recurrent stress and strain cracks, coastal, and offshore lead systems (long linear openings); zones of convergence and compaction (as against windward shores or in constrictions such as narrow straits); zones of divergence (where boundary constraints are eased); the generally labile pack ice of the more southerly seas; and the margins of front zones of broken ice, the characteristics of which are strongly influenced by the open sea. Ice margins are particularly productive in that ice-edge blooms of phytoplankton and the associated consumers extend many tens of kilometers away from them.

III. Role of Sea Ice

There are great differences in how marine mammals exploit ice-dominated environments (Fig. 2). Many are a function of evolutionary constraints imposed on the different linages of

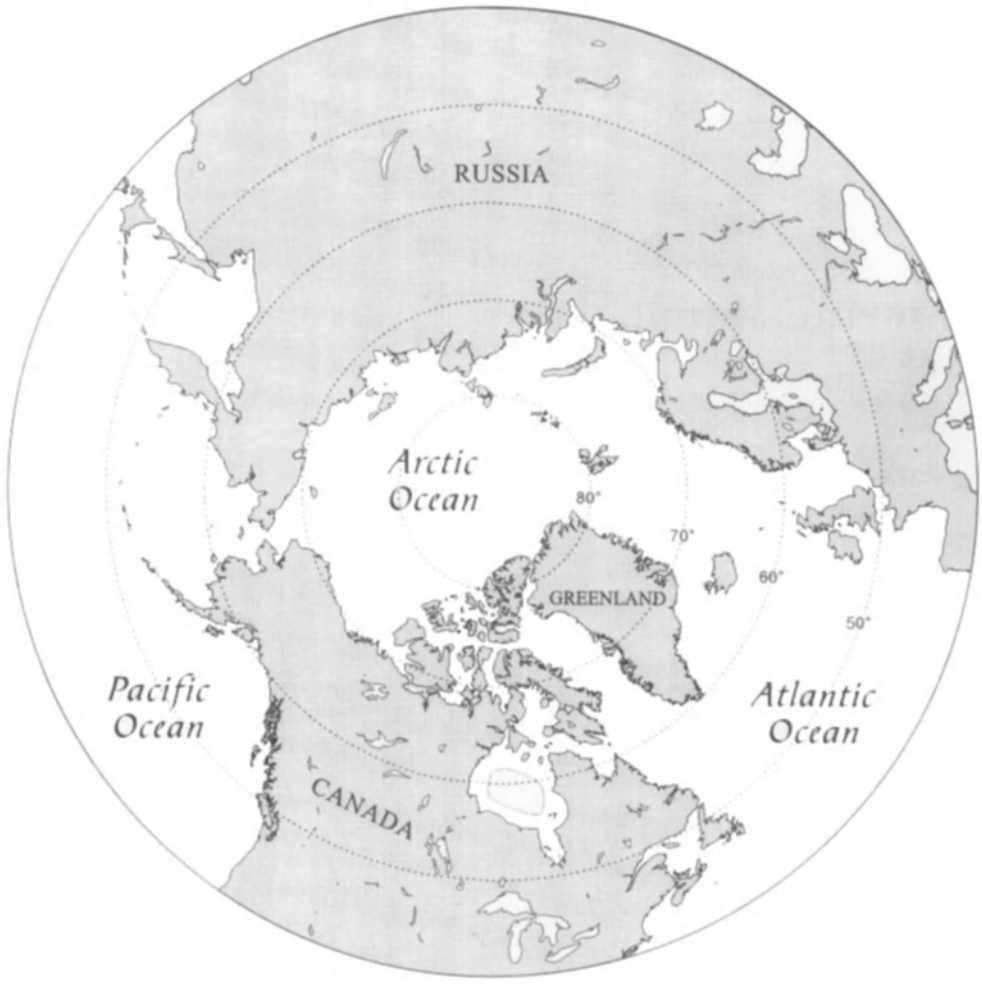

Figure 1 *Map of the Arctic Ocean.*

mammals. Polar bears (*Ursus maritimus*) are the most recent arrivals in the high-latitude northern seas, having evolved directly from brown bears (*U. arctos*). They utilize relatively stable ice as a sort of *terra infirma* on which to roam, hunt, den, and rest. Like their contemporary terrestrial cousins, they are generally not faced with the problem of ice being a major barrier through which they must surface to breathe. Cetaceans are at the other extreme. They live their entire lives in the water and have limited (though differing) abilities to make breathing holes through ice and are therefore constrained to exist where natural openings or thin ice are present. Pinnipeds spend most of their time in the water, but they must haul out to bear their young. Most of them also haul out on ice to suckle their young, to molt, and to rest.

For cetaceans, obvious benefits are protection from predators, access to ice-associated prey without competition from other animals, and a less turbulent winter environment shielded from perpetual and often storm force winds.

Pinnipeds have flourished in ice-dominated seas both in terms of the number of different species and in the number of individuals. All are obliged to haul out either on land or on ice for at least part of the year. As noted by Fay (1974), ice has several special advantages over land, including *isolation* from many predators and other disturbing terrestrial animals; vastly increased *space* away from seashores; a *variety* of different habitats that accommodate more species than does land; easy access to their *food supply*, especially for those that are benthic feeders or that utilize concentrations of prey associated with ice fronts and polynyas; passive *transportation* to new feeding areas and during migrations; *sanitation* resulting from the ability to avoid or reduce crowding and to haul out on clean ice; and *shelter* among pressure ridges or in snow drifts.

IV. Ice-Breeding Marine Mammals

Ice-breeding marine mammals in the Northern Hemisphere include eight pinnipeds: gray (*Halichoerus grypus*) (some populations), harp (*Pagophilus groenlandicus*), hooded (*Cystophora cristata*), bearded (*Erignathus barbatus*), ringed (*Pusa hispida*), spotted (*Phora largha*), and ribbon seals (*Histriophora fasciata*) as well as the walrus (*Odobenus rosmarus*); three cetaceans: narwhal (*Monodon monoceros*), beluga (or bulukha)

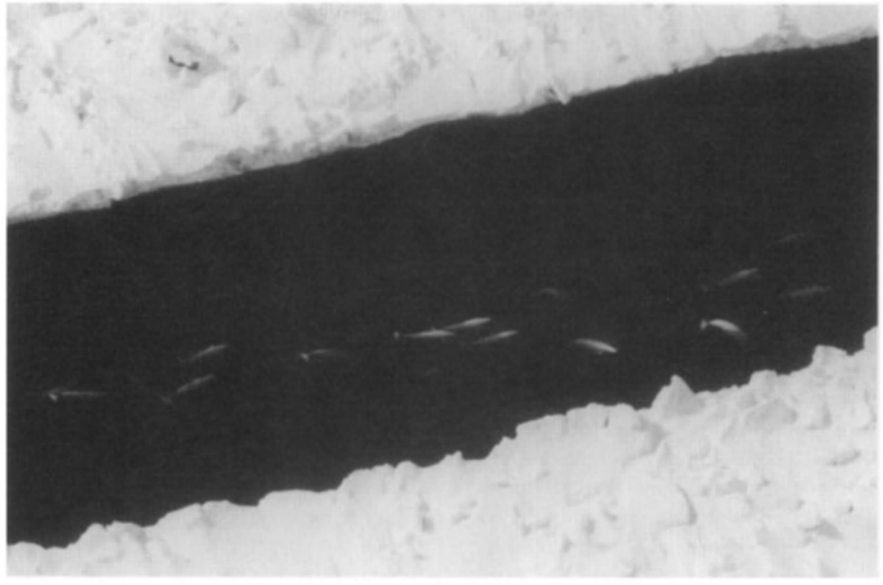

Figure 2 *Distribution of sea ice influences the distribution of many marine mammals. In the winter, thickening ice can threaten the survival of individuals if they become trapped in areas away from open sea. In the spring and summer, pack ice fragments provide avenues of transit for whales, such as the beluga whales pictured. Photo by S. Leatherwood.*

(*Delphinapterus leucas*), and bowhead whale (*Balaena mysticetus*); and one fissiped: the polar bear.

A. Pinnipeds

A common theme in the ecology of ice-breeding pinnipeds is that of an obligatory, or nearly obligatory, association with ice during the breeding season, which occurs during or shortly after the period of maximal ice extent and relative stability. Seal pups become independent during the spring onset of ice disintegration and retreat. Most species also molt on the ice, after which they disperse to a variety of habitats during the open water season, a few continuing to remain with the diminishing cover. They resume their increasing association with ice during autumn, as it again forms and expands. They haul out on the ice in all seasons during which it is present, although with highly variable frequency depending on species and weather. The maximum number of species and the greatest total number of seals are associated with ice when it is most extensive, and vice versa.

The lanugo of most seals born on ice or in snow lairs, and remaining in one place for long periods of time, is primarily an adaptation for maintaining body heat. Such pups tend to be small, have little insulating BLUBBER, and have a relatively large surface area to body mass ratio at birth. White-coated pups presumably also benefit from the cryptic coloration it provides during the period before they are weaned and begin to enter the water. Prenatal molting occurs in those ice-breeding pinnipeds that are relatively large at birth and can enter the water within hours or days. Detailed discussions of northern ice-breeding seals are presented in the following species accounts, although general comments are noted below.

Gray seals are usually not included in the category ice-associated marine mammals. However, some populations breed on the ice. Gray seals largely inhabit the temperate zone in the North Atlantic region. Their distribution is coastal, often in association with harbor seals (*Phoca vitulina*). There are three populations: those in the Baltic Sea, the eastern North Atlantic, and the western North Atlantic. There is a very wide range in timing of the breeding season. In the eastern Atlantic, pups are born on shore during late autumn to early winter. In both the Baltic and the western Atlantic, however, pups are born during mid- to late winter on ice near shore, or on shore when ice is absent. At birth, gray seals weigh about 15 kg. In all populations almost all pups are born with a silky, whitish coat of lanugo that is retained during the nursing period. They remain on ice or land until after weaning. The late pupping season of the marginally ice-associated breeding populations is thought to be an adaptation to that environment. Gray seals move extensively, although they are not considered to be migratory. None are associated with sea ice during late spring through autumn.

Spotted seals (or larga seals) occur in continental shelf waters of the Pacific region that are seasonally ice covered. During winter and spring they mainly inhabit the temperate/subarctic boundary areas, occurring in the southern ice front (mainly) of the Bering and Okhotsk seas or in the very loose pack ice of the northern Yellow Sea and Sea of Japan. The birth season is from January through April, depending on latitude. All populations give birth and nurture their pups on the ice. Newborn pups weigh about 10 kg and have a dense, whitish, wooly lanugo, which is shed toward the end of the month-long nursing period. Seals older than pups usually haul out on the ice to molt, although they also use land when the ice disappears early. As the seasonal ice disintegrates and recedes, all spotted seals disperse, moving to the ice free coastal zone where they use haulouts on land. The seasonal dispersal can be extensive: in

the Okhotsk Sea to its entire perimeter and from the central Bering Sea to most of its perimeter, as well as northward into the northern Chukchi and Beaufort seas. Therefore, some spotted seals reside in the higher latitudes of the subarctic zone during the open water season. They range widely over the continental shelves. There is a close association with sea ice during autumn through spring.

Ribbon seals are animals of the temperate and temperate/subarctic boundary zones in the North Pacific region. Breeding populations are in the Bering and Okhotsk seas and Tartar Strait. During the open water season they live a completely pelagic existence in the cold temperate waters along and beyond the continental shelves, often far from the locations of their winter habitat. The breeding cycle is similar to that of the spotted seal, and the two occur in relative close proximity to each other during late winter and spring. At the time of pupping and molting, ribbon seals utilize ice of the inner ice front where floes are larger, thicker, more deformed, and more snow covered than in the adjacent ice margin favored by spotted seals. They are noted for hauling out on very clean ice. They pup in late March and April. At birth the pups weigh about 10.5 kg and have a coat of dense, white lanugo. During the nursing period the pups remain on the ice and gradually shed their lanugo. They remain on the ice for some time after they are weaned. In the opinion of this writer the preference for heavier ice of the inner front, which persists longer than that of the spring ice margin, is because it permits all age classes of these otherwise pelagic seals to haul out until the molt is completed. Ribbon seals do not come ashore unless debilitated. They appear to be the pinniped analogue of the Dall's porpoise (*Phocoenoides dalli*) during the pelagic phase of their annual cycle (June through late autumn), dispersing near the shelf breaks and the deeper waters beyond. They have the morphological and physiological attributes of a seal that can dive to great depths and remain submerged for a long time. Relatively few move north of their breeding range, except during years of minimal spring ice cover.

Harp seals occur in the North Atlantic region. There are three breeding populations: those of the White Sea, the Greenland Sea, and the Gulf of St. Lawrence. They are a gregarious and highly migratory species that lives primarily in the subarctic zone during winter and spring and is broadly distributed in the open sea from the coastal zone to near the ice margin during the open water season. The birth period extends from late January to early April, depending on the region. During the pupping season they form large aggregations in which pups are born in close proximity to each other (often closer than 2.5 m). They prefer large ice fields within the ice front, usually at some distance from the pack ice margins. Here the floes are extensively deformed and ridged, providing shelter to the otherwise exposed pups. At birth the pups weigh about 11.8 kg and have a coat of dense white lanugo. The nursing period lasts from 10 to 12 days and they fast, remaining on the ice floes, for some time after weaning. MATING, which occurs after pups are weaned, is followed by the molt. As with the ribbon seal (which is also pelagic after the molt) it seems that the preference of harp seals for the thicker and more stable ice of the inner front zone is because it provides the selective advantage of persisting until the molt is completed. Harp seals make one of the longest annual migrations of any pinniped, with some traveling more than 3000 miles from wintering to summering areas. Part of the spring migration is passive as the seals drift on the receding ice.

Hooded seals are a high subarctic, strongly migratory, deep water species that occurs in the North Atlantic region and whelps in four different areas: near Jan Mayen, in Davis Strait, off the Labrador coast, and in the Gulf of St. Lawrence. Shifts to heavier ice in the more northerly whelping areas reportedly occur during periods of warmer climate and diminished ice (drift ice pulsations). Pups are mainly born on thick heavily ridged ice floes well within the subarctic pack during late March and early April. At birth the pups weigh about 22 kg (relatively large) and are comparatively precocious. Their lanugo is shed *in utero* and their birth coat (the blue-back stage) does not resemble the pelage of adults. The nursing period is amazingly brief, averaging 4 days, during which the mothers remain on the ice with their pups. Pups enter the water shortly after weaning, although they spend considerable time on the ice during the postweaning fast. Mating occurs after lactation, and molting after mating. They migrate, both passively on the ice and by swimming, and disperse widely in the open sea (to the Grand Banks), near high-latitude shores, and along the edge of the summer pack ice. Extralimital occurrences are common, even to the North Pacific region.

Bearded seals are primarily benthic feeders that have a circumpolar distribution in arctic and subarctic seas. They have evolved in the face of heavy predation pressure by polar bears. Their range broadly overlaps that of all the other ice-breeding pinnipeds. They are the least selective of the seals with respect to ice type, provided that it generally overlies water less than about 200 m deep. Bearded seals are usually solitary and occur from the southern ice margins and fronts (few) to the heavy drifting pack around the rim of the arctic basin, although infrequently in landfast and multiyear ice. Within the heavier pack ice they occur mainly in association with those features that produce open water or thin ice (polynyas, persistent leads, flaw zones, etc.). They are capable of breaking holes in thin ice ($\leq$10 cm) and can make or at least maintain breathing holes in thicker ice with their stout foreclaws. The large pups (about 34 kg) are usually born on the edges of small detached, first year floes very close to the water. The lanugo is shed *in utero*. The pups can swim from birth if necessary, and usually do so, at least in order to move away from the afterbirth. Beyond that they remain on the ice for a day or so. Nursing, which is usually on the ice, lasts 12 to 18 days, during which time the pups spend a considerable amount of time in the water and begin independent feeding prior to the end of the nursing period. Mating occurs after pups are weaned. The main period of molt is during May and June, and the greatest numbers of all age classes haul out on the ice during that time. However, molting seals are encountered throughout the year. In some areas, such as the Bering and Chukchi seas, the adults and most juveniles migrate to maintain a year-round association with ice. They haul out on it throughout the year, although infrequently during winter. In areas where ice disappears during summer (i.e., the Okhotsk Sea) or recedes beyond the continental shelf, they occur in the open sea, in nearshore areas, in bays and estuaries, and sometimes haul out on land.

Ringed seals have a circumpolar distribution that includes the arctic and subarctic seas. They have evolved in the face of heavy predation pressure, primarily by arctic foxes, which take pups, and polar bears, which take all age classes. Unique species and subspecies of the genus *Pusa* also occur as landlocked populations in Eurasia and include the seals of lakes Baikal, Ladoga, and Saimaa, as well as the Caspian Sea. Ringed seals are the most numerous and widely distributed of the northern ice-associated pinnipeds. During winter to early summer they utilize all ice habitats from the drifting ice margins and fronts (relatively few) to thick stable shore-fast and multiyear ice. Their range extends farther north and includes areas of heavier ice cover than that of any other marine mammal except the polar bear. They occur from shallow coastal waters to the deeps of the Arctic Basin. During winter through late spring the adults tend to be solitary and territorial and are most abundant in moderate to heavy pack and shore-fast ice. Ringed seals can make and maintain holes through the ice and crawl out to construct snow lairs above them. In regions where conditions permit, they migrate and maintain a year-round association with ice. In some regions where the pack ice completely or mostly disappears during summer (i.e., the Okhotsk Sea, Baffin Bay, Lake Baikal) they move to nearshore areas and sometimes haul out on land.

Pups are born during late March through April, in snow lairs or cavities in pressure ridges. The pups are small, averaging about 4 kg at birth, and have a thick woolly lanugo, which is usually shed by the end of the nursing period. Lactation lasts 4 to 6 weeks. Pups mostly remain in the birth lair for the first several days, but are soon capable of entering the water and periodically returning to a lair. Mating occurs after the nursing period and is followed by the molt. The peak period of molt in nonpups is during May and June, when the seals haul out above collapsed (melted) lairs, at enlarged breathing holes, or next to natural openings in the ice. Ringed seals are extremely wary when hauled out. During the open water season, depending on the region, they occur in the much reduced pack ice and in open water over a broad area. In some regions they haul out on land.

Walruses are the largest and most gregarious of the ice-breeding northern pinnipeds. They have a discontinuous although nearly circumpolar distribution around the perimeter of the Arctic Ocean and the contiguous subarctic seas. They are benthic feeders mainly restricted to foraging in waters less than 110 m deep. In all areas their distribution is limited by water depth and in some (i.e., the Laptev and Kara seas) it is further constrained by the severity of ice conditions. In most regions, walruses haul out on ice in preference to land. However, during the open water season, they (mainly males) use land haulouts near the wintering grounds and, in more northerly areas, most come ashore to rest when ice drifts beyond shallow water, as occurs frequently in the Chukchi Sea. During autumn, walruses that migrate southward ahead of the advancing ice also come ashore to rest. All populations are associated with seasonal pack ice during winter to spring/early summer. They mainly use moderately thick floes well into the winter/spring ice cover. The combined requirements for floes low enough to haul out on, but thick enough to support these large animals (usually herds of them) and that are also over shallow productive continental shelves, make walruses particularly dependent on regions within which persistent natural openings are present. They make (batter) holes through ice as thick as 22 cm, using the head, and sometimes maintain them with the aid of their tusks.

Calves are born mainly in early May, which for the Bering Sea population is during the northward spring migration of females, calves, subadults, and some adult males. Walruses shed their lanugo *in utero*. Calves are born on the ice. They weigh about 60 kg and enter the water from birth, although they haul out frequently. Cows with young calves often form large nursery herds and migrate passively on the drifting ice, as well as by swimming. The nursing period lasts more than a year. Walruses haul out in all months of the year.

B. Cetaceans

Ice-associated cetaceans include two odontocetes (toothed whales), the beluga and the narwhal, and one mysticete (baleen) whale, the bowhead. None have a completely circumpolar distribution. Morphological adaptations to ice seem minimal and include the lack of a dorsal fin in all three and the high "armored" promontory atop, which the blowhole of the bowhead is situated. In winter, all three species occur in drifting ice where there are persistent natural openings or where the ice cover is thin. Polynyas, shear zones, and leads are important features for them in regions of heavy pack ice.

The narwhal is a North Atlantic species of the high subarctic and low arctic, which, in winter, consistently occurs in regions of heavy drifting ice over deep water or shelf edges. Adult males have a unique, long unicorn-like tusk that has an unknown function but is presumably used in male sexual display. The largest population is that in Davis Strait and Baffin Bay. Seasonal movements of narwhals are directly tied to the advance and retreat of ice. During summer they move to high-latitude, ice-free coastal and nearshore areas, which are often penetrated by deep fjords. Calves are born during the summer, reportedly during July and August, and are nursed for more than a year. This whales' preference for heavy pack ice during winter and spring makes them particularly vulnerable to entrapment during periods of rapid ice formation or when the pack becomes tightly compressed. Most episodes of entrapment are probably brief, although prolonged confinement and rapid ice formation sometimes result in death either by drowning or by polar bears, for which entrapped whales are easy and plentiful prey. Confined whales are also harvested by Inuit hunters whenever they are found.

Beluga whales have a nearly circumpolar distribution that extends from roughly 40°N (the Gulf of St. Lawrence and the northern Sea of Japan) into the summer multiyear pack of the Arctic Ocean. During winter they are most abundant near the southern ice margins and fronts and as far into the seasonal pack as conditions permit. Again, polynyas, flaw zones, persistent leads, and other features that permit belugas to surface for air are important in the more northerly regions. Belugas often make holes through thin (to about 10 cm) newly formed ice by pushing it up with their head and back. They also surface in openings made by bowheads, with which they often associate during spring migration.

DISTRIBUTION during the open water season is quite variable depending on region. In most cases these whales move into the

coastal zone in May to July or early August, where they enter lagoons and estuaries to feed, bear calves in warmer water, and molt. They frequently ascend rivers to feed on seasonally abundant fishes. Telemetry studies have shown that belugas in the Beaufort Sea and the Canadian high arctic spend slightly less than 2 weeks in lagoons, and spend most of their summer feeding in offshore waters (unlike belukhas farther south). Some males from the eastern Chukchi and Beaufort Sea stocks are now known to penetrate much farther into the pack ice of the Arctic Ocean during summer than was previously supposed (to beyond 80°N). Other belugas range widely throughout Amundsen Gulf and the Beaufort and northern Chukchi seas during summer and early autumn.

The Bering Sea population includes multiple stocks, some of which migrate north through the disintegrating ice cover in spring and use both ice-free coastal waters and the summer pack of the Arctic Ocean. Most belugas leave the coastal zone by September, although some remain or revisit areas where food is abundant. This habit has resulted in some large and fatal entrapments. Smaller entrapments at sea are not uncommon. All move with the advancing ice in autumn, either migrating southward with it or moving into it as it forms and expands.

Bowhead whales occur in subarctic waters during winter and spring and, depending on the population, in productive marginal arctic waters during the open water season. These large whales are highly specialized zooplankton feeders and seek areas of high prey abundance. Bowheads may be the slowest growing and latest maturing mammal on earth. Females are thought to become sexually mature between their late teens to midtwenties (later than humans or elephants). They may live to be well over 100 years old.

The range of bowheads includes the North Atlantic region (three stocks) and North Pacific region (two stocks), with extensive gaps between the two. During winter through early spring they occur from the southern margins of the ice pack to as far into it as persistent natural opening in the ice permit. Large polynya systems are of great importance during winter and spring. In the Pacific sector the Okhotsk Sea stock remains there after the ice has completely disappeared. Most whales of the other stocks migrate northward during spring and southward during autumn. Most whales of the Bering Sea stock maintain a loose association with the summer ice margin, mainly feeding in the open waters south of it. The northward migration begins in late March or early April when they move from the Bering Sea into the eastern Chukchi, and then the Beaufort seas through heavy ice in a very long corridor cleaved by a linear system of stress cracks, polynyas, shore leads, and flaw zones. Some migrate into the western Chukchi Sea. Beluga whales commonly migrate with bowheads. Bowheads can stay submerged for long periods and push up through relatively thick ice. These abilities allow them to reside and travel in waters where natural openings in the ice are continually forming and refreezing. Calves are born mainly during April to early June, during the spring migration.

C. Fissipeds

Two fissipeds roam the high-latitude ice-covered seas: the polar bear and the arctic fox (*Vulpes lagopus*). The latter, which rarely enters the water and pups in dens on shore, is not usually considered to be a marine mammal.

Polar bears have a circumpolar distribution in the Arctic and contiguous high subarctic. They are not "marine" in the sense that whales or seals are, but occupy a marine environment in which ice is the substrate on which they live. They prey on other marine mammals, particularly the ringed seal. Depending on the region, they remain with the ice and hunt year round or, where it completely disappears, they come ashore and usually fast. Exceptions to the latter are some islands (i.e., Wrangel and Herald) where they feed on beachcast carcasses or hunt animals that haulout on shore, particularly walruses. On the ice, the availability (access) of prey seems to be a more important factor affecting the distribution of bears then is maximum prey abundance. It is difficult for bears to catch marine mammals, except pups, when there are unlimited escape routes and places to surface in a very labile ice cover. For example, few polar bears range south of the northern Bering Sea during winter, even though the majority of other marine mammals (except ringed seals) are south of there. Also, polar bears are not present in the Okhotsk Sea.

Pregnant females make and enter snow dens in early November. These maternity dens can be on the heavy pack ice, on shore-fast ice (relatively few), or on land. The altricial cubs are born in late December or early January, during the arctic winter, and do not emerge with their mothers until late March or early April. Sows that bore their cubs on shore go immediately back to the sea ice. Ringed seal pups, born in lairs beneath the snow starting in late March, are important prey for sows with cubs.

V. Possible Effects of Climate Change

It is now well recognized that we are in a phase of accelerated global warming and that the multiyear and seasonal ice cover is being affected. The seasonal ice cover is becoming generally less extensive and thinner, and it is forming later and disintegrating earlier than at any time in recorded history. In the Arctic Ocean the ice cover is also thinning. Similar changes have occurred in the past. In addition to a somewhat diminished ice cover, warming conditions also produce rising sea levels, increased ocean circulation, and increased nutrient flow into the northern seas. These changes are likely to have varying effects on the different species of ice-breeding marine mammals. For some species, e.g., the walrus, ringed seal, and polar bear, ameliorating conditions might be positive as they would result in more favorable habitat over a broader area then at present. For others, especially those now dependent on limited ice habitat, the changes are likely to have negative impacts. Spotted seals in the Yellow Sea and the Sea of Japan are likely to be affected negatively. At a minimum, global warming will likely result in geographic shifts of the seasonal centers of abundance of all ice-associated marine mammals.

Artiodactyla

Jessica M. Theodor
University of California, Los Angeles

Artiodactyls are the closest living relatives of the Cetacea (whales and dolphins), although whales may be more closely related to an extinct group of mammals, the mesonychids. It seems odd to think of the whales being closely related to terrestrial ungulates, but biologists have long appreciated that artiodactyls and whales share several unusual morphologies despite their vastly divergent ways of life. One such feature is that lumps of tissue, called umbilical pearls, are found along the umbilical cord between the fetus and the mother. Male whales and artiodactyls share distinctive features of the penis, which is composed primarily of fibroelastic tissue, unlike the penis of other mammals, largely made up of spongy tissue. Because the penis is fibroelastic and not spongy, the mechanism of erection of the penis differs from most mammals, utilizing specialized retractor muscles, which are found in both artiodactyls and cetaceans.

I. Diagnostic Characters

Artiodactyls are even-toed ungulates because they have two or four toes on each foot. They have elongated legs and stand on the tips of their toes, which bear hooves instead of nails. Artiodactyls are characterized by paraxonic foot symmetry, in which the main axis of weight bearing of the foot passes between the third and the fourth digits. The ankle of artiodactyls is uniquely specialized. The astragalus, the main bone transferring force from the leg to the foot, has a deeply grooved, pulley-shaped surface on both the tibial and foot ends, whereas other mammals have only the tibial pulley. The double-pulley joint strongly limits lateral rotation of the foot on the hind leg, permitting only fore and aft movements of the leg.

II. Taxonomy

Artiodactyla includes nine families today: the Suidae (pigs), Tayassuidae (peccaries), Hippopotamidae (hippos), Camelidae (camels and llamas), Tragulidae (mouse deer), Giraffidae (giraffe and okapi), Antilocapridae (pronghorn antelope), Cervidae (deer), and Bovidae (cows, sheep, goats, and antelope). Of the 211 extant artiodactyl species, close to 65% are in the Bovidae. The families Hippopotamidae, Tragulidae, Giraffidae, and Antilocapridae are very low in diversity, with one or two species each.

III. Distribution and Ecology

Living artiodactyls are native to North America, Eurasia, Africa, and South America, and they have been introduced to other areas. Artiodactyls occupy a wide range of habitats, from deserts to taiga, and show a wide range of dietary specialization, social structure, locomotor modes, and habitat preferences. However, the majority of artiodactyls are terrestrial, and only the hippo is semiaquatic. There is a considerable range of body sizes, from 0.7 to 3000 kg. Most artiodactyls are herbivores, except the pigs and peccaries, which also eat small prey and eggs. The pigs, peccaries, hippos, and mouse deer are nocturnal, whereas most other species are diurnal. Most artiodactyls bear precocial young in small litters, although pigs have large litters of relatively helpless young who are reared in nests.

IV. Notable Anatomy

The most notable anatomical system of artiodactyls is foregut rumination, which allows ruminant artiodactyls (bovids, cervids, antilocaprids, giraffids, and tragulids) the ability to break down cellulose, a plant material ordinarily indigestible to vertebrates.

This is accomplished by symbiotic bacteria housed in an elaborate system of chambers within the stomach (part of the foregut). Ruminants break down the plant material by swallowing the food, which is fermented by the bacteria in the first stomach chamber, the rumen. The cud, or fermented food, is later regurgitated, chewed, and swallowed again, passing into the rest of the digestive tract. Bacteria break down the cellulose from the food into components that can be digested by the ruminant. All ruminants have some ability to use foregut rumination, and it is also found to a more limited degree in the camels.

V. Phylogeny

Artiodactyla is a diverse group today, but it also contains a number of extinct types. This diversity has made it difficult to understand the interrelationships within this group. Artiodactyls have been thought to be monophyletic based on their morphology, but recent molecular studies indicate that whales may be closely related to hippos, which implies that whales actually belong within Artiodactyla.

Most morphologists place the living families into three major groups: the Suiformes (pigs, peccaries, and hippos), the Tylopoda (camels, protoceratids, and oromerycids), and the Ruminantia (bovids, cervids, antilocaprids, giraffids, and tragulids). Tylopoda and Ruminantia are usually considered to be more closely related to one another than either is to the Suiformes, based on their dental and gut morphology (see Fig. 1 for summary). However, molecular evidence linking whales to hippos also suggests that the Ruminantia may be more closely related to Suiformes and whales than to the Tylopoda. This hypothesis conflicts strongly with morphological data from living and extinct artiodactyls and whales. Further investigation may help clarify the relationships between whales and artiodactyls, but it is unlikely that molecular analyses of the extinct forms will be feasible.

VI. Fossil Record

The oldest artiodactyls are known from the earliest Eocene of Europe, North America, and Pakistan, about 56 million years ago, around the same time as the earliest fossil whales. The oldest fossil artiodactyls, usually referred to the genus *Diacodexis*, were rabbit-sized omnivores, but during the middle Eocene many other new groups evolved (see Fig. 1). The majority of these lineages became extinct, including some which were enormously diverse and successful for long periods of time, such as the oreodonts, an endemic North American group of sheep-sized herbivores. A number of these fossil groups are usually described as pig-like, meaning that they have long trunks and short legs, with low-crowned teeth suitable for an omnivorous diet. These groups include the entelodonts, which were very large animals, with skulls as long as 1 m in length and with large bony bumps on the facial region. The anthracotheres are another of these groups, and they are usually thought to be related to the hippos. Other groups were obviously herbivores, including the oreodonts, and seem to be related either to the

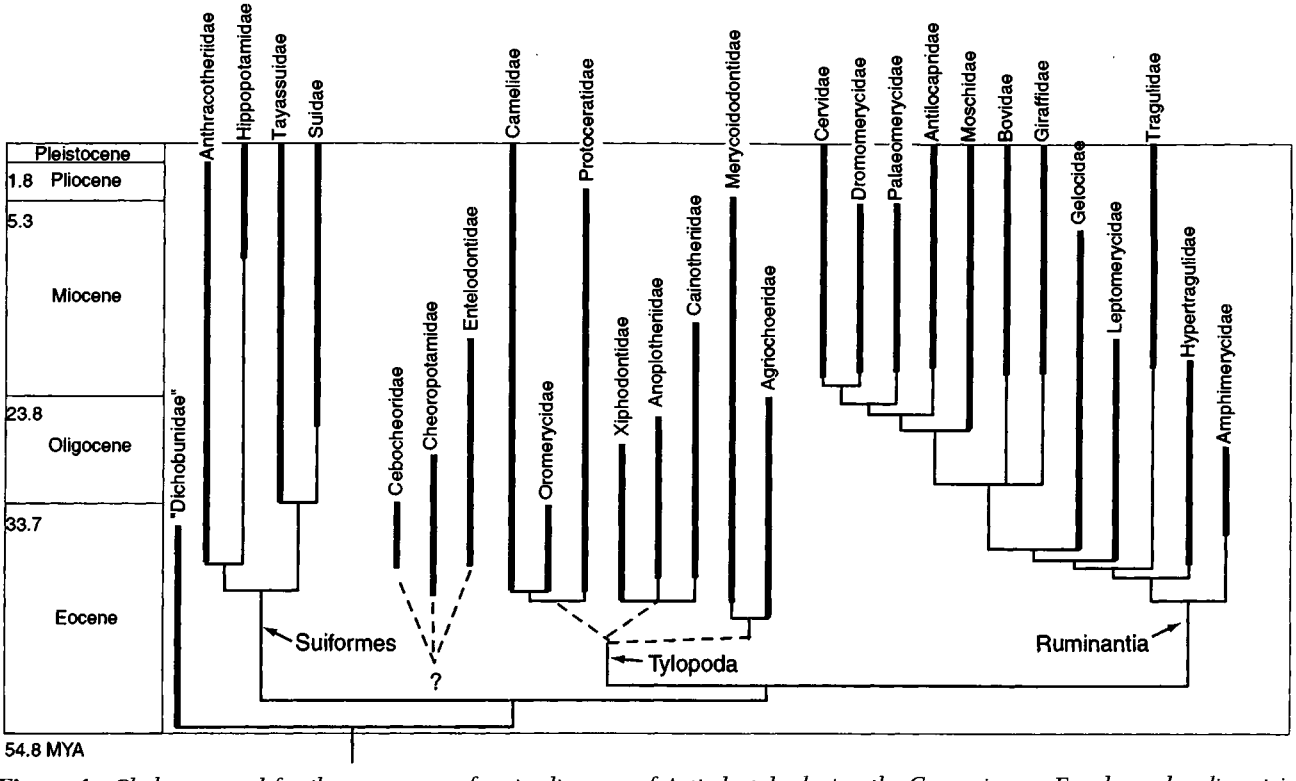

Figure 1 *Phylogeny and fossil occurrences of major lineages of Artiodactyla during the Cenozoic era. Epochs and radiometric ages are marked on the left.*

Tylopoda (oromerycids, protoceratids, and xiphodontids) or to the Ruminantia (hypertragulids, leptomerycids, gelocids, dromomerycids, and paleomerycids). A number of these groups had very complex antlers or horns, especially the extinct protoceratids, some of whom had large slingshot-shaped horns on the snout. Many extinct members of the Dromomerycidae, Antilocapridae, and Giraffidae had much more elaborate cranial ornamentation than any species alive today.

Another successful group was the Camelidae, which became very diverse during the Miocene in North America. The camels and llamas emigrated out of North America and were the only members of the family to survive the extinctions of large mammals in the Pleistocene. The bovids underwent a rapid radiation during the Miocene and Pliocene. The cervids diversified during the Pleistocene, and both groups are diverse today. It is especially important to realize that the modern geographic distribution of the order Artiodactyla is very different from what it was at different times in the past and has been heavily influenced by human activity.

Atlantic Spotted Dolphin

Stenella frontalis

William F. Perrin

Southwest Fisheries Science Center, La Jolla, California

This sturdy spotted dolphin (Fig. 1) is found only in the Atlantic and is commonly seen around the "100-fathom curve" along the southeastern and Gulf U.S. coasts, in the Caribbean, and off West Africa.

I. Characters and Taxonomic Relationships

The Atlantic spotted dolphin is not always spotted. A large heavy-bodied form found along the coast on both sides of the Atlantic (formerly called *Stenella plagiodon* along the U.S. coast) may be so heavily spotted as to appear white from a distance, but a smaller more gracile form occurring in the Gulf Stream and out into the central North Atlantic can be lightly spotted or entirely unspotted as an adult (Perrin *et al.*, 1987; Viallelle, 1997). A constant diagnostic external feature of *S. frontalis* is a spinal blaze sweeping up into the dorsal cape; this distinguishes it from the very similar pantropical spotted dolphin, *S. attenuata*, also found in the tropical Atlantic. In addition, the peduncle does not exhibit the dorsoventral division

Figure 1 *Atlantic spotted dolphin in the Gulf of Mexico. Photo by R. L. Pitman, from Perrin* et al. *(1994a).*

into darker upper and lighter lower halves present in *S. attenuata*. The calf of the heavily spotted form is born unspotted, with a three-part color pattern of dark dorsal cape, medium-gray lateral field, and white ventral field. Spots first appear at 2–6 years and increase in size and density up to 16 years (Herzing, 1997).

The beak is of medium length (intermediate between those of *Tursiops truncatus* and *S. attenuata*) and sharply demarcated from the melon. The dorsal fin is tall and falcate. Measured adults range from 166 to 229 cm in body length (n = 106) and weigh up to 143 kg (n = 37) (Perrin *et al.*, 1994a; Nieri *et al.*, 1999). Weight at length is greater than for *S. attenuata* (Perrin *et al.*, 1987).

As in *S. attenuata*, *T. truncatus*, and *T. aduncus*, the skull is characterized by a long rostrum, distal fusion of maxillae and premaxillae in adults, convergent premaxillae, large rounded temporal fossae, and arcuate mandibular rami. Tooth counts are 32–42 in the upper jaw (n = 115) and 30–40 in the lower (n = 107) vs 35–48 (n = 315) and 34–47 (n = 315) (Perrin *et al.*, 1994a; Perrin and Hohn, 1994; Nieri *et al.*, 1999). This species and *S. attenuata* overlap in all skull measurements as well as in tooth counts (Perrin *et al.*, 1987). Both species vary greatly geographically. Some specimens of the two species can be identified only with multivariate analysis. However, vertebral counts for the two species do not overlap [67–72 (n = 52) in *S. frontalis* vs 74–84 (n = 75) in *S. attenuata*].

Taxonomy of the spotted dolphins was long confused, with specimens of this species and the pantropical spotted dolphin (*S. attenuata*) classified or identified under various permutations of the nominal species *S. attenuata*, *S. frontalis*, *S. plagiodon*, *S. froenatus*, *S. pernettyi*, and *S. dubia* (e.g., see Hershkovitz, 1966). A revision (Perrin *et al.*, 1987) recognized one pantropical species (*S. attenuata*) and a second species endemic to the tropical Atlantic (*S. frontalis*), both highly variable geographically in size, tooth size, and color pattern. While the skull of the Atlantic spotted dolphin shows close affinities with that of the pantropical spotted dolphin, the two species did not emerge as sister taxa in a cladistic phylogenetic analysis based on cytochrome *b* mtDNA sequences (LeDuc *et al.*, 1999). *S. frontalis* was imbedded in a strongly supported polytomic clade with *S. coeruleoalba* and *S. clymene* (sister taxa), *Tursiops aduncus*, and *Delphinus* spp. *T. truncatus* was a sister taxon to this clade, with the resulting higher clade imbedded in the five-part polytomic delphinine clade with *S. attenuata*, *S. longirostris*, *Sousa chinensis*, and *Lagenodelphis hosei*. Despite a high degree of cranial similarity, this wide phylogenetic separation suggests that the similarity represents either convergence (homoplasy) or retention of primitive character states (plesiomorphy). The interspecific relationships in color pattern may accord better with the molecular phylogeny; e.g., the pattern of head stripes in *S. frontalis* is closer to those of *T. truncatus* and *T. aduncus* than that of *S. attenuata* (Perrin, 1997). In any case, the existing genus-level taxonomy of the group badly needs revision; *Stenella* is presently polyphyletic and *Tursiops* paraphyletic (LeDuc *et al.*, 1999). A cladistic analysis of morphology (not yet attempted) is in order.

II. Distribution and Ecology

This species is endemic to the tropical and warm-temperate Atlantic; it is not known to occur in the Pacific or Indian Oceans. The range extends from about 50°N to about 25°S (Jefferson *et al.*, 1993). In the western Atlantic, the large heavily spotted form inhabits shallow, gently sloping waters of the continental shelf and the continental-shelf break, usually within or near the 200-m curve but occasionally coming close to shore in pursuit of prey (Perrin *et al.*, 1994a; Davis *et al.*, 1998; Würsig *et al.*, 2000). It is usually replaced in nearshore waters by the coastal form of the bottlenose dolphin, *Tursiops truncatus*. Shallow water (6–12 m) over sand flats is utilized as habitat in the Bahamas (Herzing, 1997). A wide variety of prey items has been recorded, including small-to-large epipelagic and mesopelagic fishes and squids and benthic invertebrates; diet may differ between coastal and Gulf Stream forms. Sharks are the only known predators, but it is probably also preyed on by killer whales and other small-toothed whales.

III. Behavior and Life History

Dives to 40–60 m and lasting up to 6 min have been recorded, but most time is spent at less than 10 m (Davis *et al.*, 1996). Behavior of the Atlantic spotted dolphin has been studied extensively in the Bahamas (e.g., Herzing, 1997; Herzing and Johnson, 1997), where it associates closely with bottlenose dolphins during foraging and traveling. Schools may be segregated by age and sex and fluctuate in size and composition, consisting of up to 100 individuals (Perrin *et al.*, 1994a).

Little is known of the life history of this species. Age at sexual maturation is estimated at 8–15 years in females (Herzing, 1997). First parturition is associated with the mottled phase of spotting development. The average calving interval is about 3 years, with a range of 1–5 years. Nursing has been observed to last up to 5 years. Average first-year natural mortality in a study in the Bahamas was 24%.

IV. Interactions with Humans

This species does not do well in CAPTIVITY; most captive animals have died within a year or less, many refusing to eat (Perrin *et al.*, 1994a). It is killed incidentally in fisheries in Brazil, the Caribbean, the western North Atlantic, and Mauretania, mostly in small numbers (Perrin *et al.*, 1994b; Nieri *et al.*, 1999).

Atlantic White-Sided Dolphin

Lagenorhynchus acutus

FRANK CIPRIANO
San Francisco State University, California

I. Distribution

Inhabitants of the cold-temperate North Atlantic, Atlantic white-sided dolphins are usually encountered in waters over the continental shelf and slope, extending into deeper oceanic waters and occasionally into coastal areas (Fig. 1). The southern limit of this species in the western Atlantic is Cape

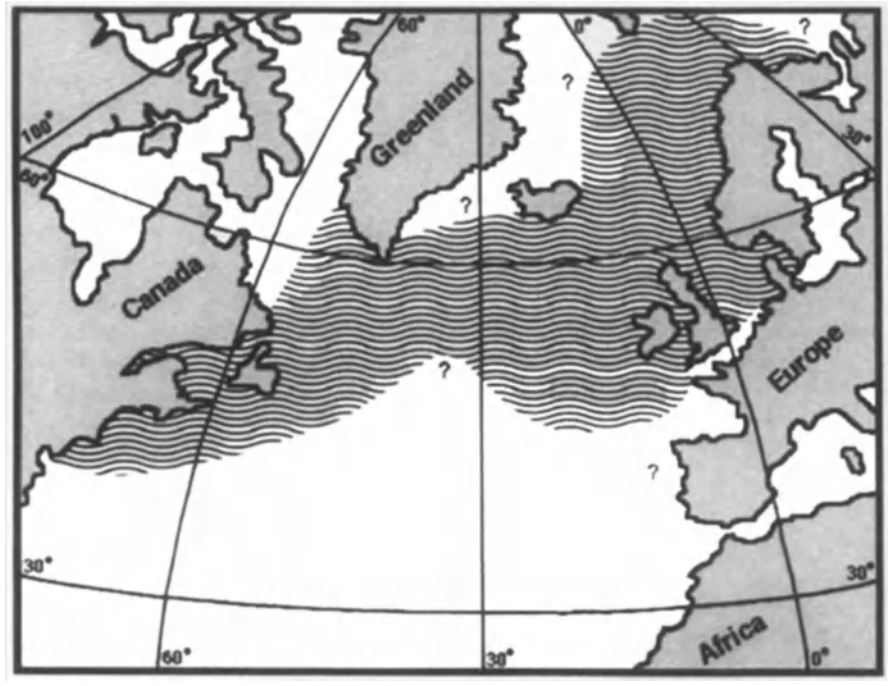

Figure 1 *Known distribution limits of the Atlantic white-sided dolphin. The patterned area indicates areas of regular occurrence and question marks indicate uncertainty about occurrence in particular areas.*

Cod and the submarine canyons south of Georges Bank, and Brittany in the east. Groups of Atlantic white sides are often seen by fishermen and deep-water sailors off the coasts of New England, Nova Scotia, and Newfoundland, the western British Isles, northern Europe, and in the Norwegian Sea. There are no records of this species from the inner Baltic Sea, although some sightings and strandings are known from the straits between Denmark, Norway, and western Sweden. The northern distribution limits are poorly known but extend at least to southern Greenland, southern Iceland, and the south coast of Svalbard Island.

II. Appearance and Life History

Atlantic white-sided dolphins are robust and powerful, impressively patterned, and more colorful than most dolphins. A narrow, bright white patch on the side extends back from below the dorsal fin and continues toward the flukes as a yellow-brown blaze above a thin dark stripe (Fig. 2). The back and dorsal fin are black or very dark gray, as are the flippers and flukes, whereas the belly and lower jaw are white, and the sides of the body a lighter gray. A black eye ring extends in a thin line to the upper jaw, and a very thin stripe extends backward from the eye ring to the external ear. A faint gray stripe may connect the leading edge of the flipper with the rear margin of the lower jaw. The beak is short and grades smoothly into the "melon" (forehead). The upper jaw contains 29–40 and the lower jaw 31–38 small, conical teeth.

Male Atlantic white-sided dolphins are known to reach a maximum body length about 270 cm and a weight of 230 kg, whereas adult females reach a maximum size about 20 cm shorter and 50 kg lighter. This is smaller than that well-known oceanarium inhabitant, the bottlenose dolphin, *Tursiops truncatus* (around 380 cm/270 kg maximum), and a bit longer and a lot heavier than the short-beaked common dolphin, *Delphinus delphis* (around 230 cm/75 kg). Females reach sexual maturity at 200–220 cm, at ages from 6 to 12 years. Males reach sexual maturity at lengths of 215–230 cm, corresponding to ages of 7–11 years. Maximum ages recorded were 22 and 27 years for males and females, respectively. At birth, Atlantic white-sided dolphins are around 120 cm long, after an approximately 11-month gestation period, and weigh about 25 kg. In the western Atlantic, the calving season peaks in midsummer, whereas in the eastern Atlantic the calving season may extend several months longer. The lactation period lasts around 18 months, and some stranded individuals were observed to be both pregnant and lactating, suggesting that some individuals may breed annually.

III. Group Size, Behavior, and Ecology

The number of Atlantic white-sided dolphins observed in a group ranges from a few individuals to several hundred, and mean group size appears to vary with location. In Newfoundland inshore waters, 50–60 dolphins in a group are typical; in inshore waters of the British Isles and near Iceland, groups usually contain less than 10 individuals; off the New England coast, group size ranges from a few to around 500, but the usual group size is around 40. Some segregation by sex and age has been suggested from mass stranding records—larger juveniles are absent from some mass-stranded groups that contain many calves, adult males, and pregnant females.

Analysis of the stomach contents of mass-stranded, incidentally entangled, and drive-caught dolphins is used to assess their diet, as diagnostic "hard parts" (crustacean shells, fish ear bones, and squid beaks) accumulate in stomach chambers. A general indication of the importance of particular prey items can be inferred from the percentage contribution of each type, although the number of meals represented by such traces is usually unknown and there may be bias in the retention of different types. Major prey species of Atlantic white-sided dolphins include herring, small mackeral, gadid fishes (codfish and their relatives), smelts and hake, sand lances, and several types of squid. Different prey species may predominate at different times of year, representing seasonal movements of prey, or in different areas, indicating prey and habitat variability in the environment. For example, different species of squid are eaten by these dolphins on opposite sides of the Atlantic, whereas in spring and autumn, sand lance and dolphin distributions in the Gulf of Maine appear to mirror each other. Atlantic white-sided dolphins are probably not deep divers—the maximum dive time recorded from a tagged dolphin was 4 min and most dives were less than a minute in duration.

IV. Abundance and Human Impacts

Censusing oceanic dolphins is a difficult task, requiring extensive aerial surveys or long observation tracks from survey ships (or both) and then extrapolation of the densities observed to immense ocean areas. Given the wide distribution of At-

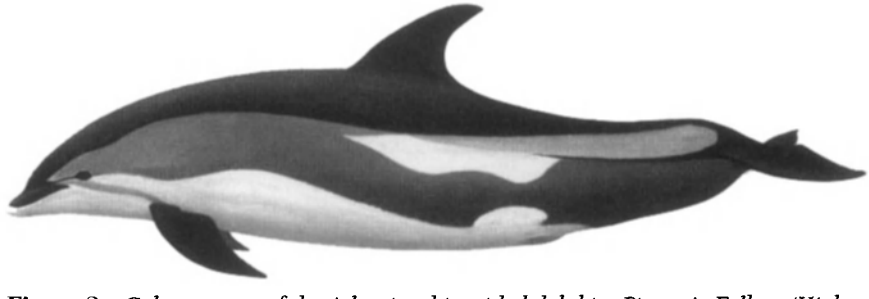

Figure 2 *Color pattern of the Atlantic white-sided dolphin. Pieter A. Folkens/Higher Porpoise DG.*

lantic white-sided dolphins across the northern reaches of the Atlantic, rather wide confidence limits on abundance estimates are to be expected. Estimates for the western Atlantic total about 40,000 animals, and for the entire Atlantic a few hundred thousand. This species is not currently hunted on a large scale anywhere throughout its range, although historically many were killed in drive fisheries in Norway and Newfoundland, and smaller numbers taken off Greenland and the Faroe Islands. Incidental mortality has been documented in many areas and these dolphins may be particularly susceptible to ENTANGLEMENT in midwater trawl nets, including some recent large catches in pelagic trawl nets in the Atlantic Frontier off Ireland.

V. Evolutionary Relationships

Molecular analysis has been used to examine the evolutionary relationships of *Lagenorhynchus acutus* and other dolphins, including the five other currently recognized members of the genus *Lagenorhynchus*. Although formal taxonomic revision awaits a more comprehensive review of morphological and molecular characters, molecular evidence suggests that *L. acutus* is not closely related to other putative members of *Lagenorhynchus* and should be recognized in a separate genus.

Australian Sea Lion

Neophoca cinerea

JOHN K. LING
Clare, South Australia

The indigenous Australian sea lion (Fig. 1) is one of the world's rarest and most unusual seals: rare in terms of very small numbers and unusual in its having a sesquiennial reproductive cycle. It is also a temperate species, inhabiting waters around much of the southern part of the island continent between latitudes 28 and 38°S. Its current breeding range extends from Houtman Abrolhos (29°S,114°E) in Western Australia to The Pages Islands (36°S.138°E), just east of Kangaroo Island, South Australia, with stragglers reaching central New South Wales on the east coast (Fig. 2).

I. Color and Size

At birth the pups are a dark chocolate brown to charcoal gray in color, which changes to the smoky gray (hence the specific name *cinerea*) and cream adult color after the postnatal molt. Females retain this coloration throughout life, but males gradually develop a brownish-black coat with increasing age. Males of breeding age have a cream patch on the back of the head and nape of the neck. This species has flattened guard hairs but no underfur—the pelage apparently being adapted to a temperate environment. It also has a relatively thin layer of blubber beneath the skin, about 2 cm thick. Pups measure 62 to 68 cm in length (nose–tail) and weigh 6.4 to 7.9 kg at birth, males tending to be heavier than females. Adult females range in length from 132 to 181 cm and weigh between 61 and 105 kg (for a pregnant specimen); males measure up to 200 cm in length and attain weights well in excess of 200 kg.

II. Distribution and Abundance

There are only 9300 to 11,700 Australian sea lions occupying their wide geographic range in more than 50 scattered colonies, of which only 5 produce more than 100 pups in a breeding season. Three-quarters of the population resides in South Australia and a quarter occurs in Western Australia, where more than half the breeding colonies are located, all of which are small. The largest breeding colonies are on Purdie Island (32°S,133°E), Dangerous Reef (35°S,135°E), Seal Bay (36°S.137°E) on Kangaroo Island and the two islands of The Pages. Australian sea lions once ranged as far as the eastern end of Bass Strait, but today only stragglers occur there and beyond. They were hunted during the sealing era from the late 18th to the mid-19th century for their skins and oil, when only a few thousand skins are reported to have been harvested. It is not possible to estimate the number killed for oil, because "seal oil" included fur seal oil as well in the cargoes. However, there may not have been many sea lions to be taken anyway compared with the large fur seal populations, which are increasing today after having been almost exterminated by early sealers. However, because the first complete census over the sea lion's en-

Figure 1 Neophoca cinerea, *adult male (note white "cap" on head), three adult females, and juvenile (circa 18 months) resting on center female at Seal Bay, Kangaroo Island, South Australia. Photo by John K. Ling.*

tire breeding range has been carried out only recently, it cannot be determined at this stage whether numbers are increasing or decreasing. Future surveys of all breeding colonies will need to be undertaken, as counts of live and dead pups provide the most accurate estimates of the size of the total population.

III. Life History

The life history of *Neophoca* is unique in a number of aspects: the approximately 17.5-month reproductive cycle, a protracted (i.e., 5-month) pupping season, and prolonged gestation and lactation until the next pup is born. This life history is likely to be an adaptation to the sea lion's environment, which is characterized as a low-energy, stable milieu associated with the eastward flowing Leeuwin Current.

Pups are born a few days after the females have moved to their BREEDING SITES, to which they are known to return for successive birthings. Viable twins have never been observed, but two aborted fetuses, believed to be twins and estimated to be about 3 months postimplantation, were found on Kangaroo Island in 1985.

MATING takes place 7 to 10 days postpartum; there is a 3- to 4-month-free blastocyst (embryonic diapause) stage, followed by a gestation period up to 14 months in duration. The pup is suckled for the next 15–18 months and during this time it learns to forage for food that it will consume in later life. The milk is low in energy (fat) compared with other pinnipeds and its quality may vary according to the foraging success of the mother and stage of lactation. After they are weaned, sea lions feed on cephalapods, crustaceans, and fish. It is not known how far offshore they forage, but diving appears to begin as soon as females leave the rookery and continues to mean depths of 92 m for up to 8 min per dive over the continental shelf. This is a longer duration than dives of most other otariids (eared seals). Prey is generally seized in the mouth and shaken violently at the surface to remove cuttle bones, skin, or skeletons before swallowing. Depending on size, experimental markers take from 5 to 48 hr to pass through the alimentary tract. Australian sea lions are infected by the usual array of external and internal parasites: lice and mites, and acanthocephala, nematodes, cestodes, and trematodes. Dissections often reveal very heavy infestations.

While the pelage is unlikely to be involved in thermoregulation, the flattened hairs overlap each other and provide a smooth but flexible outer surface that reduces turbulence when swimming. Periodic renewal of the hair coat ensures that it functions efficiently in whatever role it has. The timing of pelage renewal or molt is variable. Immature sea lions molt during the breeding season, females begin their molt about 4 months after parturition, and adult males do not start their molt until about 9 months after breeding occurs.

The Australian sea lion's unusual life history enables it to survive as a very small population scattered over a wide, nutrient-poor longitudinal range. The longer than normal (pinniped) gestation and lactation periods allow the female to nurture a developing fetus and growing pup while having to forage for scarce food resources. Normal growth rates can also be achieved despite the low-energy content of the milk. At the same time, the long maternal association confers many learning and protective advantages on the young sea lion. The protracted, asynchronous pupping season spread out over a wide geographic area again means that food resources can be better shared and there is not a sudden influx of newly independent sea lions, such as occurs with more highly synchronized species that occupy nutrient-rich, higher latitudes.

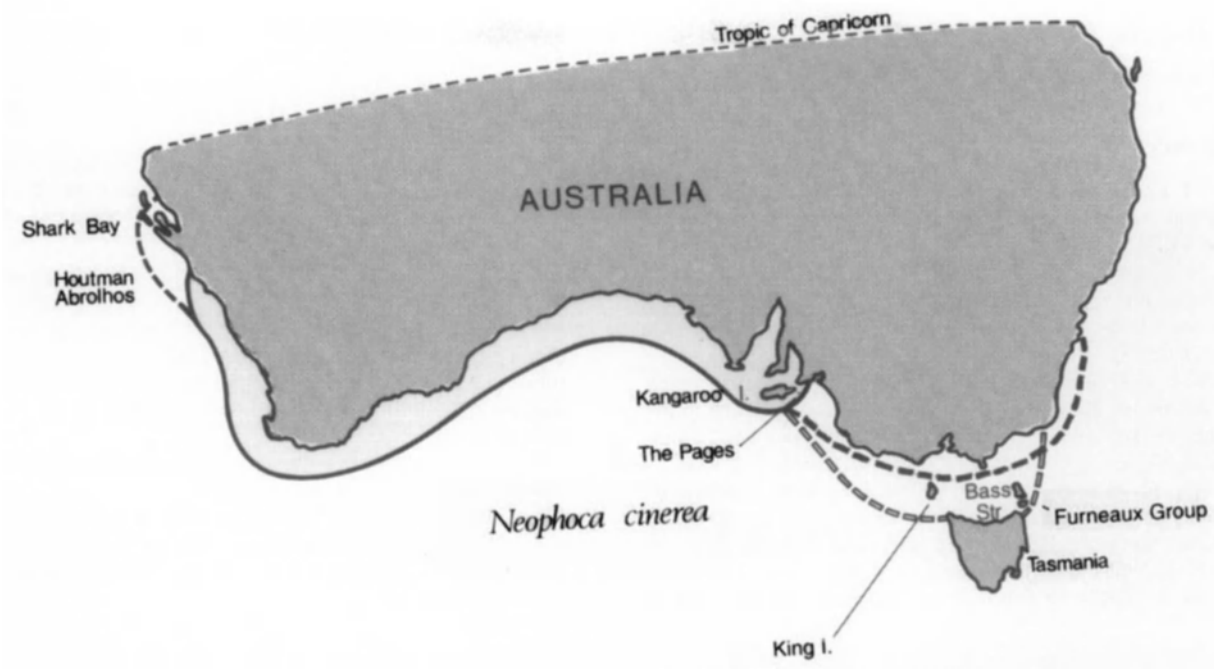

Figure 2 *Present and past distribution of* Neophoca cinerea. *Unbroken solid line depicts current known breeding range, broken solid line depicts extent of seasonal stragglers, and broken open line depicts extent of former breeding range. Reproduced with permission from the Royal Zoological Society of South Australia.*

IV. Behavior

The protracted pupping season, during which mating is effected, ensures that there is a high turnover of territories and a breakdown of any harem system. In contrast to many otariids in which dominant males control small to large numbers of females, *Neophoca* practices what is known as sequential polygyny, which still allows males access to several females in a season, but one at a time. Nevertheless, aggressive encounters do take place between rival breeding males and are a significant cause of mortality among young pups that are unfortunate enough to be attacked or trampled by rampaging bulls. Their lumbering gait resembles something of an ungainly gallop a little above a fast human walking pace and punctuated by frequent rests.

Females are most solicitous of their young, and several tourist visitors to Seal Bay and other breeding colonies have received nasty bites when they approached too close to a cow with her pup. When returning from a foraging trip, a female will call from the sea with a soft "moo" and wait for her pup's answering call, which resembles a lamb's bleat. Site fidelity is very strong, so little searching for each other is necessary. Once the two are reunited, recognition is confirmed by smelling.

Sea lions are powerful and skillful swimmers, using their large front flippers to propel them rapidly through the water. They are also excellent surfers and can often be seen riding the waves right into the shallows or "porpoising" along wave crests and troughs further out to sea.

Large males tend to lie apart from other sea lions, but females and immature animals often lie close together wriggling, squirming, and scratching constantly. On hot days when the sun temperature may exceed 45°C they will occasionally go into the sea and return a short while later to allow evaporative cooling to take effect. Sea lions may also venture some distance inland to lie under bushes or up steep slopes to find a shelter: they are quite agile on land.

V. Conservation and Management

The Australian sea lion colony at Seal Bay on Kangaroo Island, South Australia, is internationally famous because of its proximity to a large city (Adelaide) and the public being able to view the animals at close quarters. In view of the near-threatened (IUCN) status of this species and its importance to the tourist industry on Kangaroo Island (no other colonies are so easily accessible), the South Australian government has embarked on an intensive management strategy.

The whole Seal Bay area has been designated a conservation park. Public access is limited to the main beach and only in the company of authorized personnel, but there are also viewing platforms overlooking the beach and other restricted areas. The main pupping sites in coves to the west of Seal Bay have been declared prohibited areas. Regular classified censuses are conducted to monitor the status of the Seal Bay colony and enhance its chances of survival and value to tourism.

However, many other Australian sea lion colonies appear to be suffering very high pup mortality (30–40%) and decreasing pup production. Only with a widespread and cooperative research and management effort will the species be perhaps more secure.

B

Baculum

EDWARD H. MILLER
Memorial University, St. Johns, Newfoundland, Canada

The baculum (os penis) is a bone in the penis of Insectivora, Chiroptera, Primates, Rodentia, and Carnivora; it is absent from Cetacea and Sirenia. The corresponding element in females is the os clitoridis. In marine mammals the baculum and os clitoridis have been studied mainly in pinnipeds.

The baculum develops in the proximal part of the penis in association with the fibrous septum between the paired corpora cavernosa penis or in their fibrous noncavernous portion; in the dog, centers of ossification on left and right sides fuse early in development. The developing baculum grows distally above the urethra and thickens. The bacular base becomes firmly attached to the corpora cavernosa and the fibrous tunica albuginea which surrounds them. In rodents, the bacular shaft is true bone and includes hemopoietic and fatty tissue in the enlarged basal portion.

During development, bacula may become progressively straighter (southern elephant seal, *Mirounga leonina;* northern fur seal, *Callorhinus ursinus*) or curved (harbor seal, *Phoca vitulina;* hooded seal, *Cystophora cristata*). Pinniped bacula grow throughout life in mass and thickness (particularly at the basal end) but not in length. Growth is rapid around puberty and may exhibit a secondary spurt at social maturity (e.g., Cape fur seal, *Arctocephalus p. pusillus*). In Otariidae, the bacular apex, shaft, and base differ from one another in their growth patterns.

The urethral groove is shallow to absent in bacula of marine mammals (Fig. 2; lower drawings in Figs. 3A–3D). Typically the baculum is slightly arched dorsally (Figs. 1, 2, and 3). The apex is relatively elaborate in Mustelidae and Otariidae (Fig. 4) and is simple in Ursidae and Phocidae. In adults of some Antarctic seals a prominent crest develops on the anterior dorsal surface, however (upper drawing in Fig. 3D; Fig. 3E). In some species the bacular apex has a prominent cartilaginous cap (e.g., hooded seal). Bacula are variable in size, shape, cross section, and specific structural features within species (even among animals of the same age). For example, a dorsal keel may be present or absent in adult southern elephant seals; processes on the shaft near the apex may be present or absent in adult California sea lions (*Zalophus californianus*); and bacula may be bilaterally asymmetrical or slightly twisted (Fig. 3D; Fig. 3E1).

Bacula of Carnivora are fairly large. In pinnipeds and indeed among all mammals, walruses (*Odobenus rosmarus*) have the largest baculum both absolutely (to 62.4 cm in length and 1040 g in mass) and relatively (18% of standard body length). Bacular length in a large polar bear (*Ursus maritimus*) was 17.3 cm. Interspecific differences in bacular size in mammals have been linked to aquatic copulation, copulatory duration or pattern, mating strategy, and risk of fracture. Fractures possibly result from accidents (e.g., falls in walruses), sudden movements during intromission (e.g., in aquatically copulating species such as Caspian seal, *Pusa caspica*), or aggressive social interactions (e.g., fights between adult male sea otters, *Enhydra lutris*). Healed fractured bacula have been observed in several species.

Bacula likely serve several functions, including (1) a mechanical aid to intromission (especially in the absence of full erection) or maintenance of intromission in aquatic copulations and (2) to initiate or engage neural or endocrinological responses in females. Bacular form and diversity reflect multiple functions and hence have multiple adaptive explanations.

Bacular characteristics have been informative in phylogenetic studies of Otariidae and MUSTELIDAE, suggesting needed taxonomic revisions and revealing interesting developmental and evolutionary trends.

Bacular size can aid in estimating age, and bacula grow quickly at puberty so are a good indicator of when it occurs. Bacular growth may be affected by pollutants, so bacular size and form may also be informative in studies on pollution biology.

Baiji

Lipotes vexillifer

ZHOU KAIYA

Nanjing Normal University, China

The baiji, or Chinese river dolphin (*Lipotes vexillifer*), which inhabits the middle and lower reaches of the Yangtze River in China, is the rarest and most endangered cetacean in the world. Together with the vaquita in the eastern central Pacific, it is one of the two cetaceans classified as critically endangered in the 2000 IUCN red list of threatened species. In China, it is known by the name baiji, meaning white dolphin. The name dates from classical times and is to be found in the ancient dictionary, "Erh Ya," published as long ago as 200 B.C. At that time, the Yangtze flowed clean and largely unencumbered from its source to the rich, sprawling Yangtze Delta, in the western Yellow Sea and East China Sea. The baiji has lived generation after generation and multiplied in number in the desirable environment of the Yangtze River for thousands of years. However, the population has declined in recent decades because of habitat degradation, accidental capture, and collisions with vessels. Recent information estimates a total population of only a few dozen animals.

I. Diagnostic Characters

The baiji is a graceful animal with a very long, narrow and slightly upturned beak. It can be easily identified by the rounded melon, longitudinally oval blowhole, very small eyes, low triangular dorsal fin, and broad rounded flippers (Fig. 1). The color is generally bluish gray or gray above and white or ashy-white below. Females are larger than males. The maximum recorded length for females is 253 cm and for males 229 cm (Zhou, 1989). Significant differences between the sexes in external proportions have been demonstrated in nine characters, and skull size is also sexually dimorphic (Gao and Zhou, 1992).

The Yangtze River is turbid. Visibility from the surface downward is about 25–35 cm in April and 12 cm in August. A corresponding regression has taken place in the eye of the baiji. The eyes are much smaller and placed much higher than those of other dolphins. However, they are functional, and objects on the surface or near the surface directly in front of the eye can be distinguished (Zhou, 1989).

II. Taxonomy

The species was classified previously as either in the family Platanistidae or Iniidae (Brownell and Herald, 1972). Zhou *et al.* (1978) established the new family Lipotidae for it based

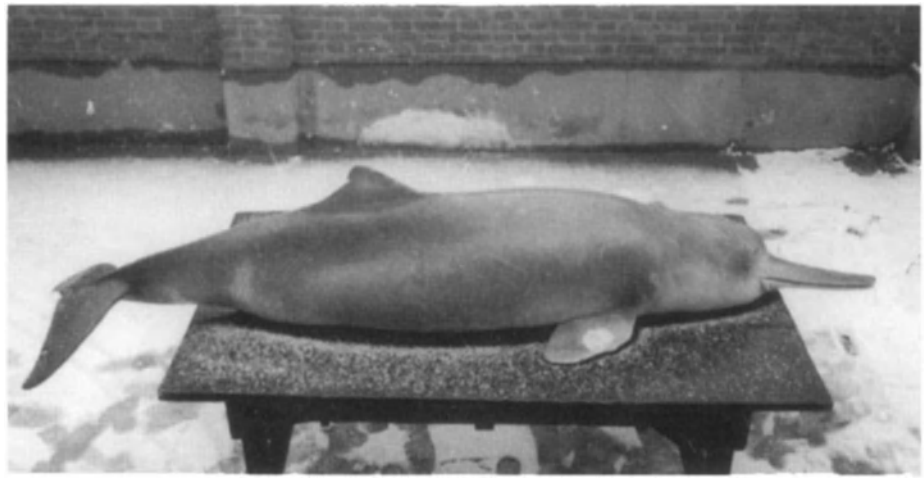

Figure 1 *Carcass of a 2.45 m adult female baiji with a notch on dorsal fin; found drifting down river near Jiangyin on January 15, 1996. From Zhou* et al. *(1998).*

on osteological studies and anatomy of the stomach. Barnes (1985) recognized a fossil, *Parapontoporia*, as morphologically intermediate between *Pontoporia* and *Lipotes* and placed *Lipotes* and the fossil taxon each in a subfamily of Pontoporiidae. Conversely, de Muizon (1988) placed the fossil taxon with *Lipotes* in Lipotidae, and Rice (1998) following de Muizon ranked Lipotidae as a family. Studies of mitochondrial cytochrome *b* gene sequences indicate that the sequence difference between *Lipotes* and *Pontoporia* is similar to or greater than those among other odontocete families. Molecular evidence also supports ranking Lipotidae as a family rather than as a subfamily of Pontoporiidae (Yang and Zhou, 1999). The only fossil placed close to *Lipotes* is *Prolipotes*, based on a fragment of mandible with teeth of Tertiary age from China (Zhou *et al.*, 1984). This indicates that the baiji is a relict species.

III. Distribution

Baiji are found mainly in the mainstream of the middle and lower reaches of the Yangtze River, although individuals might occasionally enter some tributary lakes during intense flooding. Dongting Lake was originally incorrectly reported to be the only habitat. The presence of this dolphin in the Yangtze River is noted in documents going back about 2000 years. In the 1940s, the uppermost records in the Yangtze River were at Huanglingmiao and Liantuo in the Three Gorges area, approximately 50 km upstream of the Gezhouba Dam near Yichang (Zhou *et al.*, 1977). Baiji could be found up to Yichang in the 1970s, which is about 1700 km up from the mouth of the river. However, the range was no further upstream than Zhicheng in the 1980s, and than Shashi in the 1990s; the latter is approximately 150 km downstream of the dam site. In the lower part of the river, specimens of the baiji were obtained in the Yangtze estuary, off the eastern end of Chongming Island, Shanghai, in the 1950s and 1960s. The range has been no further downstream than Liuhe since the 1970s (Fig. 2). Results of recent surveys of almost all the species' previous range, Shanghai to Yichang, suggest that the population is very small and is still declining. Baiji were also seen in the Fuchun River during the great flood of 1955 but disappeared from that river after the construction of a hydropower station in 1957 (Zhou *et al.*, 1977).

IV. Ecology

Baiji are generally found in eddy countercurrents below meanders and channel convergences. They live in small groups.

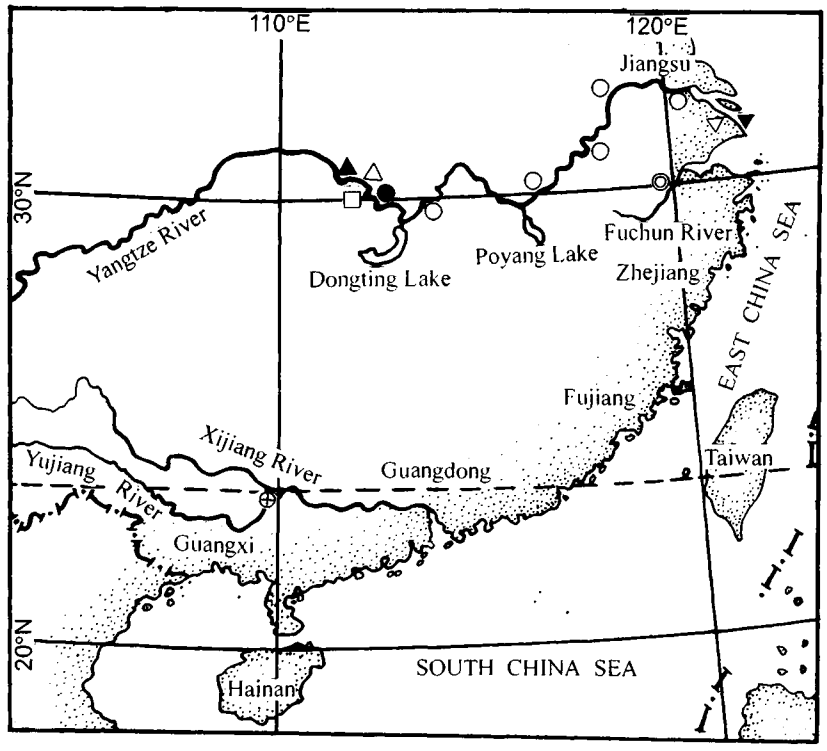

Figure 2 *Map of China showing distribution of baiji,* Lipotes vexillifer, *and the fossil* Prolipotes yujiangensis. *Baiji,* L. vexillifer: ▲, *Huanglingmiao and Liantuo, the uppermost records in the 1940s;* △, *Yichang, the uppermost records in the 1970s;* □, *Zicheng, the uppermost records in the 1980s;* ●, *Shashi, the upstream limit of distribution in the 1990s;* ○, *distribution in the 1990s;* ▼, *Yangtze estuary, the lowest records in the 1950s and 1960s;* ▽, *Liuhe, the downstream limit of distribution in the 1990s; and* ◎, *Tonglu and Fuyang, records in the 1950s in the Fuchun River.* P. yujiangenesis: ⊕. *Guiping, locality where the fossil was found.*

Figure 3 *Free-ranging baiji in the Yangtze River near Tongling. From Zhou and Zhang (1991).*

In the 1980s, the most common group size was 3 to 4 animals; the largest group observed was about 16 individuals in the middle reaches of the Yangtze River. These larger groups were probably temporary aggregations of several groups. The baiji usually surfaces without causing white water and breathes in a smooth manner (Fig. 3). It has a sequence of several short breathing intervals (10–30 sec) alternating with a longer one, the longest one up to 200 sec (Zhou *et al.*, 1994). Photographic identifications and sighting records show that baiji groups make both local and long-range movements. The largest recorded range of a recognizable baiji was 200+ km from the initial sighting location (Zhou *et al.*, 1998).

The baiji appears to take any available species of freshwater fish, the only selection criterion being size. The fish should not be so large that it cannot go down the throat. Sometimes, dead fish are seen floating on the Yangtze with patches of scales torn off. They are believed to have been prey of baiji. At times, a baiji may try a number of times to swallow a large fish, but in vain and finally letting go (Zhou and Zhang, 1991).

Body length at birth is estimated to be 91.5 cm for both males and females. The sexes have about the same growth rate until they are about 4 years old based on estimates of dentinal growth layer groups (GLGs), which is the age at sexual maturation for males. After sexual maturation, males grow more slowly than females. Females attain sexual maturation at about 6 years. They continue to grow until about age 8. The smallest mature male and female described were 180 and 200 cm long, respectively. The oldest animal that was age-determined was a 242 cm female of 24 years of age, and a 21-year-old male was estimated to be about 214 cm in body length (Gao and Zhou, 1992). The baiji probably breeds and gives birth in the first half of the year. The peak calving season appears to be February to April.

V. Threats

The Yangtze is suffering massive habitat degradation. The banks of the Yangtze have been modified extensively to prevent destructive flooding of agricultural areas, thus reducing the floodplain area. Construction of dams and other barriers along the river and its tributaries has led to changes in fish abundance and distribution. Wastewater volume discharged into the Yangtze is about 15.6 billion cubic meters per year. Approximately 80% of the wastewaters are discharged directly into the environment without treatment.

The threats against the baiji include river traffic, fishing gear (Fig. 4), reduction of fishery resources, and water pollution (Chen and Hua, 1989; Zhou *et al.*, 1998). Unfortunately, the major threats are continuing and appear to be rapidly becoming more serious. Although it is one of the nationally protected animals in China, the baiji population is reported to have declined from about 400 animals in 1979–1980, to 200 or so in 1986, to about 100 in 1989–1991, and to a few dozen in 1998. The species is facing a very high risk of EXTINCTION.

Baleen

DALE W. RICE

National Marine Mammal Laboratory, Seattle, Washington

The term baleen (also called whalebone) is a mass noun that refers collectively to the series of thin keratinous plates ("baleen plates") that make up the filtering apparatus in the mouth of a baleen whale. The word derives from the classical Latin *Balaena* and ultimately from the Greek φάλλαινα [phallaina], "whale."

Baleen plates are suspended from the whale's palate and are arranged in a row down each side of the mouth, extending from the tip of the rostrum back to the esophageal orifice. The left and right sides are separated by a prominent longitudinal ridge down the midline of the palate, but in the rorquals the two sides are continuous around the tip of the palate. Depending on the species, each "side" of baleen may contain anywhere betweeen 140 and 430 plates. The plates are transversely oriented and are spaced 1 or 2 cm apart, leaving a narrow gap or slot between adjacent plates. The plates are roughly triangular, with their horizontal basal edges embedded in the palate, their near-vertical labial edges facing outward, and their oblique, fringed lingual edges facing the inside of the mouth. Each plate is slightly curved, with its convex side facing forward, so that its labial edge is directed slightly backward; when the whale is swimming forward, this arrangement helps direct the flow of water through the interplate gaps from the mouth cavity to the exterior side of the baleen row. The sizes of the plates are smoothly graded, with the longest ones half to two-thirds of the way back from the tip of the rostrum and only rudimentary ones at the anterior and posterior ends of the row (Williamson, 1973; Pivorunas 1976, 1979).

Each baleen plate is made up of a middle layer, the *medulla*, which is sandwiched between the thin, smooth outer layers or *cortex*. The medulla consists of a mass of fine, hollow, hair-like keratinous tubules that run parallel to the labial side of the plate and terminate along the lingual side; the tubules are embedded in and cemented together by a horny matrix.

Evoluntarily the plates were presumably derived by an elaboration of the transverse ridges present on the palates of many terrestrial mammals. In whale fetuses the baleen first appears as a series of crosswise ridges along each side of the palate. The palatial tissue of baleen whales is arranged in three layers. The basal layer, several centimeters thick, is the *corium*. This is overlain by a thin *epithelial layer* only a few millimeters thick. The outermost epidermal layer, several centimeters thick, is simply called the *gum tissue*. The corium gives rise to, and is continuous with, the medulla of each baleen plate, whereas the adjacent epithelial layer is deflected downward to produce the cortical layers of each plate. The dense, rubbery gum tissue does not contribute to the formation of the plates, but simply fills the spaces between their bases, where it provides them a firm support. As each plate grows downward, its cortical layers become cornified sooner than the medulla does. This leaves the first few centimeters of the base of the plate with a layer of soft, highly vascular, corial tissue sandwiched between the keratinous outer layers; this soft layer is often called the pulp, by analogy with the pulp in mammalian teeth (van Utrecht, 1965).

Throughout the life of the whale its baleen plates grow continuously at their base and wear away along their lingual margin. The cortex and the matrix of the medulla erode away first, freeing the ends of the fibrous tubules for a distance of about 10–20 cm. The freed tubules form a hairy fringe along the entire lingual side of the plate. The fringes of each plate lie back across the lingual edges of the plates immediately behind them, with the whole forming a dense hairy mat that covers the internal apertures to the gaps between the plates. This mat effectively filters out the food organisms while allowing the water to flow out of the whale's mouth through the gaps.

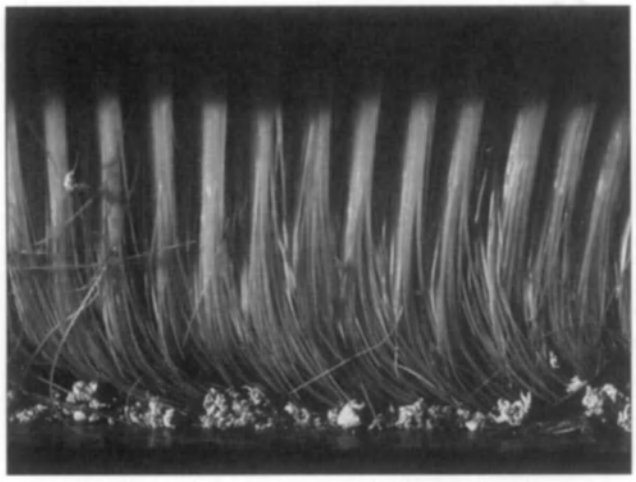

Figure 1 *Baleen in whales such as the gray whale,* Eschrichtius robustus, *is used to filter seawater for food. Notice the arrangement of these keratinous plates in rows. Photo by François Gohier.*

Like human fingernails, the thickness of the baleen plates varies with the nutritional state of the whale. Alternating periods of summer gorging and winter fasting leave a regular series of visible growth zones on the surfaces of the plates. These zones have been used to infer the ages of whales, but because of the constant wear, it is rare for more than five or six zones to remain in a plate (Ruud, 1945). A claim that evidence of individual ovulations could be detected in the growth patterns of baleen plates was never confirmed (van Utrecht-Cock, 1965).

The number of baleen plates per side and their maximum size, shape, color, and other physical attributes are diagnostic for each species of whale. The right whales (family Balaenidae) with their narrow, highly arched rostrum have 250 to 390 narrow and extremely long plates, about 0.15–0.25 m wide and up to 2.50 m long in the black right whales (*Eubalaena* spp.) and 4.00 m in the bowhead whale (*B. mysticetus*); they are black with a fine whitish fringe. The pygmy right whale (*Caperea marginata;* family Neobalaenidae) has about 230 narrow, short plates up to 0.70 m long and 0.12 m wide; they are white with a black labial margin. The gray whale (*Eschrichtius robustus;* family Eschrichtiidae) has 140 thick but narrow and short plates, up to 0.10 m wide and 0.50 m long; they are white with a coarse white fringe that resembles excelsior (Fig. 1). The rorquals (family Balaenopteridae) with their wide, flat rostrum have 270 to 430 plates with a basal width 50 to 95% of their length, which varies from about 0.20 m in small minke whales to 1.00 m in huge blue whales. Each species of rorqual has a different color pattern on its baleen plates: humpback (*Megaptera novaeangliae*)—black with dirty-gray fringe; common minke (*Balaenoptera acutorostrata*)—white, sometimes with a narrow black stripe along labial margin; Antarctic minke (*B. bonaerensis*)—white with a wide black stripe along the labial margin; Bryde's (*B. edeni*)—black with light gray fringe; sei (*B. borealis*)—black with fine, silky, white fringe; fin (*B. physalus*)—gray and white longitudinal bands, with fringe the same colors; and blue (*B. musculus*)—solid black with black fringe. All of the species of *Balaenoptera,* except the blue whale, usually have at least a few all-white baleen plates at the tip of the rostrum, mostly on the right side; this asymmetry is most prominent in the fin whale.

In the 19th century, the long baleen plates of the bowhead and right whales were much in demand for uses where a tough but limber material was needed so they were the most valuable product of the whale fishery. Landings of whalebone at United States ports reached their highest in 1853, with 5,652,300 pounds worth $1,950,000. The last year that any baleen reached the commercial market was 1930. Much of it was made into umbrella ribs, corset busks, and hoops for skirts. The fibrous fringes were used for brooms and brushes (Stevenson, 1907).

Baleen Whales

Mysticetes

JOHN L. BANNISTER
Western Australian Museum, Perth

I. Diagnostic Characters and Taxonomy

Baleen or whalebone whales (Mysticeti) comprise one of the two recent (nonfossil) cetacean suborders. They differ from the other suborder (toothed whales, Odontoceti), particularly in their lack of functional teeth. Instead they feed on relatively very small marine organisms by means of a highly specialized filter-feeding apparatus made up of BALEEN plates ("whalebone") attached to the gum of the upper jaw.

Other differences from toothed whales include the baleen whales' paired blowhole, symmetrical skull, and absence of ribs articulating with the sternum.

Baleen whales are generally huge (Fig. 1). In the blue whale they include the largest known animal, growing to more than 30 m long and weighing more than 170 tons. Like all other cetaceans, baleen whales are totally aquatic. Like most of the toothed whales, they are all marine. Many undertake very long migrations, and some are fast swimming. A few species come close to the coast at some part of their life cycle and may be seen from shore; however, much of their lives is spent remote from land in the deep oceans. Baleen whale females grow slightly larger than the males. Animals of the same species tend to be larger in the Southern than in the Northern Hemisphere.

Within the mysticetes are four families: right whales (Balaenidae, balaenids), pygmy right whales (Neobalaenidae, neobalaenids), gray whales (Eschrichtiidae, eschrichtiids), and "rorquals" (Balaenopteridae, balaenopterids). Within the suborder, 13 species are now generally recognized (Table I).

Right whales are distinguished from the other three families by their long and narrow baleen plates and arched upper jaw. Other balaenid features include, externally, a disproportionately large head (*ca.* one-third of the body length), long thin rostrum, and huge bowed lower lips; they lack multiple ventral grooves.

TABLE I
Mysticetes (Baleen Whales)

Family	*Genus*	*Species*	*Subspecies*	*Common name*	*Maximum length (m)*	*Generalized distribution*
Balaenidae				Right whales		
	Balaena	*B. mysticetus*		Bowhead whale	19.8	Circumpolar in the Arctic
	Eubalaena	*E. glacialis*		North Atlantic right whale	17.0	Temperate–Arctic
		E. australis		Southern right whale	17.0	Temperate–Antarctic
		E. japonica		North Pacific right whale	17.0	Temperate N. Pacific
Neobalaenidae				Pygmy right whales		
	Neobalaena	*Caperea marginata*		Pygmy right whale	6.4	Temperate, Southern Hemisphere only
Eschrichtiidae				Gray whales		
	Eschrichtius	*E. robustus*		Gray whale	14.1	North Pacific–Arctic
Balaenopteridae				Rorquals		
	Megaptera	*M. novaeangliae*		Humpback whale	16.0	Worldwide
	Balaenoptera	*B. acutorostrata*		Common minke whale		Worldwide
			B. a. acutorostrata	N. Atlantic minke whale	9.2	Temperate–Arctic
			B. a. scammoni	N. Pacific minke whale	?	Temperate–Arctic
			B. a. subsp.	Dwarf minke whale	?	Temperate–sub-Antarctic, Southern Hemisphere only
		B. bonaerensis		Antarctic minke whale	10.7	Temperate–Antarctic
		B. edeni		Bryde's whale	14.0	Circumglobal, tropical–subtropical
		B. borealis		Sei whale	17.7	Worldwide, largely temperate
		B. physalus		Fin whale	26.8	Worldwide
		B. musculus		Blue whale		Worldwide
			B. m. musculus	Blue whale	26.0	N. Atlantic, N. Pacific
			B. m. indica	Great Indian rorqual	?	N. Indian Ocean
			B. m. brevicauda	Pygmy blue whale	24.4	Southern Hemisphere, temperate–sub-Antarctic
			B. m. intermedia	"True" blue whale	30.5	Southern Hemisphere, temperate–Antarctic

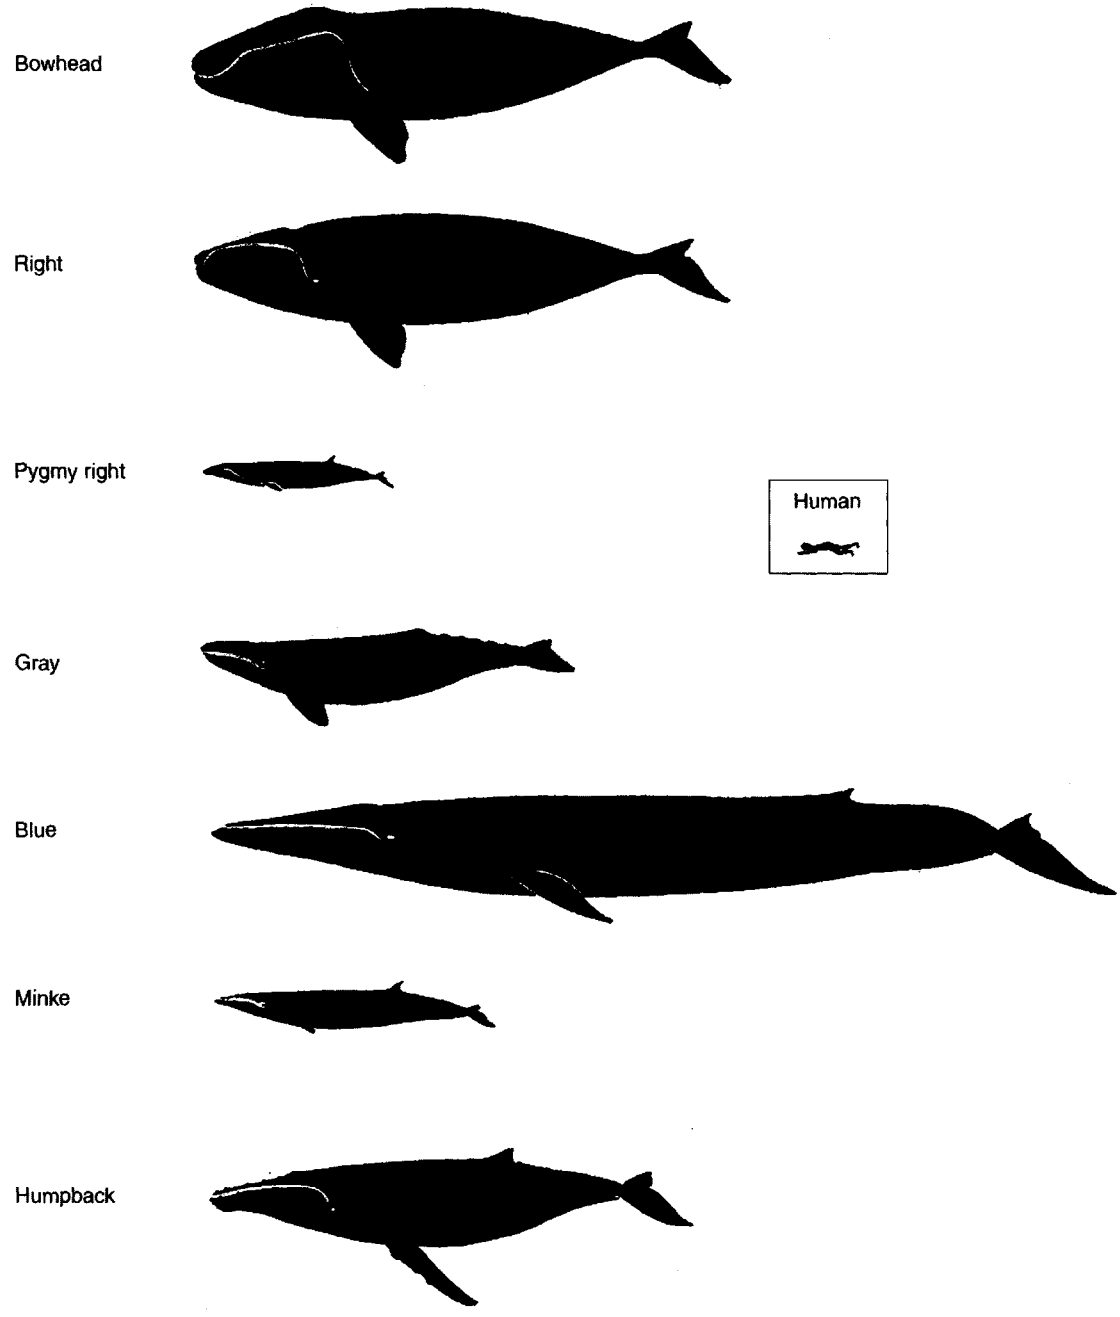

Figure 1 *Lateral profiles of representative baleen whales, with a human figure, to scale.*

Internally, there is no coronoid process on the lower jaw and cervical vertebrae are fused together. Within the family are two distinct groups: the bowhead (*Balaena mysticetus*) of northern polar waters (formerly known as the "Greenland" right whale) and the three "black" right whales (*Eubalaena* spp.) of more temperate seas (so called to distinguish them from the "Greenland" right whale). All balaenids are robust.

Pygmy right whales (*Caperea marginata*) have some features of both right whales and balaenopterids. The head is short (*ca* one-quarter of the body length), although with an arched upper jaw and bowed lower lips, and there is a dorsal fin. The relatively long and narrow baleen plates are yellowish-white, with a dark outer border, quite different from the all-black balaenid baleen plates. Internally, pygmy right whales have numerous broadened and flattened ribs.

Gray whales (*Eschrichtius robustus*) are also somewhat intermediate in appearance between right whales and balaenopterids. They have short narrow heads, a slightly arched

rostrum, and between two and five deep creases on the throat instead of the balaenopterid ventral grooves. There is no dorsal fin, but a series of 6 to 12 small "knuckles" along the tail stock. The yellowish-white baleen plates are relatively small.

Balaenopterids comprise the six whales of the genus *Balaenoptera* (blue, *B. musculus;* fin, *B. physalus;* sei, *B. borealis;* Bryde's, *B. edeni;* common minke, *B. acutorostrata* and Antarctic minke, *B. bonaerensis*) and the humpback whale (*Megaptera novaeangliae*). All have relatively short heads, less than a quarter of the body length. In comparison with right whales, the baleen plates are short and wide. Numerous ventral grooves are present, and there is a dorsal fin, sometimes rather small. Internally, the upper jaw is relatively long and unarched, the mandibles are bowed outward, and a coronoid process is present; cervical vertebrae are generally free. All seven balaenopterids are often known as "rorquals" (said to come from the Norse "whale with pleats in its throat"). Strictly speaking, the term should probably be applied to the six *Balaenoptera* species, recognizing the rather different humpback in its separate genus, but many authors now use it for all seven balaenopterids.

Baleen whales are sometimes called "great whales." Despite their generally huge size, some of the species are relatively small, and it seems preferable to restrict the term to the larger mysticetes (blue, fin, sei, Bryde's, humpback) together with the largest odontocete (the sperm whale, *Physeter macrocephalus*).

In a recent review of the systematics and distribution of the world's marine mammals, Rice (1998) has drawn attention to the derivation of the Latin word Mysticeti and clarified the status of a variant, Mystacoceti. He describes the former as coming from Aristotle's original Greek *mustoketos,* meaning "the mouse, the whale so-called" or "the mouse-whale" (said to be an ironic reference to the animals' generally vast size). Mystacoceti means "moustache whales," and although used occasionally in the past (and more obviously appropriate for whales with baleen in their mouths) it has been superseded by Mysticeti.

The 13 species in Table I differ somewhat from those listed by Rice. Some authors disagree with his use of the genus *Balaena* for *Eubalaena* and his preference for the single species *glacialis* rather than the three species, *Eubalaena glacialis, E. japonica,* and *E. australis* (the North Atlantic, North Pacific and southern right whales). While acknowledging the need for further investigation, they refer to present-day biologists' usage, and genetic information, in preferring a separation between Northern and Southern Hemisphere animals and in recognizing two species in the northern hemisphere; *Eubalaena* is, however, the only mysticete genus where one or more separate species is recognized in each hemisphere. Rice also distinguishes between two species of Bryde's whale: *Balaenoptera edeni* and *B. brydei.* The taxonomic status of these "inshore, smaller" and "offshore, larger" forms has yet to be determined and here they are subsumed within *B. edeni.* In the case of the blue whale, Rice's inclusion of a northern Indian Ocean form (*B. m. indica,* referred to by Rice as "the great Indian rorqual") has been followed. Similarly, his listing of three subspecies of minke whale, including the Southern Hemisphere dwarf minke, which has yet to be formally described, has been retained. However, other subspecies, e.g., two sei whales and two fin whales, have not been included.

II. Distribution and Ecology

A. Habitat

In addition to the subspecies listed in Section I, many stocks or populations have been recognized, some mainly for management purposes, based on more or less valid biological grounds. Some significant examples include:

1. Bowhead Whales In addition to the currently most abundant population (the Bering-Chukchi-Beaufort Seas stock), four others are recognized: Baffin Bay/Davis Strait, Hudson Bay, Spitzbergen, and Okhotsk Sea.

2. Right Whales In the North Atlantic species, two populations are currently recognized, western and eastern, with calving grounds off the southeastern United States and northwestern Africa. The latter may now represent only a relict population(s). In the North Pacific species, the current view is that there well may once have been two or more stocks, based on feeding ground information: at least one now centered in summer on the Sea of Okhotsk and another, although possibly not now a functioning unit, summering in the Gulf of Alaska.

In the southern right whale, there are several populations, defined by currently occupied calving grounds, but these cover only a proportion of the many areas known from historical whaling records to have once been occupied by right whales. Up-to-date information is available on presumed discrete populations off eastern South America, South Africa, southern Australia, and sub-Antarctic New Zealand.

3. Gray Whales A western North Atlantic population may have persisted until the 17th or 18th centuries, but is now extinct. The species now survives only in the North Pacific, where, in addition to a flourishing "Californian" stock, wintering on the coast of Baja California, and summering in the Bering Sea, animals are now being reported from a remnant western stock, summering in the northern Okhotsk Sea.

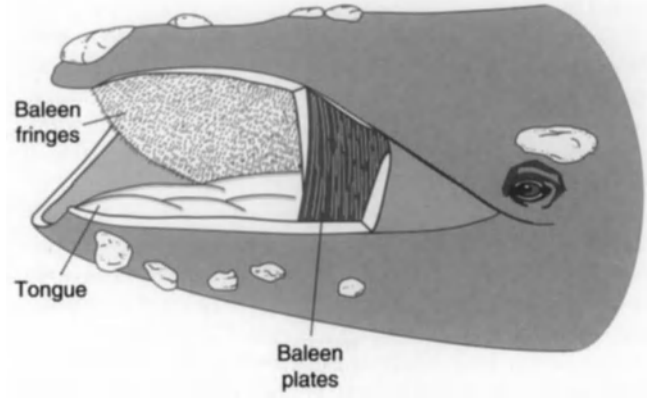

Figure 2 *Head of a right whale showing the arrangement of the filter-feeding apparatus. From Bonner (1980).*

4. Humpback Whales In the North Atlantic, two major populations are recognized: one based on animals wintering in the West Indies and the other, now possibly only a relict population, wintering around the Cape Verde Islands. In the North Pacific, three discrete wintering grounds have been recorded: around the Bonin, Mariana, and Marshall Islands in the west; around the Hawaiian Islands in the center; and off Mexico in the east.

In the Southern Hemisphere, seven populations have been postulated. Six are well defined, based on calving (wintering) grounds on either side of each continent (one off eastern Australia is closely related to animals wintering off Fiji and Tonga), and a possible seventh in the central Pacific. In the northwest Indian Ocean, there seems to be a separate population where animals have been reported present throughout the year.

Baleen whales thus occupy a wide variety of habitats, from open oceans to continental shelves and coastal waters, from the coldest waters of the Arctic and Antarctic, through waters of both hemispheres and into the tropics.

Most specialized is the bowhead, *Balaena*, restricted to the harsh cold and shallow seas of the Arctic and sub-Arctic. The black right whales (*Eubalaena*) are more oceanic and prefer generally temperate waters, but come very close to coasts in winter to give birth, particularly in the Southern Hemisphere. Once believed not to penetrate much further south than the Antarctic convergence (*ca* 50–55°S), there have been recent records in the Antarctic proper, south of 60°S. Whether this is a new phenomenon is unclear: a report by Sir James Clark Ross of many "common black" (i.e., right) whales in the Ross Sea (eastern Antarctic) at 63°S in December 1840 was discounted when their presence there later that century could not be confirmed. It has been suggested that the currently greatly reduced population of the western North Atlantic right whale, now wintering off the southeastern United States and summering in coastal waters north to the Bay of Fundy (*ca* 45°N), may represent the peripheral remnant of a more widely distributed stock, formerly summering north to Labrador and southern Greenland, i.e., to at least 60°N.

The pygmy right whale (*Caperea*) is restricted to Southern Hemisphere temperate waters, between about 30 and 52°S; it can be found coastally in winter in some areas, and all-year round in others.

Gray whales (*Eschrichtius*) are the most obviously coastal baleen whales. The long coastal migration of the "Californian" stock, from Mexico to Alaska, supports a major whale-watching industry from December to April. In spring the animals migrate through the Bering Strait into the more open waters of the Bering Sea, but still favoring more shallow waters.

Among the balaenopterids, fin and sei whales are probably the most oceanic, with the former penetrating into colder waters than the latter in summer. Blue whales can be found closer inshore, but are often associated with deep coastal canyons, e.g., off central and southern California. The Southern Hemisphere pygmy blue whale (subspecies *B. m. brevicauda*) has been regarded as restricted to more temperate waters than the "true" blue whale (*B. m. intermedia*), not often being found much beyond 55°S. The most coastal balaenopterid is the humpback (*Megaptera*), with long migrations between temperate/tropical breeding grounds and cold water feeding grounds. In the Southern Hemisphere, much of its journey occurs along the east and west coasts of the three continents. In the Northern Hemisphere, humpbacks are rather more oceanic, but still coastal at some stage in their migration: in the North Pacific they can be found wintering off the Hawaiian Islands and summering off Alaska, and in the western North Atlantic they winter in the Caribbean and summer between New England, the west coast of Greenland, and Iceland.

Minke whales are wide ranging, from polar to tropical waters in both hemispheres. In the Southern Hemisphere the Antarctic species can, with blue whales, be found closest to the ice edge in summer. Elsewhere they can often occur near shore, in bays and inlets. Their migrations are less well defined and predictable than other migratory balaenopterids; in some regions they are present year-round.

The most localized balaenopterid is Bryde's whale. It is the only species restricted entirely to tropical/warm temperate waters and probably does not undertake long migrations. The two forms—inshore and offshore, in several areas—can differ in their movements. Off South Africa, for example, the inshore form is thought to be present throughout the year, whereas the offshore form appears and disappears seasonally, presumably in association with movements of its food, shoaling fish.

B. Food and Feeding

Although they include the largest living animals, baleen whales feed mainly on very small organisms and are strictly carnivorous, feeding on zooplankton or small fish. In "filter feeding"—sieving the sea—baleen whales are quite different from toothed whales, where the prey is captured individually.

FILTER FEEDING has been described as requiring, in addition to a supply of food in the water, three basic features: a flow of water to bring prey near the mouth; a filter to collect the food but allow water to pass through; and a means of removing the filtered food and conveying it to the stomach for digestion. Baleen whales meet those requirements by (a) seeking out areas where their food concentrates, (b) either swimming open-mouthed through food or gulping it in, (c) possessing a highly efficient filter formed by the baleen plates, and (d) forcing the water containing the food out through the baleen plates and then transferring the trapped food back to the gullet and hence to the stomach. In the latter the tongue is presumed to be involved; in balaenopterids the process is aided by the distensible throat.

While all baleen whales possess a filter based on baleen plates, two rather different systems—essentially "skimming" and "gulping"—have evolved to filter a large volume of water containing food. Each relies on a series of triangular baleen plates, borne transversely on each upper jaw. The inner, longer border (hypotenuse) of each plate bears a fringe of fine hairs, forming a kind of filtering "doormat." Quite unrelated to teeth (which appear as early rudiments in the gums of fetal baleen whales), baleen is closest in structure to mammalian hair and human fingernails. In the right whales, filtration is achieved with very long and narrow plates in the very large mouth, itself carried in the very large head. The plates, up to 4 m long in bowheads and 2.7 m in other right whales, are accommodated in the mouth by an arched upper jaw and are enclosed in mas-

sively enlarged and upwardly bowed lower lips. There is a gap between the rows at the front of the mouth, and the whole arrangement allows the whale to scoop up a great quantity of water while swimming slowly forward. In balaenopterids, with their much smaller heads, the baleen plates are shorter and broader and the rows are continuous at the front. Taking in a large volume of water and food is usually achieved by swimming through a food swarm and gulping, while simultaneously enlarging the capacity of the mouth greatly by extending the ventral grooves and depressing the tongue. The two systems allow, on the one hand, the relatively slow-swimming balaenids to concentrate their rather sparse slow-swimming food over a period, and on the other, the faster-swimming balaenopterids to take in large amounts of their highly concentrated fast-swimming prey over a shorter time.

Typically, baleen whales feed on zooplankton, mainly euphausiids or copepods, swarming in polar or subpolar regions in summer. That is particularly so the Southern Hemisphere, where the summer distributions of several balaenopterids depends on the presence of *Euphausia superba* (known to whalers by the Norwegian word "krill") in huge concentrations in the Antarctic. In the Northern Hemisphere, with a more variable availability of food, balaenopterids are more catholic in their feeding. Humpbacks and fin whales, for example, feeding almost exclusively on KRILL in the south, commonly take various species of schooling fish in the north.

The variety of organisms taken by the various species in different regions is listed in Table II. While most feeding occurs in colder waters, baleen whales may feed opportunistically elsewhere. All baleen whales but one, the gray whale, feed generally within 100 m of the surface and, consequently, unlike many toothed whales, do not dive very deep or for long periods. Gray whales feed primarily on bottom-living organisms, almost exclusively amphipods, in shallow waters.

The baleen plate structure, particularly the inner fringing hairs, to some extent mirrors the food organisms taken or (in

TABLE II
Baleen Whale Food Items

			Food items	
Species	*Subspecies*	*Common name*	*Northern Hemisphere*	*Southern Hemisphere*
B. mysticetus		Bowhead whale	Mainly calanoid copepods; euphausiids; occasional mysids, amphipods, isopods, small fish	
E. glacialis		North Atlantic right whale	Calanoid copepods; euphausiids	
E. australis		Southern right whale		Copepods; postlarval *Munida gregaria; Euphausia superba*
Caperea marginata		Pygmy right whale		Calanoid copepods
E. robustus		Gray whale	Gammarid amphipods; occasional polychaetes	
M. novaeangliae		Humpback whale	Schooling fish; euphausiids	*E. superba* (Antarctic); euphausiids, postlarval *M. gregaria,* occasional fish (ex-Antarctic)
B. acutorostrata	*B. a. acutorostrata*	N. Atlantic minke	Schooling fish; euphausiids	
	B. a. scammoni	N. Pacific minke	Euphausiids; copepods; schooling fish	
	B. a. subsp.	Dwarf minke		? Euphausiids, schooling fish
B. bonaerensis		Antarctic minke		*E. superba*
B. edeni		Bryde's whale	Pelagic crustaceans, including euphausiids	Schooling fish; euphausiids
B. borealis		Sei whale	Schooling fish	Copepods, including *Calanus; E. superba*
B. physalus		Fin whale	Schooling fish; squid; euphausiids; copepods	*E. superba* (Antarctic); other euphausiids (ex-Antarctic)
B. musculus	*B. m. musculus*	Blue whale	Euphausiids	
	B. m. indica	Great Indian rorqual	?Euphausiids; copepods	
	B. m. intermedia	"True blue"		*E. superba* (Antarctic); other euphausiids (ex-Antarctic)
	B. m. brevicauda	Pygmy blue		Euphausiids, mainly *E. vallentini*

the case of *E. superba)* different size classes. Thus there is some correlation between decreasing size of prey and fineness of baleen by species, viz. gray, blue, fin, humpback, minke, sei, and right whales. Where food stocks are very dense, e.g., around sub-Antarctic South Georgia, fin, blue, and sei whales may all overlap in their feeding on *E. superba.*

Baleen whale food consumption per day has been calculated as some 1.5–2.0% of body weight, averaged over the year. Given that feeding occurs mainly over about 4 months in the summer in the larger species, the food intake during the feeding season has been calculated at some 4% of body weight per day, *ca.* 400 kg per day for a large blue whale. To survive the enormous drain of pregnancy and lactation, it has been calculated that a pregnant female baleen whale needs to increase its body weight by up to 65%. The ability to achieve such an increase in only a few months' feeding indicates the great efficiency of the baleen whales' feeding system.

C. Predators and Parasites

Apart from humans, the most notable baleen whale predator is the killer whale (*Orcinus orca*). Minke whales have been identified as a major diet item of some killer whales in the Antarctic. Killer whale attacks have been reported on blue, sei, bowhead, and gray whales, although their frequency and success are unknown. Humpbacks often have killer whale tooth marks on their bodies and tail flukes. Humpback and right whale calves in warm coastal waters are susceptible to attack by sharks. There are anecdotal reports of calving ground attacks on humpbacks by false killer whales (*Pseudorca crassidens*).

A form of harassment, only recently described, occurs on right whales on calving grounds off Peninsula Valdes, Argentina. Kelp gulls have developed the habit of feeding on skin and blubber gouged from adult southern right whales' backs as they lie at the surface. Large white lesions can result. The whales react adversely to such gull-induced disturbance and calf development may be affected.

External parasites, particularly "WHALE LICE" (cyamid crustaceans) and BARNACLES (both acorn and stalked) are common on the slower-swimming more coastal baleen whales, such as gray, humpback, and right whales. In the latter, aggregations of light-colored cyamids on warty head callosities have facilitated research using callosity-pattern photographs for individual identification. External parasites are much less common on the faster swimming species, although whale lice have been reported on minke whales (in and around the ventral grooves and umbilicus); the highly modified copepod *Penella* occurs particularly on fin and sei whales in warmer waters. The commensal copepod *Balaenophilus unisetus* often infests baleen plates in such waters, especially on sei and pygmy blue whales.

A variety of internal PARASITES have been recorded, although some baleen whales seem less prone to infection than others. They appear, for example, to be less common in blue whales, but prevalent in sei whales. Records include stomach worms (*Anisakis* sp), cestodes, kidney nematodes, liver flukes, and acanthocephalans ("thorny-headed" worms) of the small intestine.

The cold water diatom *Cocconeis ceticola* often forms a brownish-yellow film on the skin of blue and other baleen whales in the Antarctic. Because the film takes about a month to develop, its extent can be used to judge the length of time an animal has been there. Its presence led to an early common name for the blue whale: "sulfur bottom."

For many years the origin of small scoop-shaped bites on baleen whale bodies in warmer waters remained a mystery until they were found to be caused by the small "cookie-cutter" shark, *Isistius brasiliensis.* Some species are highly prone to such attacks. In Southern Hemisphere sei whales the overlapping healing scars can impart a galvanized-iron sheen to the body.

III. Life History

A. Behavior

1. Sound Production Unlike toothed whales, baleen whales are not generally believed to use sound for echolocation, although bowheads, for example, are thought to use sound reflected from the undersides of ice floes to navigate through ice fields. However, sound production for communication, for display, establishment of territory, or other behavior, is well developed in the suborder. Blue whales produce the loudest sustained sounds of any living animal. At up to nearly 190 decibels, their long (half-minute or more), very low-frequency (<20 Hz) moans may carry for hundreds of kilometers or more in special conditions. Fin whales produce similarly low (20 Hz) pulsed sounds. Minke whales also produce a variety of loud sounds. Right whales produce long low moans; bowhead sounds, recorded on migration past hydrophone arrays in nearshore leads, have been used in conjunction with sightings to estimate population size off northern Alaska. Southern right whales, at least, seem to use sound to communicate with their calves.

Humpbacks produce the longest, most complex sound sequences in "songs," described as an array of moans, groans, roars, and sighs to high-pitched squeaks and chirps, lasting 10 or more minutes before repetition, sometimes over hours. It seems that only the adult males sing, generally only in or close to the breeding season. In any one breeding season, all the males sing the same SONG, changing slightly over successive seasons. Different populations have different songs; so much so, for example, that those off western Australia have a distinctly different song—less complex, less "chirpy"—than that heard on breeding grounds separated by the Australian continent, off the east coast. "Songs" may also be heard in migrating humpbacks, but less so on the cold water feeding grounds, where if they occur at all, they appear generally only as "snatches" or isolated segments.

2. Swimming and Migration With their streamlined bodies, rorquals include the fastest-swimming baleen whales. Sei whales have been recorded at around 35 knots (more than 60 km/hr) in short bursts; minke and fin whales are also known as fast swimmers, the latter up to 20 knots (37 km/hr). Blue whales are among the most powerful swimmers, able to sustain speeds of over 15 knots (28 km/hr) for several hours. On migration, humpbacks and gray whales average about 4 knots (8–9 km/hr) and bowheads only about 2.7 knots (5 km/hr). Migration speeds for southern right whales are not known, but medium range coastal movements off southern Australia indicate 1.5–2.3 knots (2.7–4.2 km/hr) over 24 hrs for cow/calf pairs.

Baleen whales undertake some of the longest MIGRATIONS known. Gray whales cover 10,000 nautical miles (18,000 km) on the round trip between the Baja California breeding grounds and the Alaskan feeding grounds, among the longest migrations of any mammal. Southern Hemisphere humpbacks may cover as much as 50° of latitude either way between breeding and feeding grounds, a round trip of some 6000 nautical miles (11,000 km). Not all baleen whale migrations are so well marked. The biannual movements of Bering Sea bowheads are governed by the seasonal advance and retreat of sea ice, which varies from year to year. Although Southern Hemisphere blue and fin whales all feed extensively in the Antarctic in summer, the locations of their calving grounds are not known. Sei whale migrations are relatively diffuse and can vary from year to year in response to changing environmental conditions. By comparison, Bryde's whales hardly migrate at all, presumably being able to satisfy both reproductive and nutritional needs in tropical/warm temperate waters. Even among such migratory animals as humpbacks, it may be that not all animals migrate every year; studies off eastern Australia indicate that a proportion of adult females may not return to the calving grounds each year, and individuals have even been reported in summer farther north. However, Southern Hemisphere migrating humpbacks show segregation in the migrating stream: immatures and females accompanied by yearling calves are in the van of the northward migration, followed by adult males and nonpregnant mature females; pregnant females bring up the rear. A similar pattern occurs on the southward journey, with cow/calf pairs traveling last. Very similar segregation is recorded among migrating gray whales.

Baleen whale migrations have generally been regarded as taking place in response to the need to feed in colder waters and reproduce in warmer waters. Explanations for such long-range movements have included direct benefits to the calf (better able to survive in calm, warm waters), evolutionary "tradition" (a leftover from times when continents were closer together), and the possible ability of some species to supplement their food supply from plankton encountered on migration or on the calving grounds. Corkeron and Connor (1999) have rejected these explanations, suggesting that there may be a major advantage to migrating pregnant female baleen whales in reducing the risk of killer whale predation on newborn calves in low latitudes. They cite in its favor the greater abundance of killer whales in higher latitudes, that their major prey (pinniped seals) is more abundant there, and that killer whales do not seem to follow the migrating animals.

3. *Social Activity* Large aggregations of baleen whales are generally uncommon. Even on migration, in those species where well-defined migration paths are followed (e.g., gray whales and humpbacks), individual migrating groups are generally small, numbering only a few individuals. It has been stated that predation is a main factor in the formation of large groups of cetaceans, e.g., open ocean dolphins. Given the large size of most adult baleen whales, predation pressure is low and group size is correspondingly small.

Blue whales are usually solitary or in small groups of two to three. Fin whales can be single or in pairs; on feeding grounds they may form larger groupings, up to 100 or more. Similarly, sei whales can be found in large feeding concentrations, but in groups of up to only about six elsewhere. The same is true for minke whales, found in concentrations on the feeding grounds, but singly or in groups of two or three elsewhere. Social behavior has been studied most intensively in coastal humpbacks, e.g., on calving grounds. Male humpbacks compete for access to females by singing and fighting. The songs seem to act as a kind of courtship display. Males congregate near a single adult female, fighting for position. Such aggression can involve lunging at each other with ventral grooves extended, hitting with the tail flukes, raising the head while swimming, fluke and flipper slapping, and releasing streams of bubbles from the blowhole. As a result of such encounters, individuals can be left with raw and bleeding wounds caused by the sharp barnacles. Among southern right whales, similar "interactive" groups are often observed on the coastal calving grounds in winter, involving a tight group with up to seven males pursuing an adult female, but not generally resulting in wounded animals. As for humpbacks, it is not yet certain whether such behavior results in successful mating, although, at least in such right whale groups, intromission is often observed.

Feeding balaenopterids have often been reported as circling on their sides through swarms of plankton or fish. It has been suggested that gray whales feed on their right sides, as those baleen plates are more worn down, presumably through contact with the seabed. The most remarkable behavior, however, is reported from humpbacks. In the Southern Hemisphere, on swarms of krill, they may feed in the same "gulping" way as other balaenopterids. In the Northern Hemisphere, two methods are commonly reported: "lunging" and "bubble netting." In the former, individuals emerge almost vertically at the surface with their mouths partly open, closing them to force the enclosed water out through the baleen. In the latter, an animal circles below the food swarm; as it swims upward, it exhales a series of bubbles, forming a "net" encircling the prey. It then swims upward through the prey with its mouth open, as in lunging.

B. Growth and Reproduction

Young baleen whales, particularly the fetus and the calf, grow at an extraordinary rate. In the largest species, the blue whale, fetal weight increases at a rate of some 100 kg/day toward the end of pregnancy. The calf's weight increases at a rate of about 80 kg/day during suckling. During that 7-month period of dependence on the cow's milk, the blue whale calf will have increased its weight by some 17 tons and increased in length from around 7 to 17 meters. Blue whales attain sexual maturity at between 5 and 10 years, at a length of around 22 meters, and live for possibly 80–90 years. Adult female blue whales give birth every 2–3 years, with pregnancy lasting some 10–11 months.

Other balaenopterids follow the same general pattern (Fig. 3). Mating takes place in warm waters in winter, with birth following some 11 months later. A 7- to 11-month lactation period may be followed by a year "resting," or almost immediately by another pregnancy. Most adults are able to reproduce from between 5 and 10 years of age and reach maximum growth after 15 or more years. The smallest balanopterid, the common minke whale, is born after a pregnancy of some 10 months, at

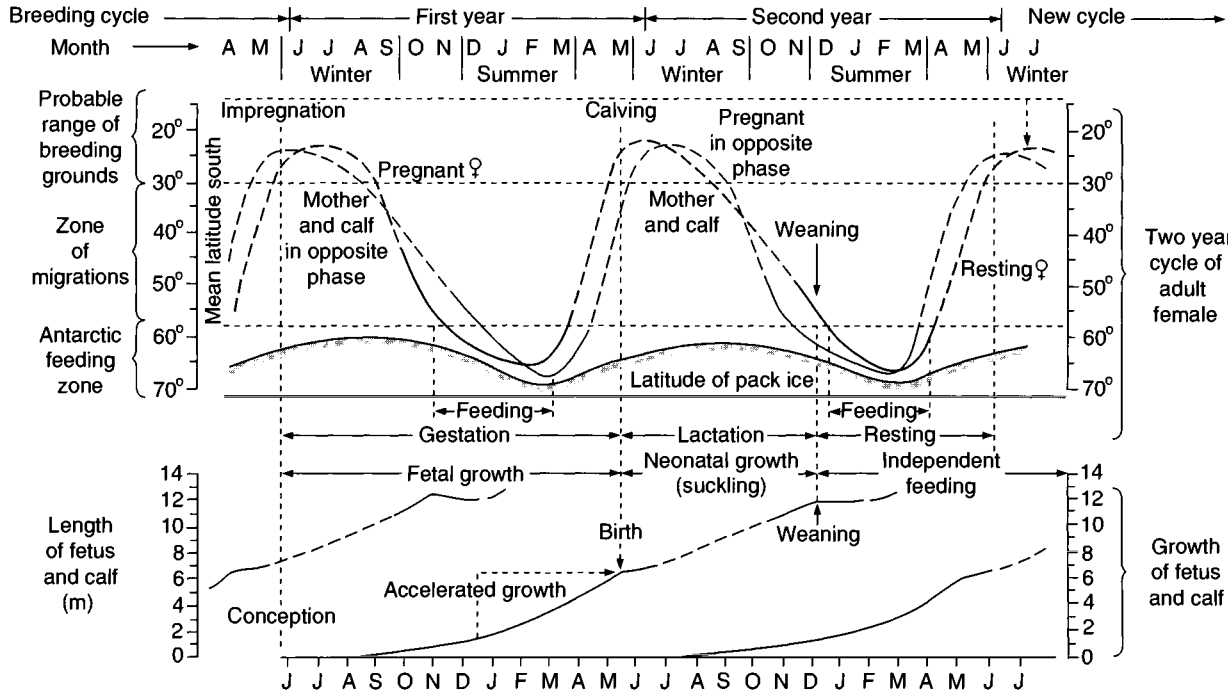

Figure 3 *"Typical" life cycle of a southern baleen whale. As modified by Bonner (1980), from Mackintosh (1965).*

a length of just under 3 meters. Weaning occurs at just under 6 meters, after 3–6 months. The adult female can become pregnant again immediately following birth, but the resulting short calving interval is generally uncommon in baleen whales: 2–3 years is the norm, although female humpbacks can achieve a similar birth rate, enabling their stocks to recover rapidly after depletion (see Section IV).

Right whales follow a similar general pattern, but there are some differences. In right whales, gestation lasts about 11 months and weaning for about another year. Females are able to reproduce successfully from about 8 years (there are records of successful first pregnancies from 6 years), but the calving interval is usually a relatively regular 3 years. For bowheads, it has been reported, rather surprisingly, that while growth is very rapid during the first year of life (from ca. 4.5 meters), it may be followed by a period of several years with little or no growth. Sexual maturity occurs at 13–14 meters; at the reduced growth rate, that would not be reached until 17–20 years. Similarly, evidence shows considerable longevity in this species: stone harpoon heads found in harvested whales and last known to be used off Alaska early this century suggest that individual animals can be at least 100 years old.

IV. Population Status

For centuries, baleen whales have borne the brunt of human greed, for products and profit. Only the sperm whale, largest of the toothed whales, has rivaled them as a whaling target. Black right whales (*Eubalaena*) were taken in the Bay of Biscay from the 12th century, with the fishery extending across the North Atlantic by the 16th century. Attention then shifted to the Greenland whale (*Balaena*) near Spitzbergen and later off southern and western Greenland. Both species' numbers were reduced to only small remnants, and in several areas (e.g., Spitzbergen and Greenland for *Balaena* and the northeast Atlantic and the North Pacific for *Eubalaena*) the stocks were virtually exterminated. That destruction was undertaken using the "old" whaling method, with open boats and hand harpoons, on the "right" species—"right" because they were relatively easy to approach, floated when dead, and provided huge quantities of products [oil for lighting, lubrication, and soap and baleen ("whalebone") for articles combining flexibility with strength, such as corset stays, umbrella spokes, and fishing rods].

Development of the harpoon gun and steam catcher, from 1864, increased the rate of catching greatly, but also allowed attention to turn to the largest baleen whales, the blue and fin whales, whose size, speed, and tendency to sink when dead had prevented capture by the old methods. From its beginning in the North Atlantic, then, by the end of the century, in the North Pacific, "modern" whaling's next and most intensive phase moved south, first in 1904 at South Georgia in the South Atlantic, just within the Antarctic zone. Initially on humpbacks [up to 12,000 were taken in one year (1912), leading to very rapid stock decline] and then on blue and fin whales, southern whaling based on such land stations—in the Antarctic in summer and the tropics in winter—was overtaken from the late 1920s by the great development of pelagic whaling using floating factory ships. Huge annual Southern Hemisphere catches resulted—a maximum of over 40,000 in 1931—averaging

around 30,000 animals per year in the later 1930s and again after World War II until 1965. Whereas blue whales had been the preferred target in the 1930s, their great reduction in numbers led to a shift in attention progressively over the years to fin whales, to sei whales in the 1960s, and finally to minke. With depletion of stocks and more stringent conservation measures (killing of humpbacks, blue, and fin whales was banned from the mid-1960s, even though some illegal catching continued until the early 1970s or even later), catches fell to between 10,000 and 15,000 per year in the 1970s. The "old" whaling story had virtually repeated itself—enormous reductions through overfishing of one species or stock leading to exploitation of other species and stocks until, apart from minke whales, only remnants were left. Since 1989, a moratorium on all commercial whaling has eliminated that pressure, with the exception of limited whaling carried our under exemption for scientific research, and, since 1993, limited commercial catching of minke whales in the eastern North Atlantic. Some "aboriginal" whaling has also continued in the Northern Hemisphere, on bowheads off northern Alaska, on gray whales in the Bering Sea, on fin and minke whales off Greenland, and on humpbacks in the Caribbean.

Despite the great scale of the kill in "old" and "modern" whaling, no whale species has become extinct through whaling, although a number of individual stocks have been reduced greatly; at least one, the North Atlantic gray whale, has disappeared within the past 200–300 years. In its most recent (1996) "Red List" of threatened animals (Table 3), the World Conservation Union (IUCN) includes no baleen whale species or stocks as either **extinct (EX)** or **critically threatened (CR)** (the latter within the **threatened** category). Within the threatened category, eight taxa—four species, one subspecies, and three stocks—are listed as **endangered (EN);** four taxa—one species and three stocks—are **vulnerable (VU).** Six taxa—two

species, one subspecies, and three stocks—are listed as at **lower risk (LR),** and two taxa—one species and one subspecies—as **data deficient (DD).**

Those species under greatest current threat **(EN)** are the North Atlantic and North Pacific right, the sei, and fin whales, together with the "true" blue subspecies, two of the five bowhead stocks (Okhotsk Sea, Spitzbergen), and the northwest Pacific gray. Next most threatened **(VU)** are the humpback, two bowhead stocks (Hudson Bay, Baffin Bay/Davis Strait), and the North Atlantic blue. At lower risk **(LR)** are the southern right and Antarctic minke, one bowhead stock (Bering-Chukchi-Beaufort Seas), the North Atlantic minke, northeast Pacific gray, and North Pacific blue; all but one are further qualified as **conservation dependent (cd,** not vulnerable because of specific conservation efforts). The exception is the North Atlantic minke, listed as **near threatened (nt,** not conservation dependent but almost qualifying as vulnerable). The two taxa for which insufficient information is currently available **(DD)** are Bryde's whale and the pygmy blue.

The INTERNATIONAL WHALING COMMISSION'S Scientific Committee, responsible for the assessments of such stocks' current status, has reported encouraging recent reversals of stock decline for some stocks of some species. One, the northeast Pacific gray whale, has recovered under protection from commercial whaling (but with aboriginal catches up to some 150 per year) to at or near its "original" (prewhaling) state (ca. 26,000 animals). Similarly, the northwest Atlantic humpback and several Southern Hemisphere humpback populations have been showing marked increases. The latest estimate of the North Atlantic stock, some 10,600 animals in 1993 (*cf.* 5500 in 1986), must reflect some population growth in the intervening period, whereas two Southern Hemisphere stocks (off eastern and western Australia) have been increasing steadily, at 10% or more per year since the early 1980s. Indeed, in all areas where surveys have been undertaken recently on Southern Hemisphere humpback populations they have been shown to be undergoing some recovery. Three southern right whale stocks (off eastern South America, South Africa, and southern Australia) have been increasing since the late 1970s at around 7–8% per year, although at some 3000, 3000, and 1200 animals, respectively, all are still well below their "original" stock size. Even the "true" blue whale, whose future has been of considerable concern, with estimates for the late 1980s at fewer than 500 animals for the whole Antarctic, has shown recent encouraging signs. Based on a series of Antarctic sightings cruises, mainly for minke whales but including other large whales, the most recent calculations (admittedly using only small absolute numbers sighted) show that the population must have been increasing since the last estimate (1991). As yet the analyses do not permit a firm conclusion on the number now present, although it seems likely to be more than 1000.

The one species or stock for which there is now very great concern is the North Atlantic right whale. At very low absolute abundance (only some 300 animals), not recovering despite protection from whaling in the 1930s, now even decreasing through a reduced survival rate and an increase in calving interval, and subject to increasing removals from ship strikes and fishing gear entanglement, the only way to ensure the species' survival is to reduce such anthropogenic mortality (ship strike and entanglement) to zero. While research on mortality reduction measures should be pursued, immediate management action is urgently needed.

It has been calculated that the great reduction of baleen whales by whaling, for the Antarctic to around one-third of original numbers and one-sixth in biomass, must have left a large surplus of food—some 150 million tons per year—available for other consumers, such as seals, penguins, and fish. (In a different way, early whaling in the North Atlantic, particularly on right whales, is believed to have influenced the spread of one sea bird—the fulmar—by providing food in the form of discarded whale carcasses.) In response to an increase in available food, there may well have been increases in growth rates, earlier ages at maturity, and higher rates of pregnancy in some baleen whale species. However, the evidence is equivocal, as it is for competition between individual whale species. For some, e.g., right whales and sei, it has been suggested that an increase in one (right whales) could be inhibited by competition with another (sei whales). In the North Pacific, both sei and right whales can feed on the same prey—copepods—and sei whales can at times be "skimming" feeders, like right whales. However, evidence that they actually compete on the same prey, in the same area, at the same time, and even on the same prey patch is lacking. Similarly, there has been much debate and speculation on whether the recovery of the Southern Hemisphere "true" blue whale has been inhibited by an apparent increase in Antarctic minke whales. In that case, there may in fact be very little direct competition for food where the common prey is not limited in abundance (as in the Antarctic) and is available in large patches. The well-authenticated increases in the substantial annual rates for several stocks of Southern Hemisphere humpbacks and right whales and the possibility of at least a limited increase in numbers for the "true" blue whale suggest that such competition is unlikely, at least where, as in the Antarctic, food supplies are abundant.

Baleen Whales, Archaic

NICHOLAS C. FRASER AND ALTON C. DOOLEY, JR.
Virginia Museum of Natural History, Martinsville

The modern mysticetes (baleen whales) are typically characterized by the development of specialized epithelial tissue in the roof of the mouth that becomes keratinized: the so-called baleen. The baleen is used to filter organisms from water or sediment, ranging in size from microscopic copepods to crustaceans and fish as much as 5 cm in length. There is evidence for baleen in whales dating from the Oligocene, but some archaic mysticetes retained functional teeth all the way to the late Oligocene. Modern baleen whales do not have functional teeth, although incipient teeth are found in embryos. Archaic baleen whales are considered to be those mysticetes, both toothed and baleen-bearing, that do not belong to extant families. They comprise four named families: Mammalodontidae, Llanocetidae, Aetiocetidae, and Cetotheriidae, with over 20 named genera.

Modification of the rostrum is a characteristic of even the earliest mysticetes. The rostral elements extend backward to the orbits and are expanded laterally, while at the same time the occipital region extends forward. The telescoping of the skull also occurs in odontocetes, but there is an asymmetry in these forms, and the rostral elements tend to overide the frontals.

The remainder of the skeleton of mysticetes is greatly simplified. The mandibular symphysis is lost, with the two dentaries held together by a ligament. The sternum is greatly reduced. The hindlimbs are almost totally absent, the only remnant being a small splint of bone thought to be homologous with the pelvis, which no longer articulates with the vertebral column. There are trends toward compression, and ultimately fusion, in the cervical vertebrae and reduction of rib–vertebrae articulations.

I. Origins and Affinities

Although typically considered as a monophyletic group distinct from the odontocetes, certain molecular studies have indicated that mysticetes are the sister group to physeterids (sperm whales) and nested within a paraphyletic Odontoceti. This relationship was first suggested on the basis of mitochondrial ribosomal DNA sequences. However, other molecular studies (DNA–DNA hybridization, karotypes, and cytochrome DNA sequences) support the more traditional, morphology-based classification. Further support for odontocete and mysticete monophyly comes from studies of the inner ear of a number of Miocene and Pliocene "cetotheres" that shows that they did not have the high-frequency hearing that permits echolocation, and which is so typical of odontocetes.

Recent discoveries indicate that baleen whales evolved directly from archaeocete ancestors. The Llanocetidae from the late Eocene or early Oligocene of the South Pacific are heterodont and may have used their denticulate and palmate cheek teeth for filter feeding. Other primitive mysticetes from the late Oligocene of South Carolina include two heterodont genera but with skull development similar to later baleen whales. Homodont toothed mysticetes are seen in the Aetiocetidae (Fig. 1), also from the late Oligocene. This group was quite diverse, with eight species in three genera described to date. The aetiocetids retain marginal teeth in both upper and lower jaws, yet exhibit the loose mandibular symphysis, which is a characteristic feature of all later mysticetes. Another late Oligocene form is *Mammalodon*, which has an unusually short rostrum unlike any other mysticete.

Even though these toothed mysticetes are too young to be actual ancestors to the cetotheres, which also dated from the early Oligocene, they may indicate the pattern of mysticete evolution. The earliest fossils of baleen-bearing whales come from the early Oligocene of New Zealand. While baleen does not fossilize, the pattern of skull vascularization in these earliest members is consistent with those of living mysticetes.

II. Diversification of Mysticetes

The earliest records of both odontocetes and mysticetes are in early Oligocene sediments of New Zealand. While in the Northern Hemisphere cetaceans are commonly considered to have had limited diversity during Oligocene times, in the Austral realm both odontocetes and mysticetes radiated, while at the same time the archaeocetes declined. These radiations have been attributed to a series of major geographical and climatic changes. First, during the latest Eocene and earliest Oligocene major continental glaciations developed, probably together with sea ice, which resulted in marked temperature drops in the oceans. At the same time with the opening of the Drake Passage between Antarctica and South America the Circum-Antarctic Current was established. Coupled with the initiation of the psychosphere this brought about increases in

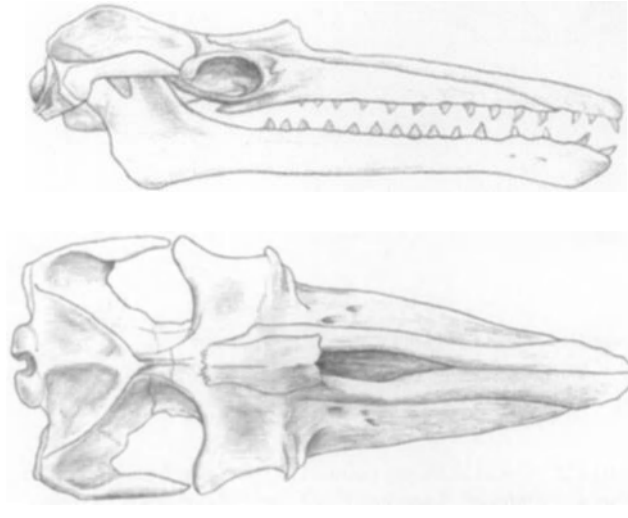

Figure 1 Aetiocetus polydentatus, *an aetiocetid from the late Oligocene Morawan Formation of Japan. Top, skull and mandible, left lateral view. Bottom, skull, dorsal view. Length of skull approximately 55 cm. After Barnes* et al. *(1994).*

local upwelling and areas of high productivity offshore. This may have led to the development of a FILTER-FEEDING lifestyle in the mysticetes and the eventual appearance of baleen.

Thus by the middle Miocene the mysticetes had peaked in diversity, with some 15 known genera compared to only 5 today. Moreover, the modern whales are largely characterized on the basis of external features. Clearly this is not possible with fossil forms, and it might be argued that solely on the basis of skeletal morphology that certain modern whales species would not have been separated as fossils. On this basis, and assuming that fossil forms also exhibited similar external variation, then the diversity of the Miocene cetotheres may have been even greater than is usually considered.

Most early mysticetes (particularly those from the late Oligocene to early Pliocene) are included in a single family, the Cetotheriidae (Fig. 2). However, this family has been acknowledged to be a "catch-all" assemblage of different taxa that really reflects our poor understanding of the early evolution of baleen whales. Cetothere species are mostly differentiated on the basis of skull proportions and, in some cases, differences in the ear region. No clearly derived shared characters have been recognized in any cetotheres that would permit a better understanding of the relationships within this family.

The cetothere grade whales still exhibit strong vertebral–rib articulations and do not have fusion of the cervical vertebrae. The cervicals tend to be quite compressed, and the hindlimbs are apparently absent. The skull is relatively smaller in the cetotheres than in the modern mysticetes, and the rostrum tends to be broad and tapering, making it more similar in outline to that of the Balaenopteridae and Eschrichtiidae than the Balaenidae. Cetotheres are also quite small. Body lengths in the Miocene range from about 3 m up to about 11 m (although only one specimen greater than 10 m is known). In modern mysticetes, adult body lengths are from 6 to 30 m, but only three species are normally less than 12 m.

Figure 2 Parietobalaena palmeri, *a cetothere from the middle Miocene Calvert Formation of Maryland and Virginia. (Top) Skull, dorsal view. (Middle) Skull and mandible, lateral view. (Bottom) Skeletal reconstruction. Length of skull approximately 120 cm. A and B after Kellogg (1965).*

Cetotheres have a worldwide distribution with a number of well-established genera, usually based at least on partial skulls. From eastern North America are *Pelocetus, Parietobalaena, Agalocetus, Diorocetus, Metopocetus, "Mesocetus," Thinocetus, Halicetus,* and *Cephalotropis*. From western North America are *Parietobalaena, Agalocetus, Herpetocetus, Tiphyocetus, Peripolocetus,* and *Cophocetus*. South American genera include *Morenocetus, Agalocetus,* and *"Plesiocetus."* European genera include *Mesocetus, Herpetocetus, Isocetus, Cetotheriopsis,* and *Cetotherium. Imerocetus* and *Cetotherium* are known from the Tethyan realm. From New Zealand is *Mauicetus* and from Japan is *Herpetocetus*. In addition, there are several unnamed specimens from most of these areas, some of which may represent new genera. There are also many nominal genera based on fragmentary remains.

III. Emergence of Modern Mysticete Fauna

The first members of some modern groups appeared in the middle part of the Miocene. These faunal changes may be correlative with worldwide environmental change and physical changes in the oceans. Among these changes were the establishment of a West Antarctic ice sheet, closure of the western opening of the Mediterranean Sea, and closure of the Indo-Pacific Seaway, all of which may have contributed to cooling, steeper temperature gradients and more complex ocean current patterns. In turn this would have resulted in a variety of pelagic habitats and increased partitioning of food resources. Thus in the same way that major changes in ocean currents resulted in the radiation of the "archaic" mysticetes (cetotheres) during the early and middle Oligocene, another major shift in ocean currents and sea temperatures could have initiated the radiation of modern mysticetes and brought about the demise of the archaic forms.

It is generally thought that all four modern mysticete families have separate origins among the cetotheres, but this is still speculative. The modern baleen whales [Balaenopteridae (rorquals and humpback whale, *Megaptera novaeangliae*), Balaenidae (right whales), Eschrichtiidae (gray whale, *Eschrichtius robustus*), and Neobalaenidae (pygmy right whale, *Caperea marginata*) all have have derived characters not presently known from any cetothere. All the modern families have weak-to-absent rib–vertebrae articulations and skulls which represent at least 25% of the body length. The balaenopterids have maxillary spurs that extend posteriorly along the top of the skull, and the supraorbital portions of the frontals are depressed well below the top of the skull. *Eschrichtius* has enlarged nasals and posterior ends of the premaxillae, a moderately arched ros-

trum, and posterior maxillary processes similar to balaenopterids, and there is no coronoid process on the mandible. The balaenids are perhaps the most divergent mysticetes, with an extremely arched and narrow rostrum, an anteroposteriorly compressed cranium, divergent zygomatic processes, the supraoccipital extending to a point anterior to the orbit, and fused cervical vertebrae. *Caperea* (Neobalaenidae) has a rostrum less arched and broader than in balaenids, although the supraoccipital extends anterior to the orbit. The balaenids and balaenopterids have fossil records extending to the Miocene, but it is not clear how they are related to the cetotheres. *Caperea* is thought to be close to the balaenids, but it does not have a fossil record. *Eschrichtius* is known only from the Quaternary. The body proportions of *Eschrichtius* are more similar to the cetotheres than to other modern mysticetes, and they still have strong rib articulations and a relatively long neck, making this genus more primitive than any of the other modern mysticetes.

Research programs on Oligocene and Miocene mysticetes are very active and new finds are continually being made. For example, additional finds from the Oligocene of New Zealand, Japan, and South Carolina will help shed further light on the origin of baleen whales from the archaeocetes, and exciting new discoveries in Virginia promise to elucidate separate lineages within the cetothere grade. One new Miocene cetothere appears to be more derived than other contemporary cetotheres in having compressed cervical vertebrae and exhibiting reduction of the capitulum. Furthermore, characters of the periotic indicate affinities with modern balaenopterids.

Barnacles

DAGMAR FERTL
Minerals Management Service, U.S. Department of the Interior, New Orleans, Louisiana

Barnacle is the common name for over 900 marine species of the subclass Cirripedia. Barnacles are unique among crustaceans in being sessile; they attach to a variety of inanimate and animate objects. Barnacles live in polar regions of the world, as well as tropical and temperate waters. The principal superorder is Thoracica, which is composed of stalked (order Lepadomorpha) and sessile (order Balanomorpha) barnacles. At least 20 barnacle species have some association with marine mammal species; those barnacles also belong to Thoracica. Barnacles attaching to marine mammals are often referred to as ectoparasites. In actuality, the barnacles do not parasitize the whale, but use their host as a substrate from which they feed on plankton in passing water. Epizoic is a more appropriate term describing this lifestyle. Barnacles attached to marine mammals have been described as an example of phoresis bordering on commensalism.

I. Life History

Barnacles have been described as "nothing more than a little shrimp-like animal, standing on its head in a limestone house and kicking food into its mouth." The barnacle's life cycle includes six free-swimming planktonic stages (nauplius) progressing by molts into a cypris (final larval stage), which searches for a place to settle. After settling, the cypris secretes cement from glands located in the base of the first antenna to anchor itself and metamorphoses to grow and molt. After attachment, the barnacle then begins the secretion of calcareous plates that become its home. Through an opening in the plates, six pairs of feathery, leg-like appendages (cirri) can emerge and spread out to sweep through the water, like a net, to entrap planktonic organisms. Most barnacles are hemaphroidites, i.e., each individual possesses reproductive structures of both sexes. The breeding season of barnacles that cling to whales is synchronous with that of the whales' breeding season.

II. Sessile Barnacles

The balanomorphs or sessile barnacles are stalkless; the barnacle "shell" attaches directly to a surface. Marine mammals have interactions with *Balanus, Cetopirus, Chelonibia, Coronula, Cryptolepas, Platylepas, Tubicinella,* and *Xenobalanus.* Three of these, *Xenobalanus, Platylepas,* and *Tubicinella*

superficially resemble stalked barnacles, but are actually aberrant sessile barnacles and can be considered pseudo-stalked. Because of their superficial resemblance to acorns of oak trees, coronuline (*Coronula* sp.) barnacles are called acorn barnacles.

III. Stalked Barnacles

The stalked, pedunculate, or goose barnacle is considered to be the more primitive. This barnacle is mounted on a muscular, flexible stalk (peduncle) that is attached to a firm base, and the upper portion of the animal is the major part of the body, bearing shell plates. *Conchoderma, Lepas,* and *Pollicipes* are all commensals of marine mammals.

IV. Barnacles and Marine Mammals

Barnacles appear to settle in greatest numbers on slower-moving cetaceans, as evidenced by the great number of barnacles found on gray whales (*Eschrichtius robustus*) and other mysticetes, compared to delphinids. Bottlenose (*Tursiops truncatus*) and striped (*Stenella coeruleoalba*) dolphins involved in mass mortality events on the U.S. Atlantic coast and in the Mediterranean, respectively, had an abundance of barnacles that might have been due to the reduced movement of sick dolphins and/or inpaired immune functioning of the skin.

Cryptolepas rhachianecti is consider to be host-specific to gray whales but has been found on a killer whale (*Orcinus orca*) that stranded in southern California and on belugas (*Delphinapterus leucas*) housed in San Diego Bay. *Xenobalanus* is almost always found on the trailing edges of the dorsal and pectoral fins and on the tail flukes of cetaceans (Fig. 1). *Platylepas* may be mistaken for *Xenobalanus;* there is one record of *Platylepas hexastylos* (found associated with *Xenobalanus*) from a bottlenose dolphin. *Tubicinella major* has been found buried cryptically among callosities of southern right whales (*Eubalaena australis*). A *Tubicinella* sp. has been collected from the flank of a stranded northern bottlenose whale (*Hyperoodon ampullatus*). *Coronula* is a large barnacle that attaches almost exclusively to the skin of mysticetes and is rarely found on odontocetes. *C. reginae* and *C. diadema* are common epizoites of humpback whales (*Megaptera novaeangliae*). Acorn barnacles can be found attached to flukes, flippers, ventral grooves, genital slit, and head of humpback whales (Fig. 2). One humpback was reported to have as much as 450 kg of acorn barnacles attached to it. Humpback males scrape each other with their barnacle-encrusted flippers on the breeding grounds. The two *Conchoderma* species (*C. auritum* and *C. virgatum*) are the only true stalked barnacles recorded from cetaceans, with the exception of one record of *Pollicipes polymerus* that was found associated with those two species on a humpback whale. The stalked barnacle *Conchoderma* requires a hard surface for attachment. *Conchoderma auritum* is identified by its rabbit-eared appendages. *C. auritum* may be found at a site where teeth are exposed and unprotected, such as on erupted teeth of adult male beaked and bottlenose whales, or because of a malformation (including bone injury) in the jaw (Fig. 3). *Conchoderma* is less commonly found on BALEEN plates and has been once recorded from the penis of a stranded sperm whale (*Physeter macrocephalus*). *C. auritum* is also often found attached to *Coronula* (most commonly to *C. diadema* and much more rarely to the barnacle *Pollicipes*). *C. virgatum* is never attached directly to a cetacean, but is epizoic on other barnacles, usually *C. auritum,* as well as the parasitic copepod *Pennella,* which may attach to cetaceans. *Cetopirus complanatus* closely resembles *C. reginae;* there are only two well-documented records from southern right whales. *Lepas* usually occurs on floating objects, yet *L. pectinata* and *L. hilli* have been found between the TEETH of some Mediterranean striped dolphins.

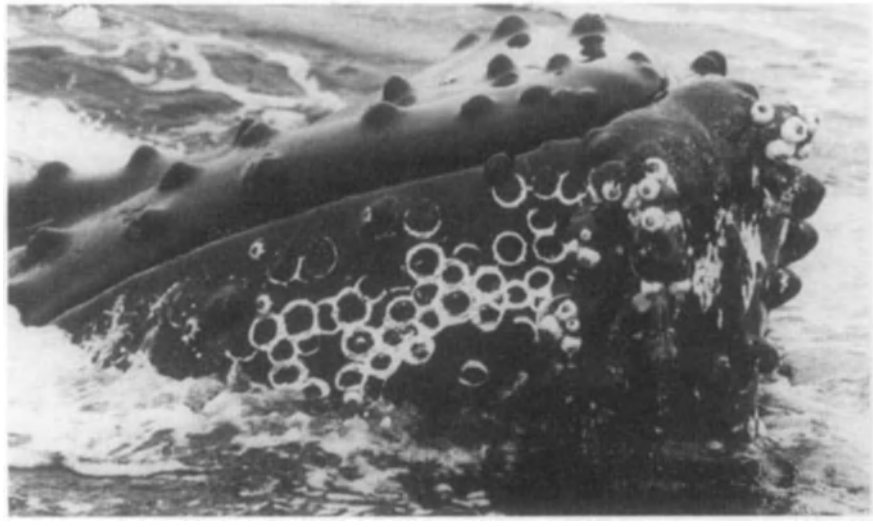

Figure 2 *Humpback whale with acorn barnacles* (Coronula) *and* Conchoderma auritum *attached to the barnacles. Also visible are white-rim scars from acorn barnacles that have dropped off. (Courtesy of Yuki Ogino, off California, 1999.)*

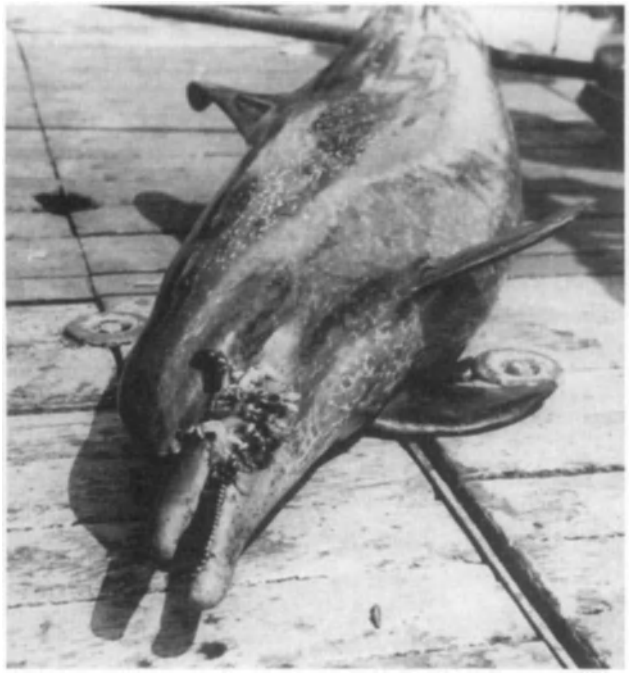

Figure 3 Conchoderma *barnacles attached to the teeth/jaw of a pantropical spotted dolphin* (Stenella attenuata). *(Courtesy of W. F. Perrin.)*

There are few published records of barnacles on pinnipeds. Three species of *Lepas* (*L. pacifica, L. australis,* and *L. hilli*) and *Conchoderma auritum* have been recorded from the dorsal body surface of various seal species. Manatees may acquire barnacles when in salt water; these barnacles die in fresh water and drop off, leaving scars. The common barnacle found embedded in the skin of West Indian (*Trichechus manatus*) and West African (*T. senegalensis*) manatees is *Chelonibia manati. Platylepas hexastylos* has been found on dugongs (*Dugong dugon*) and West Indian manatees. *Balanus amphitrite, B. eburneus, B. reticulatus, B. trigonus,* and *B. improvisus* attach to *Chelenibia* on manatees, but not directly to the skin. When population of preferred prey are reduced, sea otters (*Enhydra lutris*) in California and Alaska will eat *Balanus nubulis.*

Basilosaurids

MARK D. UHEN
Cranbrook Institute of Science, Bloomfield Hills, Michigan

Basilosaurids are a paraphyletic group of archaeocete cetaceans known from the late middle to early late Eocene of all continents except Antarctica and South America. The family includes 11 species in 8 genera in 2 subfamilies, although some authors elevate the subfamilies to familial rank. They range in size from around 4 m (*Saghacetus osiris*) to around 16 m (*Basilosaurus cetoides*). Basilosaurids are probably the earliest fully aquatic cetaceans (Uhen, 1998) and are thought to have given rise to modern cetaceans (Barnes *et al.*, 1985; Uhen, 1998).

I. Basilosaurid Characteristics

Like all archaeocetes, basilosaurids lack telescoping of the skull like that seen in modern mysticetes or like that seen in modern odontocetes (see Fig. 1; Miller, 1923). In addition, basilosaurids are diphyodont, lack polydonty, and retain a heterodont dentition in which incisors, canines, premolars, and molars are easy to distinguish based on their morphologies (Kellogg, 1936; Uhen, 1998).

Basilosaurids also share a number of characteristics that distinguish them from other archaeocetes. All basilosaurids lack upper third molars and the upper molars lack protocones, trigon basins, and lingual third roots. Also, the cheek teeth of basilosaurids have well-developed accessory denticles (Fig. 1). The hindlimbs of basilosaurids are greatly reduced (see Fig. 2; Gingerich *et al.*, 1990; Uhen and Gingerich, 2000) and lack a bony connection to the vertebral column. Basilosaurids also lack sacral vertebrae, although vertebrae that are likely to be homologs of sacral vertebrae are identifiable (Kellogg, 1936; Uhen, 1998).

Other characteristics may be found only in basilosaurids (within archaeocetes) but are currently not known from other archaeocetes. For instance, basilosaurid forelimbs had broad, fan-shaped scapulae with the distal humerus, radius, and ulna flattened into a single plane (Fig. 2). In addition, the elbow joint motion was restricted to the same plane, and pronation and supination of the forelimb were not possible based on the articular surfaces of the distal humerus, proximal radius, and proximal ulna. Because forelimbs are unknown in protocetids (Thewissen *et al.*, 1994), it is unclear whether these features are found only in basilosaurids or whether they are characteristic of a larger group.

Some of the characteristics of basilosaurids can be seen in some protocetid archaeocetes, such as *Georgiacetus*. Although the innominate of *Georgiacetus* is large, it does not appear to have been connected to the vertebral column (Hulbert, 1998). None of the vertebrae are fused into a sacrum, yielding a condition similar to that seen in basilosaurids. In addition, the cheek teeth of *Georgiacetus* have small accessory denticles, somewhat different from those in basilosaurids, but certainly larger than any of the serrations seen in other nonbasilosaurid archaeocetes.

II. Taxonomy

Taxonomy for the family Basilosauridae is after Uhen (1998). References therein and in Kellogg (1936) are the basis for the discussion of each taxon. Basilosaurinae and Dorudontinae are included here in the single family Basilosauridae following Miller (1923) because a single character state (elongate trunk vertebrae) distinguishes basilosaurines from dorudontines

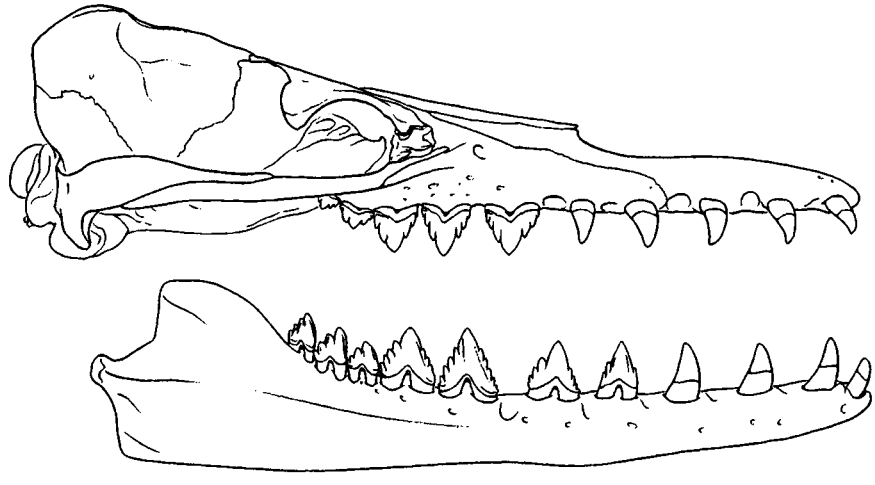

Figure 1 *Skull and lower jaw of* Dorudon atrox, *lateral view. This drawing is a composite drawn from specimens of* D. atrox *at the University of Michigan Museum of Paleontology by Bonnie Miljour.*

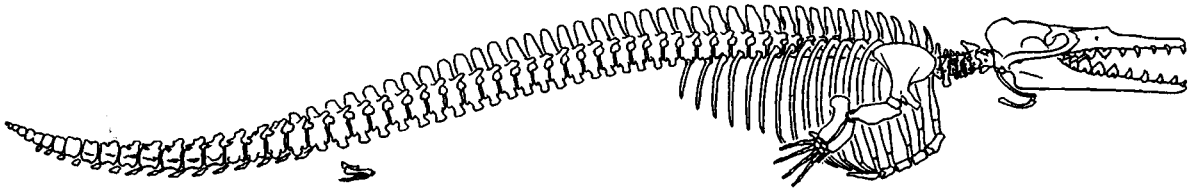

Figure 2 *Skeleton of* Dorudon atrox, *lateral view. This drawing is a composite drawn from specimens of* D. atrox *at the University of Michigan Museum of Paleontology by Bonnie Miljour.*

(Uhen, 1998). The names "zeuglodonts" and "zeuglodons" are often used colloquially to refer to basilosaurines or archaeocetes in general. These common names are derived from the generic name *"Zeuglodon"* (discussed later), and their usage should be avoided in formal works.

A. Basilosauridae Cope 1868

1. Basilosaurinae Cope 1868 Basilosaurines are basilosaurids with elongate posterior thoracic, lumbar, and anterior caudal vertebrae. All known basilosaurids are also considerably larger than all known dorudontines, with the exception of *Pontogeneus* (see later).

A. *BASILOSAURUS* HARLAN 1834 *Basilosaurus* was the first archaeocete whale named. The name was first coined in 1834 by Richard Harlan, who mistook the large vertebrae for those of a large marine reptile, thus the misnomer of "king lizard" for a cetacean. This mistake was pointed out by Richard Owen in 1842, when he attempted to rename the animal *Zeuglodon cetoides. Zeuglodon* is considered a junior subjective synonym of *Basilosaurus*, but it has been applied to so many archaeocete whales as to have become a common name for archaeocete or basilosaurid. *Basilosaurus* contains three species from the late middle and early late Eocene: *B. cetoides* is known from the southeastern United States, *B. isis* is known from Egypt and Jordan, and *B. hussaini* is known from Pakistan (Uhen, 1998).

B. *BASILOTERUS* GINGERICH *ET AL.* 1997 *Basiloterus* can be distinguished from *Basilosaurus* based on its anteroposteriorly long neural arch and more anteriorly-projecting metapophyses (Gingerich *et al.*, 1997). *Basiloterus* contains a single species, *B. drazindai*, based on a single lumbar vertebra from the late middle Eocene of Pakistan.

2. Dorudontinae Miller 1923

A. *DORUDON* GIBBES 1845 The genus *Dorudon* was erected in 1845 by Gibbes for a specimen of a small archaeocete that he dubbed *D. serratus*. This specimen is of a juvenile individual with deciduous teeth, making it difficult to compare to other specimens of adult individuals. Nonetheless, the number of species in *Dorudon* grew when Kellogg (1936) removed a number of species from the genus *Zeuglodon* and placed them in *Dorudon*. Subsequently, many of these species were synonymized and/or placed in other genera. Only *D. serratus* from the late Eocene of the southeastern United States and *D. atrox* (formerly *Prozeuglodon atrox*) from the late Eocene of Egypt remain (Uhen, 1998).

B. *ZYGORHIZA* TRUE 1908 The genus *Zygorhiza* was erected in 1908 by True for specimens of a small archaeocete from North America that he felt were different from *Dorudon serratus*. Some of these specimens had been part of Koch's *Hydrarchos* and had been called by many different names (Kellogg, 1936). *Zygorhiza kochii* can be distinguished from all other dorudontines by the presence of well-developed cuspules on the cingula of the upper premolars. *Zygorhiza* currently includes *Z. kochii* from the late Eocene of the southeastern United States and *Zygorhiza* sp. from New Zealand, as European specimens assigned to *Zygorhiza* are identified more appropriately as Dorudontinae incertae sedis (Uhen, 1998).

C. *PONTOGENEUS* LEIDY 1852 The name *Pontogeneus* was first used by Leidy for a single cervical vertebrae of a large basilosaurid archaeocete from Louisiana, which he dubbed *Pontogeneus priscus*. Some of the vertebrae of Koch's *Hydrarchos* were large in size, but not elongate like those of *Basilosaurus*, and were given the name *Zeuglodon brachyspondylus*. Kellogg (1936) suggested that these two taxa were the same and used Leidy's generic name and the specific epithet *brachyspondylus* for the new combination. Currently, the concept of *P. brachyspondylus* is a bit fuzzy, but basilosaurids of large size that lack elongate vertebrae are found in the late Eocene of the southeastern United States and Egypt to which this name could be applied (Uhen, 1998).

D. *SAGHACETUS* GINGERICH 1992 The generic name *Saghacetus* was coined in 1992 to subsume the former species *Dorudon osiris*, *Dorudon zitteli*, *Dorudon sensitivius*, and *Dorudon elliotsmithii* within a single species, *Saghacetus osiris*. *S. osiris* can be distinguished from other dorudontines based on its small size and its slightly elongate lumbar and anterior caudal vertebrate. *S. osiris* is known only from the late Eocene of Egypt.

E. *ANCALECETUS* GINGERICH AND UHEN 1996 *Ancalecetus* includes one species, *A. simonsi*, which is similar to *Dorudon atrox*, but has greatly modified forelimbs that were highly restricted in their range of motion. *A. simonsi* is known from the late Eocene of Egypt (Uhen, 1998).

F. *CHRYSOCETUS* *Chrysocetus* includes one species, *C. healyorum*, which differs from all other dorudontines in the smoothness of the tooth enamel, height of the premolar crowns, and eruption of its adult teeth in a skeletally juvenile state. *Chrysocetus* is also the only dorudontine for which the innominate is known. *Chrysocetus* is known from the late Eocene of South Carolina (Uhen and Gingerich, 2000).

B. Questionable Basilosaurids

Excluded from this list is the genus *Gaviacetus*, which was referred to the Basilosauridae by Bajpai and Thewissen (1998). The identification of *Gaviacetus* as a basilosaurid was based on the likely absence of upper third molars in both the type specimens of *Gaviacetus razai* and the type specimen of *Gaviacetus sahnii*

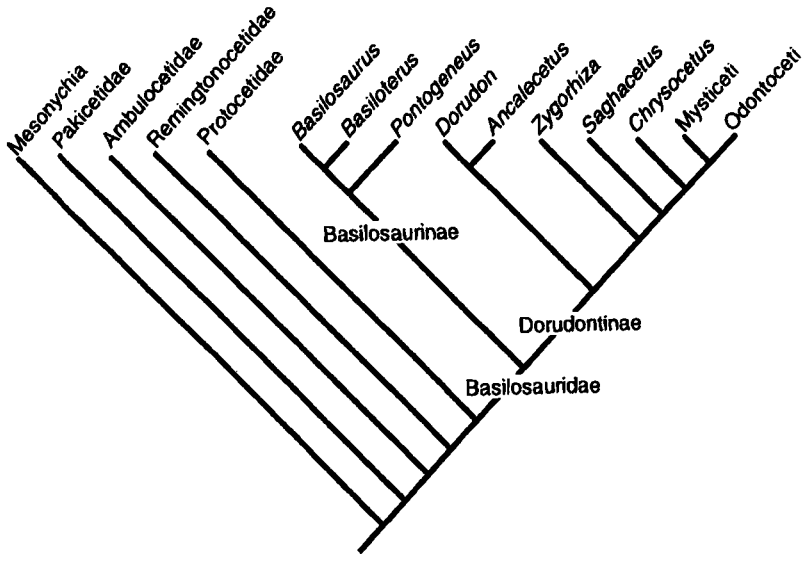

Figure 3 *Cladogram of basilosaurids, selected nonbasilosaurid archaeocetes, mysticetes, and odontocetes.*

(Bajpai and Thewissen, 1998). In addition, Bajpai and Thewissen (1998) referred some elongate vertebrae to *G. sahnii*, further supporting their placement of *Gaviacetus* in the Basilosauridae. Since no specimen of *Gaviacetus* clearly shows that the upper third molar is absent or that any of the cheek teeth have accessory denticles and since reference of postcrania to unassociated cranial material has proven problematic in the past, the author prefers to leave *Gaviacetus* in the Protocetidae as it was originally described until it can be shown clearly to have basilosaurid synapomorphies.

Species that may not be basilosaurids are *Basilosaurus hussaini* and *Basiloterus drazindai*. These species (as well as the genus *Basiloterus*) are based solely on one and two vertebrae, respectively. These vertebrae are thought to represent basilosaurines because they are elongate, like the vertebrae of *Basilosaurus*. While this feature is a distinguishing characteristic of Basilosaurinae within Basilosauridae, it is clear that vertebral elongation is not restricted to basilosaurids. *Eocetus*, a protocetid from Egypt and North America, also has elongate vertebrae, although they are not as elongate as those of *Basilosaurus*. It is possible that *B. hussaini* and *B. drazindai* are also protocetids. Once cranial or dental material associated with vertebrae is found, it will be obvious whether these taxa should be retained in Basilosauridae.

III. Phylogenetic Relationships

The phylogenetic relationships among basilosaurids and their relationships to other archaeocetes, mysticetes, and odontocetes are shown in Fig. 3. Many of the character state transformations that occur between basilosaurids and protocetids are associated with the adoption of a fully aquatic existence, such as presence of pterygoid air sinuses, extreme reduction of the hindlimb, loss of the sacrum, increase in the number of trunk vertebrae, and the presence of dorsoventrally flattened posterior caudal vertebrae (Uhen, 1998). Others, such as the loss of M^3, loss of lingual roots on the upper molars, and the development of accessory denticles on the cheek teeth, have to do with changes in feeding that are not as easy to interpret.

Within Basilosauridae, basilosaurines are united by the presence of elongate trunk vertebrae, which dorudontines lack. *Pontogeneus* may be the sister taxon to Basilosaurinae based on its large size. Each genus of dorudontine is distinguishable from other genera based on the presence of autapomorphies, but it is difficult to confidently link any of the genera based on any clear synapomorphies. The result is a polytomous relationship among the genera or an imbalanced tree with Mysticeti + Odontoceti nested well within Dorudontinae. *Chrysocetus* is preferred as the sister taxon to Mysticeti + Odontoceti based on the interpretation of it and early mysticetes and odontocetes as monophyodont. It is hoped that some of the relationships among basilosaurids will become more secure as more of the anatomy of more of the species becomes known.

Beaked Whales, Overview

Ziphiidae

JAMES G. MEAD
National Museum of National History, Smithsonian Institution, Washington, DC

Beaked whales belong to the odontocete family Ziphiidae. They are medium-sized cetaceans, with adults ranging from 3 to 13 m. They are characterized by a reduced dentition, elongate rostrum, accentuated cranial vertex, and enlarged pterygoid sinuses. There are currently 20 recognized species in five genera. They are all pelagic, living in the open oceans and feeding on deep water squid and fish.

I. Classification

Family Ziphiidae

Subfamily Ziphiinae	
Berardius arnuxii	Arnoux's beaked whale
Berardius bairdii	Baird's beaked whale
Tasmacetus shepherdi	Shepherd's beaked whale
Ziphius cavirostris	Cuvier's beaked whale
Subfamily Hyperoodontinae	
Hyperoodon ampullatus	Northern bottlenose whale
Hyperoodon planifrons	Southern bottlenose whale
Indopacetus pacificus	Longman's beaked whale
Mesoplodon bahamondi	Bahamonde's beaked whale
Mesoplodon bidens	Sowerby's beaked whale
Mesoplodon bowdoini	Andrews' beaked whale
Mesoplodon carlhubbsi	Hubbs' beaked whale
Mesoplodon densirostris	Blainville's beaked whale
Mesoplodon europaeus	Gervais' beaked whale
Mesoplodon ginkgodens	Ginkgo-toothed beaked whale
Mesoplodon grayi	Gray's beaked whale
Mesoplodon hectori	Hector's beaked whale
Mesoplodon layardii	Strap-toothed whale
Mesoplodon mirus	True's beaked whale
Mesoplodon peruvianus	Pygmy beaked whale
Mesoplodon stejnegeri	Stejneger's beaked whale

II. Common Names

The common name of the family, beaked whales, refers to their pronounced rostrum or beak. The rostrum of beaked whales is, admittedly, relatively shorter than in most dolphins but relatively longer than most "whales." The origin of the English term "beaked whale" is a translation of the Norwegian *nebhval*, which means "whale with a beak." It is an extremely old Norwegian word, the origin of which is long lost to history.

Most beaked whales are encountered rarely enough that they do not have "common names" but rather "vernacular names." There seems to be a tendency toward the feeling that the Latin names that are used in science are somehow confusing and scientists will have to coin vernacular names in the language that is used by the people.

The only beaked whales that were seen on a regular basis by fishermen (and whalers) were the northern bottlenose whale (*Hyperoodon ampullatus*) and Baird's beaked whale (*Berardius bairdii*). The English name "bottlenose whale" was actually in common use, as were the Norwegian name *nebhval* or *naebhval* and the Danish and German name *dögling* or their derivatives in other northern European languages.

The name *tsuchi-kujira* or just *tsuchi* is the Japanese common name for Baird's beaked whale (*Berardius bairdii*).

III. Diagnostic Characters and Comments on Taxonomy

Living beaked whales are characterized externally by a pronounced rostrum (beak), which blends into a high forehead (or melon) without a break (Fig. 1); a pair of throat grooves; relatively small flippers with short digits and relatively long arm bones; a small triangular dorsal fin that is placed far back on the body; and lack of fluke notches. Internally they have a reduction in teeth; fusion of the bones of the rostrum and development of extremely dense rostral elements in males; expansion of the pterygoid air sinus and elimination of its lateral bony wall; and elevation of the bones associated with the nose into a bony protuberance called the vertex (Fig. 2).

It seems that the concept of the beaked whales as a separate group of cetaceans became common in the 1860s and 1870s, as Gray used the family Ziphiidae in his "Catalogue of Seals and Whales in the British Museum" (1866) as did Van Beneden and Gervais in their epic "Ostéographie des Cétacés" (1868–1879).

IV. Notable Anatomy, Physiology, and Life History

Several similarities between beaked whales and sperm whales became evident early. Partly these were due to the retention of ancestral characters and partly due to similarities in ecology. Both groups of whales feed at considerable depth and are specialized to feed on squid.

Ziphiids in general have reduced their teeth to the point that teeth in the upper jaw are vestigial or absent and teeth in the lower jaw are reduced to one or two pairs that usually erupt only in adult males. The only exception to this is Shepherd's beaked whale (*Tasmacetus shepherdi*), which has a full dentition in both jaws.

A. Externally

The pronounced rostrum results from an anterior extension of the rostral and palatal elements of the skull, the maxilla,

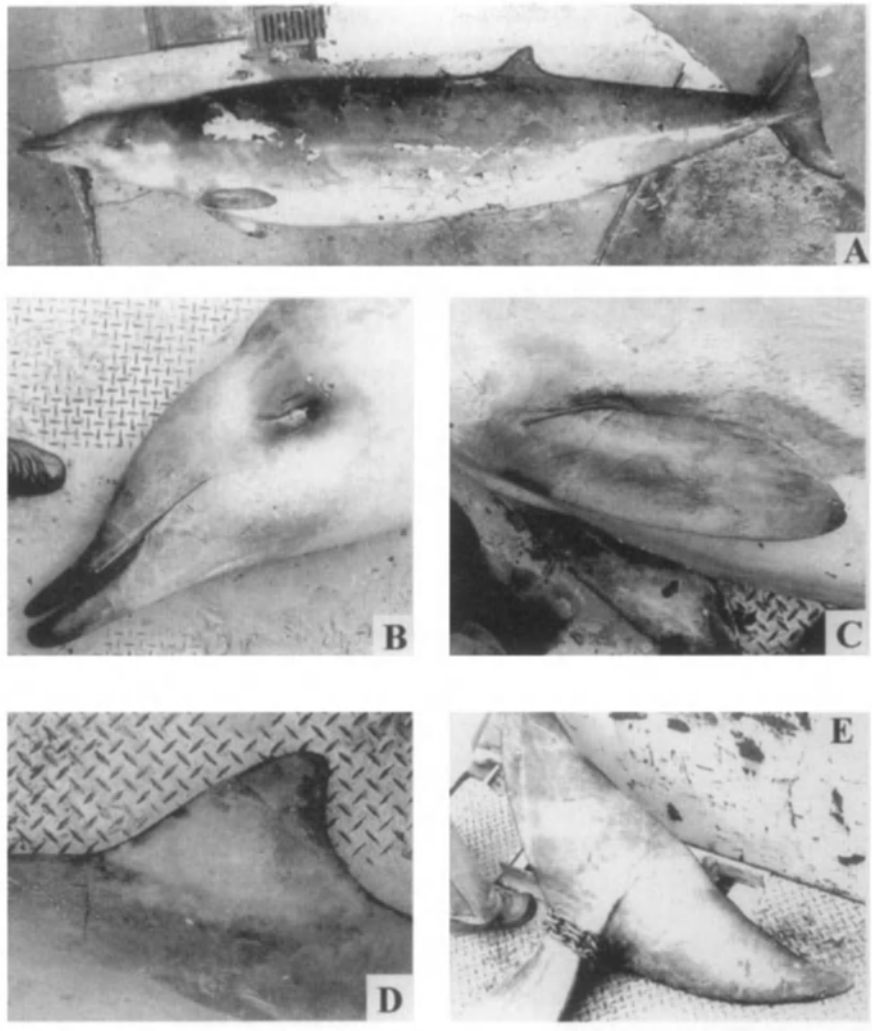

Figure 1 *Details of the external morphology of an adult male* Mesoplodon mirus *(USNM 504612). (A) Lateral view of the whole animal, (B) lateral view of head, (C) lateral view of flipper, (D) lateral view of dorsal fin, (E) oblique ventral view of flukes.*

premaxilla and vomer, coupled with a lateral compression to form a beak. Normally these bones are moderately extended in cetaceans to form a pincer-like beak, and, in fact the relative length of the rostra of some of the other toothed whales, like the river dolphins, exceeds that of beaked whales.

Beaked whales have a high forehead, which sets off the long rostrum. This forehead is composed of the soft tissue that forms the facial apparatus and the elevated cranium on which it rests. This soft tissue is responsible for sealing the nasal passages against water and modifying the emitted sound. The blowhole is crescent shaped with the horns pointing anteriorly, except in the genus *Berardius* where they point posteriorly.

The forehead merges with the rostrum without a break or groove that is characteristic of most other toothed whales. There is only one dolphin (rough-toothed dolphin, *Steno bredanensis*) that shares this character (Fig. 1B).

Beaked whales have a pair of throat grooves, which are in the shape of a "v" with its apex pointing forward. The anterior end of the throat grooves lies posterior to the symphysis of the lower jaws and anterior to the jaw joint (i.e., in the throat region). Throat grooves are present in gray whales (*Eschrichtius robustus*) and sperm whales (*Physeter macrocephalus*) but absent in all other species. They are not to be confused with ventral grooves, which stretch from the tip of the jaw back to the umbilicus in rorquals (Balaenopteridae).

Beaked whales have relatively small flippers, which are unspecialized. They consist of a relatively large forearm (radius and ulna) portion followed by a short phalangeal (finger) portion (Fig. 1C). This is also true of porpoises (Phocoenidae) and rorquals and appears to be a primitive cetacean character. Dolphins (*Delphinidae*) have an entirely different flipper shape, which tends to be falcate (hook shaped) and is the result of a lengthening of the phalangeal portion.

The dorsal fin is small and triangular instead of falcate and is situated on the posterior third of the body. The dorsal fin is usually placed over the anus at the junction of the abdomen and tail.

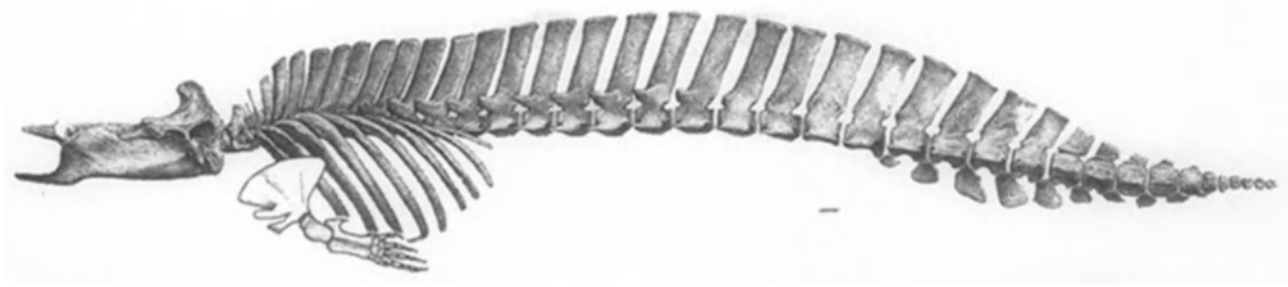

Figure 2 *Skeleton of an adult male* Mesoplodon densirostris *in the Australian Museum, Sydney (after Van Beneden and Gervais, 1868–1879). Forelimb and pelvic rudiment are from an adult male of the same species in the American Museum of Natural History (after Raven, 1942).*

The position of the dorsal fin in beaked whales correlates with a relatively long thorax and abdomen and short tail (Fig. 1D).

Beaked whales normally do not have fluke notches, and the trailing edge of the flukes is unbroken. Embryologically, the fluke notch is formed when the trailing edge of the flukes moves back beyond the end of the caudal vertebrae. Caudal vertebrae anchor the midline of the trailing edge, resulting in a notch in other whales (Fig. 1E).

B. Internally

The reduction in TEETH has proceeded to the point where all functional teeth are lost in females and immature males, and dentition is only represented by a single pair of teeth in the lower jaw of males. Females and immature males have a pair of vestigial teeth. The dentition seems to be only useful in male aggression. The two exceptions to this are the whales of the genus *Berardius*, which have two pairs of mandibular teeth, and *Tasmacetus*, which has a normal odontocete dentition in both the upper and the lower jaws. In *Tasmacetus*, the apical pair of mandibular teeth is enlarged, which strengthens the hypothesis that the single pair of teeth in all other ziphiids represents the apical pair. A row of vestigial teeth is sometimes present in the gums of both the upper and the lower jaws of some beaked whales, particularly *Mesoplodon grayi* and *Ziphius*.

Rostral fusion in some males takes place with increasing age. Because age estimation in beaked whales has been difficult, we are not sure of the age in which this process is active. The mesorostral canal is filled in by dorsal expansion of the vomer and the individual rostral elements fuse together. This is accompanied by an increase in density of the rostrum. The density of the core of the rostrum has been measured at 2.4 g/cc in a male of *Mesoplodon carlhubbsi* and 2.6 g/cc in a male *M. densirostris*.

The pterygoid air sinus has become enlarged in the ziphiids. It still is confined to the pterygoid bone but has become relatively larger and lost its lateral wall. The anterior sinus is not developed in ziphiids.

The vertex of the SKULL has been expanded both laterally and vertically beyond the state in all other odontocetes. The vertex is composed of the posterodorsal ends of the maxilla and premaxilla, the nasals, and the medial ends of the frontals. The dorsal tip of the vertex has expanded laterally and anteriorly like a mushroom. This region is deeply involved with sound production and modification.

V. Fossil Record

Ziphiids first appeared in the fossil record in the early Miocene (de Muizon, 1991). These early ziphiids had long rostra, full dentitions with the first mandibular tooth often hypertrophied, an elevated synvertex with a premaxillary crest, strong development of the pterygoid sinus with a reduction of the lateral wall of the pterygoid and an increase in the hamular process, and an auditory region of the skull that had minimal fenestration.

By the middle Miocene ziphiids were abundant. This was a period of maximum diversity of the entire order Cetacea and certainly was for the ziphiids. However, with all of this diversity, the origin of the modern genera is still in doubt.

There are about 14 genera of fossils currently recognized as ziphiids. Of these 14 genera there are at least 28 species that are based solely on rostral fragments. Critical work has demonstrated that 2 genera are based on nondiagnostic fragments and have been regarded as *nomina dubia*. With further study, particularly of the genera that are based on rostral fragments, there is bound to be a lot of demonstrated synonymy.

Muizon (1991) classified the Ziphiidae into three subfamilies: the Hyperoodontinae, which contains *Hyperoodon* and *Mesoplodon;* and Ziphiinae, which contains *Ziphius*, *Berardius*, *Tasmacetus*, and the fossil genera *Choneziphius*, *Ziphirostrum*, *Cetorhynchus*, and *Ninoziphius;* and the Squaloziphiinae, which currently contains only *Squaloziphius*. Figure 3 shows a cladogram of Ziphiidae.

VI. Interactions with Humans

Because of their pelagic habits and general lack of concentrated populations, ziphiids have not had much contact with humans. The only fisheries that had ziphiids as a target species were the bottlenose whale fishery in the North Atlantic and the *Berardius* fishery in the North Pacific.

The bottlenose whale was hunted from the middle of the 19th century by Norwegian and British whalers. Because the catches of the bottlenose whale were part of a multispecies small whale fishery, where catches of one species may serve to subsidize catches of another when the population of the second species has fallen to such a point that fishing of it would not be economical, the population was overexploited and became protected by the INTERNATIONAL WHALING COMMISSION in the late 1970s.

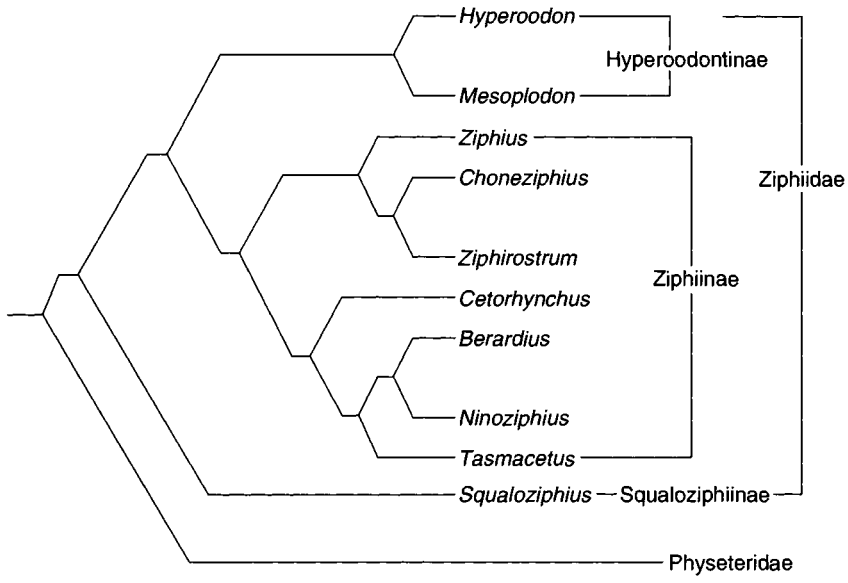

Figure 3 *Cladogram of Ziphiidae (after de Muizon, 1991).* Indopacetus *is included in* Mesoplodon.

Berardius is hunted primarily by the Japanese, who have fished it out of shore stations on the northeast coast of Japan since at least the 17th century. It was taken incidentally by other nations in the process of whaling for other species. Because the Japanese market was local to the whaling stations and would consume other species of ziphiids, they formerly sometimes took *Ziphius cavirostris* and the occasional *Mesoplodon*.

In the Southern Hemisphere, whalers rarely took the southern forms of *Berardius* (*B. arnuxii*) and *Hyperoodon* (*H. planifrons*). There were no fisheries based on them as the target species.

Ziphiids are moderately large, difficult to find and catch, and have habits (deep diving) that do not suit them to captivity. The occasional live strandings are sometimes maintained in CAPTIVITY in hopes of rehabilitating them and learning something of their behavior. The rehabilitation attempts have never been successful and the animals always died. One *Mesoplodon* calf that stranded in California in 1989 lived 25 days in an aquarium.

Bearded Seal

Erignathus barbatus

KIT M. KOVACS
Norwegian Polar Institute, Tromsø

I. Description and Distribution

The bearded seal is a large, arctic phocid. Adults are 2–2.5 m long and are gray-brown (Fig. 1). Weight varies markedly on an annual cycle, but an average would be 250–300 kg. Females, which are somewhat larger than males,

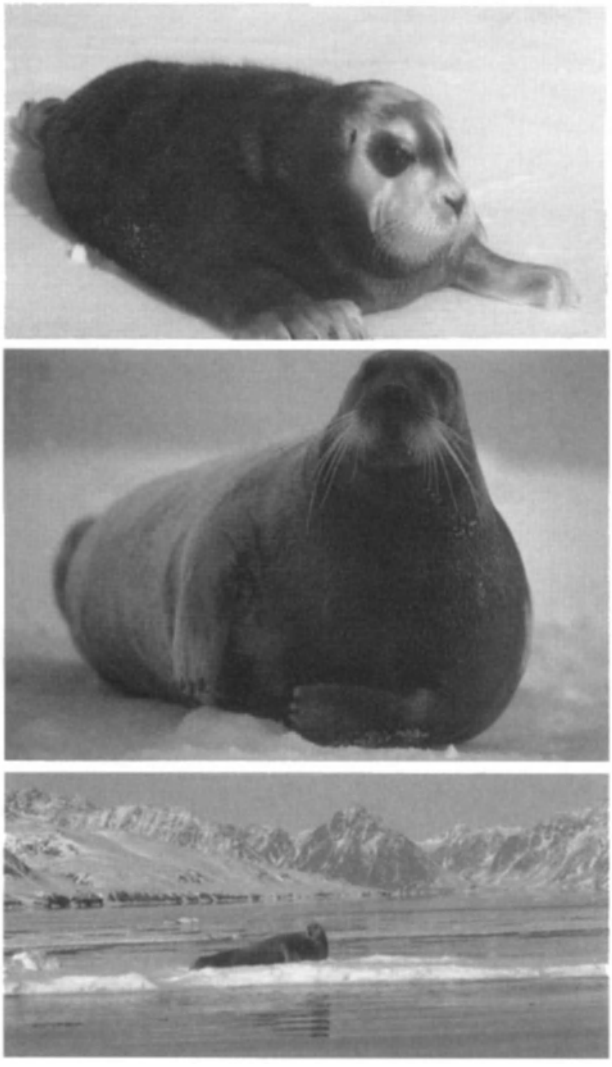

Figure 1 *Bearded seal pup, 2 days old (top). Adult male bearded seal with rust-colored face (middle). An adult bearded seal in a typical habitat (bottom).*

can weigh in excess of 425 kg in the spring. Bearded seals often have irregular light-colored patches and can, in some geographic regions, also have rust-red faces and fore flippers. The rust color comes from contact with ferrous compounds in the bottom sediments that adhere to the surface of the hair and then oxidize when brought to the surface. Pups are approximately 1.3 m long at birth and weigh an average of 33 kg. They are born partially molted but usually still bear a significant quantity of fuzzy gray-blue lanugo in combination with a second darker-gray smooth coat. Their faces have white cheek patches and white eyebrow spots, which give them a "bandit" or "teddy-bear" look (Fig. 1). Yearlings look very similar to pups, but the facial patterns are less distinct and they often have small, distinct dark spots on their bellies. Similar to adults, young animals often have patches of white here and there. Bearded seals have several distinctive physical features. Their body shape is very rectangular. Their heads appear to be small compared to their body size. They have very square-shaped fore flippers that bear very strong claws; Inuit people in the Canadian Arctic refer to this seal as "square flippers" because of the shape of their front flippers. They also have extremely elaborate, smooth, facial whiskers that tend to curl when dry; this trait gives them their other common name: bearded seal. Females have four mammary glands (a characteristic shared with the monk seals, *Monachus* spp.).

Bearded seals have a patchy distribution throughout much of the Arctic and sub-Arctic (Fig. 2). Their preferred habitat is drifting pack ice in areas over shallow water shelves. They are often found in coastal areas. Some populations are thought to be resident throughout the year, whereas others follow the retraction of the pack ice northward during the summer and the advance southward once again in the late fall and winter. They can maintain holes in relatively thin ice but avoid heavy-ice areas. During winter they concentrate in areas that contain polynyas, in areas where leads in the ice tend to be a regular feature, or along the outside of pack-ice areas. Juvenile animals wander quite broadly and can be found far south of the normal adult range. A neonate equipped with a satellite tag in Svalbard traveled south to Jan Mayen and then almost to the Greenland coast within the month following weaning, when the tag unfortunately ceased to transmit.

II. Behavior and Ecology

Bearded seals are largely solitary, although it is not unusual to see them hauled out together in small groups along leads or at holes in the spring or early summer. It is quite unusual to see a bearded seal on land, as they prefer to haul out on moving ice. They are rarely more than a body length from the water, and almost always face toward the water. However, they are not wary in a general sense; in some areas such as Svalbard, Norway, they are very tame and can be approached by humans to within meters by boat without reaction.

The time of breeding appears to vary somewhat geographically, with peaks occurring sometime between late March and mid-May, depending on the locality. Females give birth in a solitary fashion, on small drifting floes in areas of shallow water. The lanugo that is shed prior to birth is passed in the form of small, compact disks along with the afterbirth. Pups are born with a thin layer of subcutaneous BLUBBER, which is thought to be an adaptation to entering the water shortly after birth. Bearded seal pups swim with their mothers within hours following their births. This precocial entry into the sea is likely a mechanism to avoid polar bear PREDATION. Neonatal swimming skills develop quickly in this species, and pups can dive to depths > 90 m and remain submerged for periods in excess of 5 min when they are only a few weeks old. They spend approximately half of their time in the water during the nursing period, which lasts a total of 18–24 days and commence foraging on solid food while still accompanied by their mother. Female bearded seals spend little time on the surface with their pups, beyond that which is necessary for nursing. Most of the time they attend the pups from the water next to

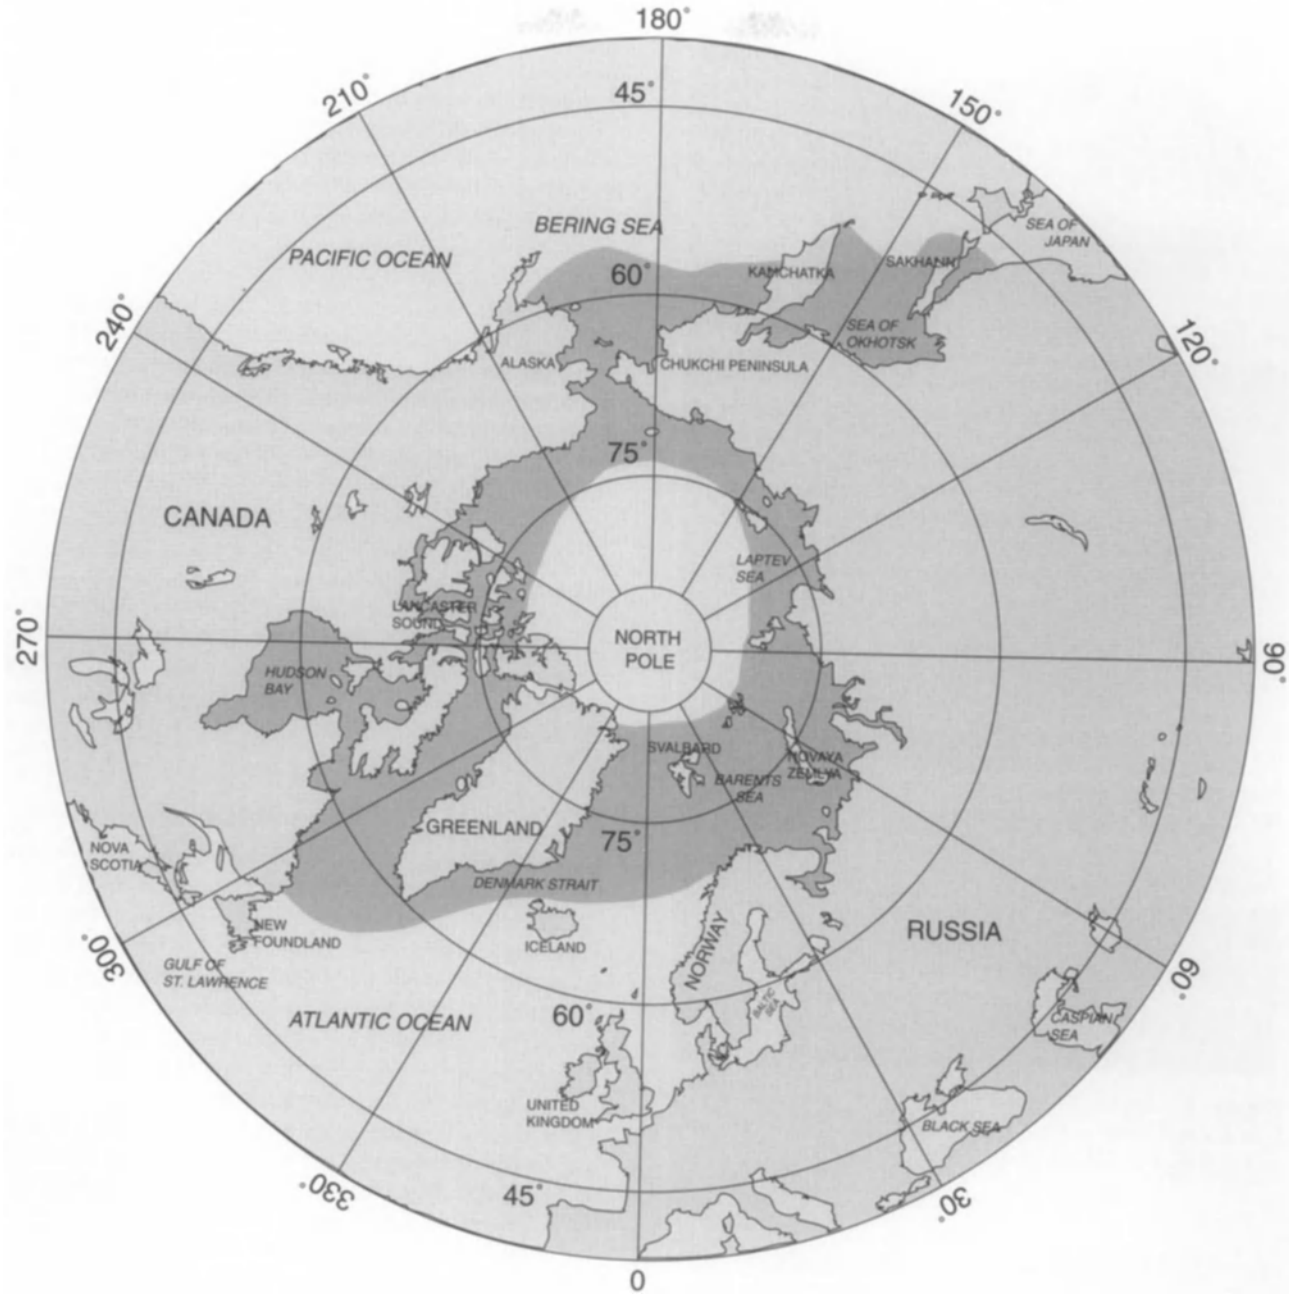

Figure 2 *Map showing the circumpolar, Arctic distribution of bearded seals (dark shaded area).*

the floe on which the pup is resting. Females do leave their pups unattended for periods to forage during the lactation period. Mother–pup pairs tend to remain in an area for some days at a time, but can also move tens of kilometers from one day to the next. Pups grow quickly during the nursing period, gaining about 3.3 kg per day while drinking > 7.5 liters of milk per day. The fat content of the milk is quite stable through lactation, at about 50%. Bearded seals pups have leaner bodies at the time of weaning than less active phocid pups but still have significant blubber stores and a body composition that is about one-third fat. Pups are about 110 kg when they are weaned. Weaning does not appear to be as abrupt as it is in most phocid species.

MATING takes place around the time that females leave their offspring. Male bearded seals sing underwater to attract females and they also fight with other males during the breeding season. Their songs are a series of complex, downwardly spiraling trills that can be heard over tens of kilometers in quiet weather. The eerie yet melodious song is well known throughout Arctic regions; it is a sign of spring. Little is known re-

garding the specifics of mating behavior of this species because pairing takes place in the water.

Bearded seals seem to have quite a diffuse molting period and seem to shed hair almost constantly. However, there does appear to be a concentrated period of hair loss and renewal during the early summer. During this period bearded seals like to remain hauled out. Relatively large concentrations of animals can occur at this time because of the limited amount of ice available in some areas of the Arctic by this time in June.

Female bearded seals reach sexual maturity when they are about 5 years old, whereas males are normally 6 or 7. Bearded seals live 20–25 years.

Bearded seals tend to be shallow divers. They are for the most part benthic feeders. They likely use their whiskers to help them find food in soft substrates. Most diving is to depths less than 100 m, although adults have been recorded to dive to almost 300 m. Pups a few months old hold the current depth record for the species, which is > 488 m. Most dives are less than 10 min in duration, although they can dive for up to 20–25 min. They feed on polar cod (*Boreogadus saida*), sculpins (*Cottidae*), rough dabs (*Hippoglossoides platessoides*), and eelblennies (*Lumpenus medius*). Bearded seals also eat a variety of invertebrates, including spider crab (*Hyas araneus*), shrimps, a variety of molluscs, cephalopods, polychaete worms, and amphipods.

Polar bears (*Ursus maritimus*) and walruses (*Odobenus rosmarus*) are bearded seal predators. Killer whales (*Orcinus orca*) and Greenland sharks (*Somniosus microcephalus*) may also take bearded seals, particularly pups and juveniles.

III. Exploitation and Conservation Status

Bearded seals are an important subsistence resource in the Arctic. A few thousand animals are harvested annually for use as food, dog food, and for their thick leather, which is important for various traditional articles of clothing in Alaska, the Canadian Arctic, and in Greenland. Russia is the only country that has had a commercial scale harvest of bearded seals. Soviet ships took catches that exceeded 10,000 animals in some years during the 1950s and 1960s. Quotas were introduced to limit the harvests of the declining populations in the Okhotsk and Bering seas, and the catch dropped to a few thousand seals annually through the 1970s and 1980s. This hunt provided food for people and dogs and also fur-farm animal feed. Sinking losses are a serious problem when hunting bearded seals. During much of the year they sink when shot in open water or too close to ice edges; sinking loss is estimated to be 50%.

The global population of bearded seals cannot be accurately assessed. However, it is likely that this species numbers in the hundreds of thousands in the Arctic. Regional populations that are subjected to harvests can easily be depleted because densities are naturally low and most populations are quite sedentary.

Behavior, Overview

PETER L. TYACK
Woods Hole Oceanographic Institution, Massachusetts

Marine mammalogists often divide behavioral research into categories defined by mode of study: "acoustics" is studied by recording underwater sounds with a hydrophone, "behavior" is often informally defined as that which can be seen by an observer watching animals, and "diving" is often studied by attaching tags to animals. This method-oriented view of behavior may be convenient for sorting different research traditions, but it obscures the integrated whole of behavior as it has been shaped by evolution. Each method yields its own view of behavior, but no one view alone can provide a complete picture.

Most behavioral ecologists divide behavior along functional lines, i.e., what is the problem the behavior has evolved to solve (Alcock, 1998)? The following is a short list of such problems:

- Foraging behavior: how to find, select, and process prey
- Predator avoidance or defense: the flip side of foraging from the prey's point of view
- Dispersal and migration
- Competition and agonistic behavior
- Sexual behavior: how to find, court, and choose mates
- Parental behavior
- Social behavior and social relationships

This functional taxonomy of behavior is mirrored by Bradbury and Vehrencamp's (1998) functional analysis of animal communication. A receiver can often be viewed as paying attention to a signal to answer a question related to one of these behavioral problems. When the receiver detects one signal out of a larger signal set, the signal can potentially help the receiver to reduce uncertainty about the correct answer. Bradbury and Vehrencamp (1998) suggest that a receiver's questions can be divided into three categories: sender identity, sender location, and behavioral context. Depending on the problem, the receiver may be interested in different levels of recognition of

the signaler: species, group, sex, age, or individual. Receivers almost always need to know something about the location of the signaler: how far away is it? Is it within the receiver's territory? Is it approaching or moving away? The behavioral contexts of animal communication bear a striking resemblance to the functional behavioral problems listed previously: conflict resolution, territory defense, sexual interactions, parent–offspring interactions, social integration, and environmental contexts such as those related to prey and predators. This article discusses marine mammal examples for each of these basic problems in the behavioral ecology of all animal species, with special emphasis on how the marine environment may affect adaptations of marine mammals.

I. Foraging Behavior: How to Find, Select, and Process Prey

The earliest studies of foraging in marine mammals focused on the stomach contents of dead animals in order to define what kinds of organisms were in the DIET of marine mammals. The best that observers could do in early field studies of living marine mammals was to identify behavior associated with feeding, where feeding was linked to observation of prey at the surface or chases, and so on. However, these observations do not do justice to the complex process by which animals find, select, and handle their prey. Increased efforts in foraging theory to identify the kinds of decisions faced by a foraging individual have focused attention on a more detailed view of foraging, and new techniques such as time-depth recorders have improved our ability to collect the required data. This section discusses the various phases of foraging.

Marine mammals use every sensory modality available to find and select their prey. The optimal senses for solving a particular foraging problem depend on the setting. For example, vision is an excellent distance sense in air, but has a limited range underwater. Even though polar bears (*Ursus maritimus*) are classed as marine mammals, they often hunt their prey in air and may use vision in air to search for their pinniped prey. Many seals and dolphins chase fish prey close enough to the surface to search for images of fish reflected from sunlight. Biologists have used video recorders attached to seals to capture images of fish as seals hunt. In many coastal areas, seals can see fish at ranges of 10 m or so. Deep-diving seals such as elephant seals (*Mirounga* spp.) have eyes specially adapted to the wavelengths and low light levels of the deep sea. Many deep-sea organisms have light-producing organs, and researchers have speculated that marine mammals may use vision to find bioluminescent organisms in the dark.

As terrestrial mammals, we humans are accustomed to thinking of vision as the best distance sense, but sound carries much better underwater than light. Some marine mammals have developed sophisticated adaptations to use sound for finding prey. Perhaps the best-known example is the sonar of dolphins. Dolphins and most toothed whales have an auditory system that is specialized for high frequencies, and they can produce a directional beam of intense high-frequency pulses of sound. Most toothed whales echolocate by producing a click and then listening for echoes from surrounding targets. When they are in a search mode, they may produce a slow series of clicks, listening for echoes. Most cetaceans wait until they hear an echo to produce another click; in search mode, this means that the interval between clicks usually is greater than the maximum expected range to a target. Once they detect an echo, they may adjust their click rate to match the expected range to the target. If they click soon after they hear an echo, then the interval between clicks can give an indication of target range. Sound travels underwater at about 1500 m/sec. If an animal waits for 1 sec for the click to travel out to a target and then return, the target could be as far as 750 m away. Dolphins can detect a target as small as a 2.5-cm sphere at a range of >100 m. Once the animal detects the target, it then knows when to expect the echo, and it can set a click rate for that target range. Dolphins may take several tens of milliseconds to process information from a returning echo, and the click rate during the target-tracking mode usually equals the round trip travel time plus this processing time. When foraging, many toothed whales produce series of these clicks. For example, foraging narwhals (*Monodon monoceros*) make a regular series of slow clicks as they dive, but these slow clicks are interrupted by rapid and accelerating bursts of pulses. One hypothesis for this behavior is that slow clicks represent a search phase of the sonar and that when a narwhal detects a potential target, it switches to a target-tracking mode. As the narwhal closes on the target, the round trip travel time for the echo would decrease, which might explain why the narwhal produces an accelerating series of clicks. As with echolocating bats, these rapid accelerating click trains probably indicate detection and pursuit of prey.

While echolocation has been well studied with captive dolphins and artificial targets, we actually know very little about how odontocetes use sound in foraging. When wild dolphins (*Tursiops truncatus*) from inshore waters near Sarasota, Florida, are feeding, they produce echolocation clicks at very low rates. Echolocation has been studied in wild dolphins either with an acoustic recording tag or by following them with a small boat and using a towed hydrophone to listen to the sounds produced by the dolphins. Dolphins in Sarasota had an overall average click rate of 0.39 click trains/min while foraging and a rate of 0.10 click trains/min while not foraging. Clicks trains lasted about 2 sec and occurred every 200–450 sec on average. Dolphins had different modes of foraging, and different senses were used in the different feeding modes. Dolphins had the highest click rates and appeared to rely more upon echolocation when they were feeding on fish hiding in seagrass. In contrast, when dolphins were feeding in clear water over sand, they seldom clicked and appeared to rely primarily on VISION.

Dolphins and toothed whales are hunters who chase down individual prey items. Many species feed on highly mobile prey such as schooling fish. When a dolphin charges into a fish school, the fish usually disperse, and this can make it less efficient to find and chase down the remaining fish. Dolphins in many settings are reported to coordinate their feeding so that some dolphins keep the fish in a tight school as other dolphins feed. Toothed whales that disperse to feed on deep prey also usually feed in groups. While members of a group of whales such as sperm whales (*Physeter macrocephalus*) often disperse at depth, they usually converge as they surface. This pattern may help them find the densest concentrations of deep prey. When sperm whales dive to

forage, they produce click sounds at rates of 0.5–2 clicks/sec, and they may also produce fast and accelerating series of clicks while feeding at depth. Most marine mammalogists have assumed that when sperm whales feed in the dark cold waters hundreds of meters below the sea surface, they use these clicks to detect their squid prey. This is a plausible hypothesis, but because we have no data on how sperm whales detect, pursue, and capture their prey, this is an area that requires further research.

Baleen whales have evolved to capture entire patches of prey in one mouthful. Balaenid whales, such as right (*Eubalaena* spp.) and bowhead whales (*Balaena mysticetus*), are specialized to feed on calanoid crustaceans. When balaenid whales feed, they swim through the prey patch with an open mouth. Because their baleen is very long and their head has a large cross-sectional area, they catch their prey by engulfing them in the water that flows into the mouth and out through the BALEEN. The basic problem faced by a feeding balaenid whale is to find a dense enough patch of prey to pay for the time and additional expense of swimming in the open-mouth foraging mode. Their prey move slowly enough that the feeding of balaenid whales is more like grazing then hunting. At times, balaenids coordinate their feeding by swimming in a staggered or "u shape" of up to 13 whales side by side. It is believed that such coordinated feeding keeps prey from escaping to the side, and may therefore more effectively "herd" prey towards each whale mouth.

Balaenopterid whales also feed on crustaceans, but their euphausiid prey are faster and more evasive than calanoid crustaceans. Balaenopterids also may capture schools of baitfish such as capelin, anchovy, sand lance, or even herring. These prey are more mobile than crustaceans, and balaenopterids have evolved a feeding mode that allows them to trap mobile prey. Balaenopterids have accordion-like pleats in the lower jaw, which can expand rapidly. When a balaenopterid feeds, it lunges while opening its mouth, forcing hundreds of gallons of prey and water into the mouth as the pleats expand. The whale then quickly closes its mouth, trapping the prey. The pleats then slowly contract, forcing the water through the baleen and leaving the prey behind. As with toothed whales, when balaenopterids such as humpback whales (*Megaptera novaeangliae*) feed on the most mobile schooling prey, such as herring, they may feed in coordinated groups. Perhaps the most striking reports concern a group of half a dozen or more female humpback whales who associated together each summer for several years in Southeast Alaska. Each individual played a specific role in prey capture, and their movements appeared to be coordinated with a regular series of vocalizations.

Marine mammals have evolved several different ways to feed on benthic prey that hides submerged in the sediment on the seafloor. Some bottlenose dolphins have been observed to echolocate on small sand dabs buried in the sand. The mustache of the walrus (*Odobenus rosmarus*) is exquisitely sensitive to touch, and walruses use the vibrissae in their mustache to detect prey in the sediment. Trained walruses have demonstrated remarkable abilities to use this mustache to determine the shape of objects, and presumably wild walruses use this ability to identify their favored prey within the sediment. Gray whales (*Eschrichtius robustus*) feed on benthic organisms by sucking mud and prey into the side of their mouth and then straining out the prey with their baleen. Gray whales make distinctive pits, measuring about 1 m wide by up to 3 m long and about one-half meter deep, in the seafloor when they feed in this way and these pits are big enough to be detected by sonar on surface ships.

Most marine mammals just swallow their prey whole, but some species face problems in handling their prey. Dolphins feeding on prey such as catfish with sharp spines may need to learn how to snap off the head and spines before they eat the rest of the fish. False killer whales (*Pseudorca crassidens*) measuring perhaps 3 m in length can capture a large mahi-mahi nearly half their size. It has been reported that one false killer whale may hold the fish while others rip off flesh. The most impressive prey handling among marine mammals involves the sea otter (*Enhydra lutris*), which feeds on shellfish such as abalone (*Haliotis* spp.) and sea urchins. Because these prey are too large or too strong for the otter to break the shell by biting it, most otters use a stone as a tool to open the shells. The sea otter will dive to get a shell, often carrying its stone tool in the axilla. When the otter surfaces, it lies stomach up with the stone on its stomach. It then uses the stone either as a hammer or as an anvil, smashing the shell open on the stone and then eating the flesh. It must be awkward to carry this stone while diving to feed, and some otters have simplified this by using a bottle for the same task. When the otter dives, it can leave the bottle floating on the surface and can then use it when it surfaces with shellfish.

II. Avoiding Predators and Defense from Predators

Many marine mammals are top predators and historically may not have faced a heavy predation pressure. The primary predators for pelagic marine mammals over evolutionary time are the killer whale (*Orcinus orca*) and sharks. However, humans have in the last few centuries been extremely effective predators of marine mammals, driving some species such as the Steller's sea cow (*Hydrodamalis gigas*) to extinction. Seals on ice face the risk of predation from polar bears, and seals hauled out on beaches, especially pups, are at risk from other pinnipeds and terrestrial predators such as foxes. Seals on land are less mobile than at sea and appear to be at a higher risk of predation, for they will usually respond to the approach of a terrestrial predator by entering the water.

The great whales such as baleen and sperm whales are so large that their main predator is the killer whale. Killer whales live in stable groups. They attack large whales in groups and appear to coordinate their attacks in much the same way as a pride of lions or African wild dogs will attack a herd of ungulates, isolate an individual, and then hold it down to kill it. Baleen and sperm whales use their flukes as a weapon during such an attack, lashing them sideways through the water. After they have been detected, most small odontocetes appear to rely on speed to escape killer whales, whereas some pinnipeds may hide from them, either on land or on the seafloor. Many cetaceans fall silent when a killer whale is detected nearby.

Early whalers had a predator's view of their marine mammal prey, and these observations make up an unusual body of data on predator defense in some species. While baleen whales often travel in groups, there is little sign of social defense from

predators. The young calves of baleen whales may be more vulnerable to predation than adults, but females with young are less likely to be seen in groups, suggesting that they may disperse to reduce the chance a predator will detect them. Sperm whales, however, appear to have a well-developed social defense from dangerous predators such as killer whales and human whalers. Sperm whale calves are born into groups of about 10 adult females with young. Because newborn calves cannot dive deep enough to follow their mothers for their 40- to 50-min foraging dives, they remain nearer the surface when the adults feed. The adults desynchronize their dives, however, so that there is less time that young calves are unattended by an adult. If a predator attacks the group, calves or wounded animals in the group will be surrounded by the rest of the adults. Most adults will face in toward the animal needing protection and will lash their tails facing outside. This must have been a formidable defense against killer whales, but was less successful with human whalers. Whalers knew how predictable this behavior was and would often intentionally injure one animal and leave it. They then could slowly kill each adult attending the injured animal, knowing that adults would be unlikely to abandon an injured group member.

The first step in lowering the risk of PREDATION is to avoid detection. Some seals alter their foraging behavior apparently to avoid visual detection by predators. Female Galápagos fur seals (*Arctocephalus galapagoensis*) are less likely to make their normal foraging trips when the moon is full. It has been suggested that this avoids the risk that a predator will see them in the moonlight. Because most small cetaceans have little chance to defend themselves from killer whales, they must emphasize strategies to avoid detection by these predators. Dusky dolphins, *Lagenorhynchus obscurus*, mill in the surf zone as killer whales pass by offshore. They will even hide in tidal lagoons and, at times, become stranded in these lagoons until the next tide. Baleen whales also have strategies to avoid detection by killer whales. For example, gray whales that were exposed to experimental playback of the sounds of killer whales fled into shallow water. The surf zone and kelp beds may be particularly good places to hide from an echolocating predator because they absorb and reflect sound, making echolocation more difficult. There is some evidence that killer whales may even have evolved countermeasures to these predator-avoidance strategies. There are two sympatric populations of killer whales in the inshore waters of the Pacific Northwest. One population, called residents, feeds primarily on fish; the other population, called transients, feeds primarily on marine mammals. When residents feed on salmon, a fish with poor hearing, the killer whales make regular series of loud clicks. When transients feed on acoustically sensitive marine mammals, such as porpoises, dolphins, or seals, they have a much more stealthy pattern of echolocation. They produce fewer clicks, and those clicks that are produced are fainter and are produced with an erratic timing. These features appear to be designed to make marine mammal prey less likely to detect and avoid the killer whale.

Cetaceans are also subject to parasitism from animals that bite tissue without causing serious injury. In the tropics, many dolphins are subject to attack from the cookie cutter shark (*Icistius brasiliensis*), which takes bites of skin and blubber about 3 to 5 cm in diameter. Right whales (*Eubalaena australis*) in coastal bays in Argentina are subject to attack from seagulls, which peck chunks of skin and blubber from the back of a whale floating at the surface. While this can evoke a strong behavioral reaction from the whale, right whales do not seem to have an effective defense from this attack, which may be made worse by the growth of seagull populations in areas with human settlements.

Evidence in several cetacean species shows that when an animal has been injured, other members of the group may support them for hours or days. Because marine mammals must breathe air, if they cannot surface on their own, they are at great risk of drowning. This caregiving behavior may cost the caregivers, but at potential benefit to the incapacitated member of the group.

III. Migration and Orientation

Most marine mammals are excellent swimmers, and many species make annual MIGRATIONS of thousands of kilometers. Most baleen whales have an annual migratory cycle that affects many aspects of their life. These whales are adapted to take advantage of a burst of productivity in polar waters during the summer. Baleen whales store enough energy reserves during their intensive summer feeding season to last for most of the year, and this annual feast/fast cycle helps to select for large size. A humpback whale that is born in the winter in a tropical breeding ground near 20° of latitude will typically migrate in the spring to summer feeding grounds in polar waters near 40–60° of latitude. Humpbacks have traditional FEEDING grounds and an individual will often visit specific banks or inshore feeding areas of scales of tens of kilometers. Dolphins on both coasts of the United States also show annual migrations of 1000 km or more. Off the east coast of the United States, harbor porpoises (*Phocoena phocoena*) and bottlenose dolphins tend to move north in summer and south in winter. It is not known whether the colder temperatures in the north during winter are more important for this seasonal migration than are seasonal changes in prey distribution. Some pinnipeds also have annual migrations of thousands of kilometers. For example, northern elephant seals (*Mirounga angustirostris*) that breed and calve near San Francisco may migrate as far as the Aleutian Islands to feed. Both males and females swim north after the breeding season, following the California Current. Some male elephant seals feed along ocean fronts on the boundary of the Alaska Stream. Very little is known about how marine mammals orient and navigate during migration, and even less is known about how they find oceanographic features such as fronts.

Other species have more limited home ranges over the year. The home ranges of sea otters may be limited to 1–17 km of coastline. Sea otters show strong fidelity to their home range. When 139 sea otters were flown 200 km to an offshore island as part of a reintroduction program, most of the otters left and at least 31 managed to return to the area where they had been captured. Bottlenose dolphins in the inshore waters of Sarasota, Florida, tend to be sighted within a home range of 125 km^2. "Resident" killer whales in the inshore waters of Puget Sound have seasonal ranges limited to an area several tens of kilometers by about 100 km. Even nonmigratory species can be

highly mobile. For example, resident killer whales will often swim 100 km or more in a day. Bottlenose dolphins (*Tursiops truncatus*) and sea otters may suddenly leave their home ranges and swim 100 km away from the normal range.

IV. Competition and Agonistic Behavior

When animals are competing for the same resource, they may fight for access. Among animals that exploit a specific substrate, this competition may be for territory. This kind of territorial defense has been well described for many pinnipeds during the breeding season. Female pinnipeds haul out onto beaches to give birth, and many species mate on land as well. This concentration of females creates a valuable resource for males. Males in many species will defend an area of beach from other males and may attempt to monopolize opportunities to mate with females there. For animals that live in the open ocean, resources are not likely to be as tied to a particular location, but rather will move. Animals in this setting are more likely to defend a particular resource at one time than to defend a patch of real estate. For example, a male humpback whale will not defend a specific location during the breeding time, but a male escorting a female will fight other males to limit their access to the female.

This pattern of males competing for access to females is common among mammals and leads to behavioral and morphological adaptations. Males in these species are often larger than females. Some behaviors appear to function to increase the apparent size of a male, and may function as visual displays. For example, male humpback whales competing for access to females may lunge with their jaws open, expanding the pleated area under the lower jaw with water. Several observers have suggested this may function to increase the apparent size of a competitor. Males may have larger weapons such as teeth or tusks than females. This is particularly striking in beaked whales. In most beaked whale species, the teeth may not erupt at all in females, whereas one or two pairs of teeth erupt in the lower jaw of males at about the time of sexual maturity. Males have scarring patterns, suggesting that these "battle teeth" are used in fights. Males may also have protection such as areas of toughened skin. Male elephant seals, for example, often strike one another on the chest, and this area has thickened and hardened skin.

Fighting often involves a gradually escalating series of threats and responses. This kind of escalated display has been hypothesized for bottlenose dolphins in captivity. The earliest stages of a threat may involve one dolphin directing pulsed sounds toward another. The threat may escalate if the dolphin produces an open-mouth threat display while emitting distinctive bursts of pulses. The longer in duration or louder in sound intensity the pulses are, the stronger the threat may be. As another step in escalation, the animal may accentuate this display with abrupt vertical head movements. One of the most intense threat displays in dolphins is called the jaw clap. A dolphin starts the jaw clap display with an open mouth. The jaw clap consists of an abrupt closure of the gaping jaw, accompanied by an intense pulsed sound. Many of the agonistic visual displays used by bottlenose dolphins are related to movements used to inflict injury. For example, the open-mouth display looks like the first step in preparing to bite.

Some animals live in situations where they interact repeatedly with the same individuals over and over again. In this setting, animals may develop a predictable hierarchy of who wins and loses in agonistic interactions. Male elephant seals establish a dominance hierarchy on the breeding beaches. The pace of competition is highest before the females appear on the beach. When males are competing using territory or dominance for access to females, they often sort out their competitive relations before the peak of the mating season. Dominance relations have also been studied in captive bottlenose dolphins (*Tursiops truncatus*). The most obvious competitive behaviors are violent fights in which each opponent responds to aggression with an aggressive response. This is not as useful for determining winners or losers as observation of more subtle submissive behaviors. A fight in which each opponent produces aggressive behaviors with no submission does not have an obvious winner or loser, but an animal can be identified as a loser of an interaction if it responds to a neutral or aggressive behavior with a submissive one. Systematic observations of winners and losers in dyadic agonistic interactions reveal that adult males are dominant over adult females. The rate of agonistic interactions is higher in males than in females. The low rate of female agonism means that dominance is rarely contested among females, and female dominance can be stable over years. Two male dolphins in a pool reversed dominance status several times over the years of study. Male dominance relations were characterized by periods of relatively low agonism interspersed with periods of high rates of agonism when one male challenged the other. Little is known about dominance relations among wild cetaceans, but because individuals in many species interact repeatedly with the same conspecifics and can recognize different individuals, dominance relations are likely to be important.

V. Courtship and Sexual Behavior

Charles Darwin made a distinction between features selected to improve chances of mating and features selected for survival. He called selection for mating sexual selection to discriminate it from natural selection. Darwin defined two kinds of sexual selection: intersexual and intrasexual. Intersexual selection can increase the likelihood that an animal will be chosen by a potential mate; intrasexual selection can increase the likelihood that an animal will outcompete a conspecific of the same sex for fertilization of a member of the opposite sex. More recent reviews have included a third mode of sexual selection where a male may attempt to limit the choice of a female by coercing her to mate with him and not to mate with other males.

Differences between male and female mammals alter the costs and benefits of different elements of reproduction. Female mammals all gestate the young internally and are specialized to provide nutrition to the young after birth. In many species, and most marine mammal species, the female provides most of the parental care. REPRODUCTION in most female mammals is limited by the amount of energy and nutrition they can acquire for pregnancy and lactation. Male mammals usually provide much less parental care to their young. This means that reproduction in most male mammals is limited by the number of females they can mate with. This situation often leads to a

polygynous mating system in which there is high variability in the mating success of different males, with some males mating with many different females and other males mating with none. Males in polygynous species often fight other males for access to females. This often leads them to have weapons and to be larger than females; the intensity of polygyny is sometimes estimated by assessing the difference in size of males vs females. Some of the most extreme cases of sexual dimorphism occur in marine mammals. Adult sperm whales may be up to 16 m long, whereas adult females seldom grow beyond 12 m.

Most traditional discussions of mating systems emphasize male strategies. For example, polygyny occurs where one male mates with more than one female; the number of males a female mates with is not included in the definition. While the variance of reproductive success is higher in males than in females for most marine mammal species, female reproductive strategies can influence male strategies and impact other areas of social behavior. Areas in which female reproductive strategies vary include the following:

How seasonal and synchronized is estrus?
Do females have one (monoestrous) or more (polyestrous) estrous cycles per year?
Do females ovulate spontaneously or do they require the presence of a male to ovulate?
How many males are available during estrus?
Can the female select a mate?
If a female mates with more than one male, can she influence which male fertilizes the egg?

There are different patterns for the reproductive strategies of males and females in different polygynous MATING SYSTEMS. This article describes five different categories of male strategy that are used in the literature. The **resource defense strategy** is adopted by males who defend a resource used by females around the time of mating. In this case females do not select a mate but rather select an area for breeding and mate with the male defending this area. The **female defense strategy** is used by males who stay with a female and prevent other males from mating with her while she is receptive. The **sequential defense strategy** differs from the female defense strategy in that a male will defend a female through mating, but then leave in search of other mating opportunities. The distinction between these two male strategies depends in part on whether the female is mono- or polyestrous and on the degree of synchronization of different females. The strategy called by the name **"scramble competition"** occurs when a male searches for a receptive female, mates with her, and the moves on to search for another female without preventing access for other males. The last three models lie on a continuum of male strategies between pure guarding and pure roving. Models suggest that males should rove between groups of females if the duration of estrus is greater than the time it takes males to swim from group to group. At any one time, a male's decision to leave or stay with a group probably includes other factors, such as his assessment of what other males are doing. **Lekking strategy** occurs when males aggregate in an area with no resources needed by the female and produce displays to attract the female. In leks, males provide no parental care and females select a male for mating.

Some of these male strategies preempt the ability of a female to select a male for mating. In the resource defense model, the female does not select a particular male, but rather will select a particular place with the resource she needs. She will then be most likely to mate with the male who happens to be defending this location. When a female can and does choose a male for mating, she may select a mate based on several different bases. A female may select a male for inherent qualities based on indicators such as size, age, or an advertisement display. She may assess competition between males and select one based on this performance. In some species, males may compete for access to a particular location, and a female can select a good competitor by mating with a male in such a preferred spot. In some species, a female may mate with several males and allow competition between their sperm to determine which male fertilizes the egg. The males in this system would be likely to devote more resources to sperm production, sperm swimming speed, and so on than species that compete by fighting. Evidence shows that sperm competition may play a role in some cetaceans. Odontocete cetaceans have larger ratios of testis:body weight than most mammals. This contrast is also seen among mysticetes. Balaenid whales form mating groups with multiple males, but there is little sign of fighting between the males. Male right whales have testes weighing more than 900 kg; their testes weigh more than six times what would be predicted for a typical mammal of their body size. In contrast, humpback whale males, which fight for access to females, have testes weighing under 2 kg.

Marine mammals are highly mobile, and in the open ocean it seems unlikely that males could defend a resource in a way that would preempt the ability of a female to use the resource yet mate with another male. Resource defense is much easier to envisage on land. While pinnipeds spend much of their life at sea, they haul out on a solid substrate (land or ice) to give birth. Some of these species, such as elephant seals, also mate on land. Females have specific requirements for a place to give birth, and they often return to traditional areas. This scarce resource creates an opportunity for males to defend these sites in order to increase their chances of mating with the females who are selecting the site. In most otariid seals, males appear to employ resource defense strategies for mating. In many of these species, males will arrive before the females and will fight to establish territories that they defend from other males. In some phocid species that mate at sea, males may establish and defend territories just off the beach where females give birth. Genetic analyses of paternity, however, show that the fathers of some pups are not among the TERRITORIAL males. This suggests that some males have alternate mating strategies.

There are marine mammal species in which males may adopt a strategy of attempting to preempt female choice by guarding a receptive female and preventing her from mating with other males. Northern elephant seal males arrive at breeding beaches before females and compete for dominance status and for position on the breeding beach. A dominant male can guard a group of females and prevent access for other males. If an alpha male can maintain his status, he can prevent access to a group of females for the entire breeding season. This pattern of guarding a group of females is less likely for cetaceans, which are highly

mobile. Most male cetaceans would take a shorter time to swim between groups than the duration of female estrus, thus favoring a roving strategy. There is some evidence for sequential female defense in bottlenose dolphins. In field studies of Indian Ocean bottlenose dolphins (*Tursiops aduncus*) in Shark Bay Western Australia and bottlenose dolphins (*Tursiops truncatus*) in Sarasota, Florida, groups of two or three adult male bottlenose dolphins may form consortships with an adult female. A coalition of males may start such a consortship by chasing and herding a female away from the group in which they initially find her. Some of these consortships appear to be attempts by the males to limit choice of mate by the female, who may try to escape from the males. Males in these alliances may form consortships with several different females during a breeding season.

Many pinnipeds and some baleen whales produce reproductive advertisement displays that may play a role in mediating male–male competitive interactions and may also used for female choice of a mate. Male humpback whales sing long complex songs during the winter breeding season. Singing males are usually alone and they usually stop singing when joined by another whale. Aggressive behavior is often seen when a male joins a singer; when a female joins, apparent sexual behavior has been observed. Male humpbacks do not seem to be able to defend any resource needed by females on the breeding grounds, so this mating system has been described as a kind of floating lek. Vocal reproductive advertisement displays have also been reported for bowhead whales and many species of seal, including polar ice-breeding seals and harbor seals (*Phoca vitulina*). Most of the phocid seals known to produce songs mate at sea. These seals breed in conditions that foster the development of leks. Females gather to breed on isolated sites, but they mate after they have weaned their pups so there are few resources males could defend. Females are so mobile that it would be difficult for males to prevent them from gaining access to other males. The females are already concentrated in hot spots around the places where they give birth. This creates an ideal setting for males to cluster near the females, producing advertisement displays to attract females for mating. Some of the songs of whales, of ice-loving seals and the bell-like sounds of the walrus (*Odobenus rosmarus*) stand as testimony to the power of sexual selection to fashion complex and fascinating advertisement signals.

VI. Parental Behavior

All mammals have some parental care when the female lactates and suckles the young. The mothering role of the female is critical to mammalian life, and female parental care impacts many aspects of social behavior. There is enormous variability in parental care among marine mammals. Some phocid seals give birth to their young on unstable ice floes, where they cannot count on a stable refuge for the young. The hooded seal (*Cystophora cristata*) has responded to this situation by an intense 4-day period of lactation when the young pup doubles in weight. While female phocid seals do not generally leave their young pup to feed, otariid females will leave their young in order to feed at sea and then they return to suckle the pup. This pattern leads to a large difference in duration of lactation, from 4 days to 2 months in phocids and from 4 months to 2 years in otariids. Most pinnipeds have yearly breeding seasons, so the longest periods of lactation are limited to about 12 months. However, tropical Galapagos sea lions at times nurse their young for >12 months and produce young at greater intervals than that. Phocoenid porpoises and some baleen whale species also have a strong annual breeding cycle. Some baleen whales, such as the blue whale (*Balaenoptera musculus*), wean their young after about 7 months so that the young can start taking solid food during the summer feeding season. All porpoises and baleen whales wean the young within a year. The toothed whales stand at the other extreme of having very prolonged periods of parental care when the young are dependent. Bottlenose dolphins only 3 m or so in length often suckle the young for 3–5 years, which is remarkably long considering that the 30-m blue whale can wean the young in 7 months.

The longest periods of PARENTAL CARE known among marine mammals involve sperm whales and short-finned pilot whales (*Globicephala macrorhynchus*). In both species, mothers appear to suckle some calves for up to 13–15 years. The young may start to take some solid food by the first few years of life, but this suckling indicates a remarkably long period of dependency for the young. Adult female pilot whales typically start having young by 8–10 years, but by the time they are near 30, many cease to reproduce. The ovaries become nonfunctional in these nonreproductive females, showing changes similar to those of human females after menopause. Female pilot whales may live into their 50s, suggesting that they may have a life expectancy 15–20 years after becoming nonreproductive. Most students of life history believe that life history evolves to maximize lifetime reproductive success. If this has influenced the life history of pilot whales, it suggests that females switch their reproductive effort from having new offspring to parental care of their existing young. The 15- to 20-year duration of this period suggests that 15–20 years of parental care are required for the young to succeed or that these older females are caring for other kin, perhaps in a grandparental role.

VII. Social Behavior and Social Relationships

Not only do marine mammals show a broad range in the duration of the maternal bond, but there is great diversity in the duration of social bonds in general and especially in the importance of individual-specific social relationships. Resident killer whales have the most stable social groups known among mammals: no dispersal of either sex has been described. The only way group composition changes among the resident killer whales of the Pacific Northwest is for an animal to die or for a new animal to be born. The best-known vocalizations from killer whales are group-distinctive repertoires of stereotyped pulsed calls. In contrast, bottlenose dolphins have very fluid social groups. In their fission–fusion society, group composition changes on a minute-by-minute and hour-by-hour basis. However, some individuals may have strong social bonds and be sighted together for years at a time. As was just discussed in the section on parental care, bottlenose dolphin calves suckle for 3–5 years. Adult male bottlenose dolphins may also form coalitions with one to two other unrelated males. Members of a coalition tend to be sighted

together 70–100% of the time, and alliances may last for over a decade. It is thought that males form alliances to improve their chances of mating with females, but lone males are also successful breeders. Males within a coalition often have highly coordinated displays, both when feeding and when escorting a female. Each bottlenose dolphin produces an individually distinctive whistle vocalization called a signature whistle, which is probably used for individual recognition.

In sperm whales, males have different life history patterns than females. Calves are born into matrilineal groups of females and young. Each matrilineal unit numbers about 10 animals, but often two units associate for days at a time. Males may leave their natal groups when 5–10 years of age, and they then will join bachelor groups. As males grow, they move to higher latitudes and associate in smaller groups of males. As the males approach social and sexual maturity at 20–25 years of age, they are increasingly likely to temporarily associate with a female group during the breeding season, when they may mate with females. The social relationships of males thus change over their lifetime, and adult males appear to have only temporary associations. Young females may stay with their natal group or may leave, but once they reach sexual maturity at 8–10 years of age, they will tend to associate with the same adult females for decades at a time. Because the matrilineal groups often join with other groups but segregate into the original groups, the females must recognize group members over periods of decades. Sperm whales make rhythmic patterns of click sounds called codas. Early reports reported individually distinctive codas, but there are also shared codas that vary with the geographic region. Most of the variation in codas involves differences between groups, and it has been suggested that codas may reaffirm social bonds when a group joins after dispersing to forage. Female sperm whales must have stable social relationships with specific other individuals. These family groups appear to be the basic social unit of sperm whales, with a primary function of vigilance against predators and social defense of calves.

Baleen whales may feed in groups as do sperm whales, but female baleen whales appear to differ from sperm whales in the importance of group care of young. On the feeding grounds, baleen whales of all sexes are often seen in groups of varying sizes. For humpback whales, the size of the feeding group correlates with the horizontal extent of the prey patch. However, during the breeding season, when a female humpback has a calf, she is extremely unlikely to associate with another adult female. When one or more adults escort a female during the breeding season, the escorts are almost always males. In baleen whales there is much less evidence for long-term social bonds than among most toothed whales. Odontocetes with little evidence for stable bonds are species such as the harbor porpoise and delphinids of the genus *Cephalorhynchus*, which also appear to have fluid groupings with few social bonds more stable than the mother–calf bond, which lasts less than 1 year in the porpoise. However, future research may find social bonds that have not yet been described.

There appears to be a correlation between the social relations of marine mammals and their communication patterns. Baleen whales and pinnipeds with large apparently anonymous breeding aggregations use reproductive advertisement displays to mediate male–male and male–female interactions on the breeding grounds. Killer whales with highly stable groups produce group-specific repertoires of stereotyped calls. Seals and dolphins with strong individual-specific bonds use a variety of different vocalizations for individual recognition, but no such recognition signals are known for porpoises or *Cephalorhynchus*. Sperm whales appear to use deceptively simple clicks to produce a diverse set of signals consistent with their diverse social groupings.

VIII. Conclusions

Marine mammals face the same basic problems that have been identified by behavioral ecologists for all animals. However, marine mammals live in an environment that differs in many important ways from the terrestrial environment. Studies since the 1980s have provided ever-growing opportunities for fascinating comparisons between marine mammals and their terrestrial relatives and between the diverse taxa that live in the sea.

Beluga Whale

Delphinapterus leucas

GREGORY M. O'CORRY-CROWE
Southwest Fisheries Science Center, La Jolla, California

The beluga or white whale inhabits the cold waters of the Arctic and sub-Arctic (Fig. 1). Its name, a derivation of the Russian "beloye," meaning "white," appropriately enough captures its most distinctive feature, the pure white color of adults (Fig. 2). The evolutionary history and ecology of

Figure 1 *Worldwide distribution of the beluga whale. The northernmost extent of its known range is off Alaska and northwest Canada and off Ellesmere Island, West Greenland, and Svalbard (above 80°N). The southern limit of distribution is in the St. Lawrence River in eastern Canada (47° to 49°N).*

belugas are inextricably linked to the extreme seasonal contrasts of the north and the dynamic nature of the sea ice. As well as adaptation to the cold, life in this region has necessitated the evolution of discrete calving and possibly mating seasons, annual migrations, and a unique feature distinguishing it from most other cetaceans, an annual molt.

I. Taxonomy and Evolutionary History

The beluga whale is a member of the Monodontidae, the taxonomic family it shares with the narwhal, *Monodon monoceros*. The Irrawaddy dolphin, *Orcaella brevirostris*, was at one point considered by some to also be a member of this family. Although superficially similar to the beluga, recent genetic evidence strongly supports its position as a member of the family Delphinidae (Lint *et al.*, 1990; LeDuc *et al.*, 1999). The earliest fossil record of the monodontids is of an extinct beluga *Denebola brachycephala* from late Miocene deposits in Baja California, Mexico, and indicate that this family once occupied temperate ecozones (Barnes, 1984). Fossils of *D. leucas* found in Pleistocene clays in northeastern North America reflect successive range expansions and contractions of this species associated with glacial maxima and minima.

II. Description and Life History

The beluga whale is a medium-sized toothed whale, 3.5–5.5 m in length and weighing up to 1500 kg. Males are up to 25% longer than females and have a more robust build. As their genus name ("apterus"–without a fin) implies, they lack a dorsal fin and are unusual among cetaceans in having unfused cervical vertebrae, allowing lateral flexibility of the head and neck. They possess a maximum of 40 homodont teeth, which become worn with age, and may live to 40 years of age, possibly longer. Neonates are about 1.6 m in length and are born a gray-cream color that quickly turns to a dark brown or blue-gray. They become progressively lighter as they grow, changing to gray, light gray, and finally becoming the distinctive pure white by age 7 in females and 9 in males (Fig. 3).

Belugas are supremely adapted to life in cold waters. They possess a thick insulating layer of BLUBBER up to 15 cm thick beneath their skin, and their head, tail, and flippers are relatively small. The absence of a dorsal fin is believed by some to be an adaptation to life in the ice or perhaps as a means to reduce heat loss. In its place, belugas possess a prominent dorsal ridge that is used to break through thin sea ice.

Females become sexually mature at age 5, males at age 8, although males may not become socially mature until some

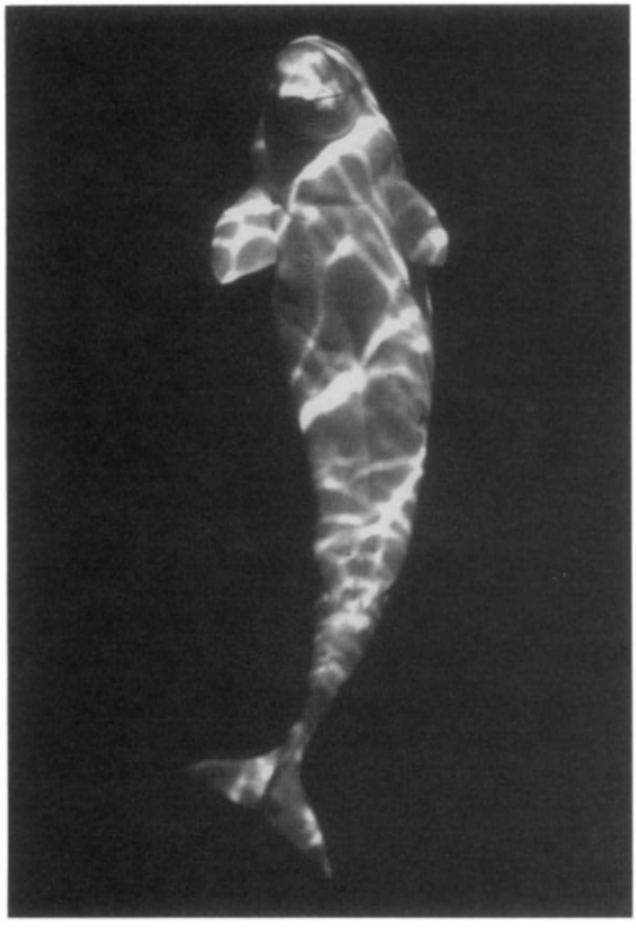

Figure 2 *Beluga whale,* Delphinapterus leucas. *Flip Nicklin/Minden Pictures.*

time later. Gestation is 14–14.5 months with a single calf born in late spring–early summer prior to, or coincident upon, entry into warm coastal waters. Mothers produce milk of high caloric content and nurse their young for up to 2 years; the entire reproductive interval averaging 3 years. Little is known about the mating behavior or mating season of beluga whales. Mating is believed to primarily occur in late winter–early spring, a period when most belugas are still on their wintering grounds or on spring migration. Mating behavior, however, has been observed at other times of the year and the question of whether they have delayed implantation is unresolved.

III. Behavior

In contrast to the frozen smile of the oceanic dolphins, the ability of belugas to alter the shape of their mouth and melon enables them to make an impressive array of facial expressions. The lateral flexibility of the head and neck further enhances visual signaling and enable beluga whales to maneuver in very shallow waters (1–3 m deep) in pursuit of prey, to evade predators, and generally exploit a habitat rarely used by other cetaceans (see later).

Belugas typically swim in a slow rolling pattern and are rarely given to aerial displays. In nearshore concentration areas, however, such as Cunningham Inlet on Somerset Island in the Canadian High Arctic, belugas may engage in more demonstrative behaviors, including spy hopping, tail waving, and tail slapping (Fig. 4).

Figure 3 *Beluga whales concentrating near the coast during the brief summer. Note the dark to light gray color of younger animals compared to the white of adults. Flip Nicklin/Minden Pictures.*

Recent findings from studies using satellite-linked transmitters attached to free-swimming whales have confirmed that belugas are capable of covering thousands of kilometers in just a few months, in open water and heavy pack ice alike, while swimming at a steady rate of 2.5–3.3 km/h (Suydam *et al.*, 2001). Sensors on these transmitters have also recorded belugas regularly diving to depths of 300–600 m to the sea floor. In

Figure 4 *Aggregation of beluga whales interacting and rubbing on the substrate of a shallow estuary during the summer molt. Flip Nicklin/Minden Pictures.*

the deep waters beyond the continental shelf, belugas may dive in excess of 1000 m, where the pressure is 100 times that at the surface, and remain submerged for up to 25 min (Richard *et al.*, 1997; Martin *et al.*, 1998)!

In areas of open water beluga whales may divide their days into regular feeding and resting bouts. Belugas appear to predominantly hunt individually, even when within a group, but have also been observed to hunt cooperatively. A typical hunting sequence begins with slow directed movement combined with passive acoustic localization (search mode) followed by short bursts of speed and rapid changes of direction using ECHOLOCATION for orientation and capture of prey (hunt mode) (Bel'kovich and Sh'ekotov, 1990).

IV. Acoustics–Vocalizations

The beluga possesses one of the most diverse vocal repertoires of any marine mammal and has long been called the "sea canary" by mariners awed by its myriad sounds reverberating through the hulls of ships. Communicative and emotive calls are broadly divided into whistles and pulsed calls and are typically made at frequencies from 0.1 to 12 kHz. As many as 50 call types have been recognized: "groans," "whistles," "buzzes," "trills," and "roars" to name but a few. Although some geographic variation is apparent, efforts to determine whether there are substantial regional differences or dialects have been hampered by differences among bioacousticians in the categorization of vocalizations. Belugas are capable of producing individually distinctive calls to maintain contact between close kin and can conduct individual exchanges of acoustic signals, or dialogues, over some distance (Bel'kovich and Sh'ekotov, 1990).

The echolocation system of the beluga whale is well adapted to the icy waters of the Arctic. Their ability to project and receive signals off the surface and to detect targets in high levels of ambient noise and backscatter enable belugas to navigate through heavy pack ice, locate areas of ice-free water, and possibly even find air pockets under the ice (Turl, 1990).

V. Ecology

As the sea ice recedes in spring, belugas enter their summering grounds, often forming dense concentrations at discrete coastal locations, including river estuaries, shallow inlets, and bays (Fig. 3). Several explanations have been proposed as to why belugas return to these traditional summering areas. In some regions, sheltered coastal waters are warmer, which may aid in the care of neonates. The occupation of estuarine waters also coincides with the period of seasonal molt. Belugas have been observed to actively rub their body surface on nearshore substrates (Smith *et al.*, 1992; Fig. 4), and the relatively warm, low-salinity coastal waters may provide conditions that facilitate molting of dead skin and epidermal regrowth (St. Aubin *et al.*, 1990; Smith *et al.*, 1994). Belugas feed on a wide variety of both invertebrate and vertebrate benthic and pelagic prey. In some parts of their range it is clear that belugas are feeding in nearshore waters on seasonally abundant anadromous and coastal fish such as salmon, *Oncorhynchus* spp., herring, *Clupea harengus*, capelin, *Mallotus villosus*, smelt, *Osmerus mordax*, and saffron cod, *Eleginus gracilis* (Kleinenberg *et al.*, 1964; Seaman *et al.*, 1982). The relative importance of these factors in determining coastal distribution patterns may vary among regions, depending on environmental and biological characteristics (Frost and Lowry, 1990). It is clear, however, that belugas exhibit some degree of dependence on specific coastal areas.

In many areas of the Arctic, belugas soon leave these coastal areas to range widely off shore. Satellite tracking has recorded belugas moving up to 1100 km from shore and penetrating 700 km into the dense polar cap where ice coverage exceeds 90% (Suydam *et al.*, 2001). How these animals find breathing holes in this environment is still a mystery. Analysis of dive profiles suggests that beluga whales may combine the use of sound at depth to find cracks in the ice ceiling overhead. Diving data also indicate that belugas are probably feeding on deepwater benthic prey as well as ice-associated species closer to the surface (Martin *et al.*, 1998).

Little is known about the DISTRIBUTION, ECOLOGY, OR BEHAVIOR of beluga whales in winter. In most regions, belugas are believed to migrate in the direction of the advancing polar ice front. However, in some areas, belugas may remain behind this front and overwinter in polynyas and ice leads. In the eastern Canadian Arctic some belugas overwinter in the North Water, a large area of open water in northern Baffin Bay (Finley and Renaud, 1980), whereas in the White, Barents, and Kara Seas, belugas occur year-round, remaining in polynyas in the deeper water during winter (Kleinenberg *et al.*, 1964).

Killer whales, *Orcinus orca*, polar bears, *Ursus maritimus*, and humans prey upon beluga whales. Belugas sometimes become entrapped in the ice where large numbers may perish or be hunted intensively by humans.

VI. Social Organization

Belugas are sometimes seen singly, but more commonly occur in groups of 2–10 that may aggregate at times to form herds of several hundred to more than a thousand animals. Single animals are always large adults, whereas in mixed herds adult males may form separate pods of 6–20 individuals. Adult females form tight associations with newborns and sometimes a larger juvenile, presumably an older calf. These "triads" may join similar groupings to form large nursery groups. At certain times of the year, age and sex segregation may be more dramatic than at others with males migrating ahead of or feeding apart from females, young, and immatures. In general, group structure appears to be fluid, with individuals readily forming and breaking brief associations with other whales. Apart from cow–calf pairs, there appear to be few stable associations. However, considering the diverse vocal repertoire of beluga whales, including individual signature calls, their wide array of facial expressions, and the variety of interactive behaviors observed, as well as the numerous accounts of cooperative behavior, this species appears capable of forming complex societies where group members may not always be in close physical proximity to each other.

VII. Population Structure

Variation in body size across the species range has been taken as evidence of separate populations. The nonuniform pattern of

distribution and predictable return of belugas to specific coastal areas further suggests population structure and has led to the treatment of these summering groups as separate management stocks. Resightings of marked or tagged individuals, as well as differences in contaminant signatures and limited evidence of geographic variation in vocal repertoire, add support to the independent identification of a number of these stocks. Although all are valid to varying degrees, many of these methods used for stock identification have limitations due to incomplete knowledge on year-round distribution, movement patterns, breeding strategies, and social organization. They provide little or no information on rates of individual or genetic exchange, and although phenotypic differences are highly suggestive, they may not provide evidence of evolutionary uniqueness.

A number of recent molecular genetic studies examined variation within the mitochondrial genome and confirmed that whales tend to return to their natal areas year after year and that dispersal among many separate summering concentrations is limited, even in cases where there are few geographic barriers (O'Corry-Crowe *et al.*, 1997; Brown Gladden *et al.*, 1997). These molecular findings reveal that knowledge of migration routes and destinations appears to be passed from mother to offspring, generation after generation. Such cultural inheritance of information leads to the evolution of discrete subpopulations, among which there is little dispersal. It is possible that many of these subpopulations may overwinter in a common area and that a certain amount of interbreeding may occur at this time. Regardless of such potential gene flow, in situations where management is concerned with the degree of demographic connectivity among areas, demonstrating that few animals disperse among subpopulations is sufficient evidence to designate them as separate management stocks.

VIII. Interactions with Humans

Because of their predictable MIGRATION routes and return to coastal areas, beluga whales have long been an important and reliable resource for many coastal peoples throughout the Arctic and sub-Arctic. A prudent subsistence tradition continues in many areas. However, primarily because of past commercial harvest excesses, current levels of subsistence taken from a number of populations may not be sustainable. Increasing human activity in the beluga's environment brings with it the threat of habitat destruction, disturbance, and pollution. In areas where there are large commercial fishing operations, belugas, particularly neonates, may be incidentally caught in gill nets. In a number of regions of the Arctic, beluga whales exhibit strong avoidance reactions to ship traffic, whereas in some coastal locations they appear to have developed a certain tolerance to boat traffic. The potential impacts of an emerging whale watching industry in more populated areas are as yet unknown. In some areas, belugas may also be victims of industrial pollution. A high incidence of various pathologies have been found in beluga whales in the St. Lawrence River in Canada and have been linked to high levels of heavy metals and organohalogens found in these whales. Some of these toxins may act by suppressing normal immune response, and there is concern that contaminants are adversely affecting population growth (Béland, 1996). Finally, there is concern over the possible downstream effects of hydroelectric dams on estuarine habitats and the environmental and health risks associated with oil and gas development and mining in the Arctic.

Beluga whales were one of the first cetaceans to be held in captivity when in 1861 a whale caught in the St. Lawrence River went on display at Barnum's Museum in New York. Today, beluga whales are one of the more common and popular marine mammals in oceanaria across North America, Europe, and Japan. The majority of these animals are wild caught, but successful breeding programs at a number of facilities are increasing the number of belugas born in CAPTIVITY. Although the majority of beluga whales in captivity educate and entertain the public, a number of whales have been put to work by the navies of the United States and former Soviet Union.

Biogeography

Rick LeDuc
Southwest Fisheries Science Center, La Jolla, California

Biogeography is the study of the patterns of geographic distribution of organisms and the factors that determine those patterns. Although marine mammals are very mobile and there is an apparent lack of physical barriers in the world ocean, only the killer whale (*Orcinus orca*), the sperm whale (*Physeter macrocephalus*), and perhaps some of the balaenopterids could arguably be considered to have cosmopolitan distributions. Other species have restricted distributions (e.g., coastal South America, Indo-West Pacific), reflecting their ecological requirements and their geographic centers of origin. Because related species tend to have similar ecological requirements and dispersal abilities, the distribution of higher taxa can also show distinct tendencies and restrictions, which reflect the cumulative distributions of their included species. For example, while delphinids, river dolphins, and sirenians have their highest diversity in tropical latitudes, the vast majority of pinniped, ziphiid, and phocoenid species occurs in temperate and polar regions. From a geographic perspective, specific regions can thus be characterized as centers of diversity for these higher taxa, and past global changes in the environment will have influenced their evolutionary history. For example, cooling of the world climates during the Tertiary may have contributed to the radiation of cold water-adapted pinnipeds and mysticetes.

I. Types of Distributions

At the species level, distribution patterns can be described at different spatial scales. Broadly speaking, individual species are usually limited to certain latitudinal zones, such as tropical, temperate, or polar regions. These descriptions can be refined further into subtropical, cold temperate, and so on and incorporated into patterns of ocean basin or hemisphere endemism. For example, the Clymene dolphin (*Stenella clymene*) occurs only in the tropical Atlantic, the Steller sea lion (*Eumetopias jubatus*) in the cold temperate North Pacific, and the dugong (*Dugong dugon*) in the tropical Indo-West Pacific. On even smaller scales, species may be associated with specific physical features, such as nearshore coastal areas (e.g., the hump-backed dolphins, *Sousa* spp.) or the continental slope (e.g., Baird's beaked whale, *Berardius bairdii*), or with oceanographic features, such as specific water masses or even bodies of freshwater (e.g., the baiji, *Lipotes vexillifer*, and the Baikal seal, *Pusa sibirica*).

A few species, notably some of the baleen whales, are highly migratory, summering at high latitudes and spending the winter breeding season at lower latitudes. Some of the migrating rorqual species occupy (at least seasonally) a wide range of latitudes in both hemispheres, although the movements of the Northern and Southern Hemisphere populations are seasonally offset so that they do not normally co-occur in the tropics. At the other end of the spectrum, there are some species (e.g., the vaquita, *Phocoena sinus*, and the Hawaiian monk seal, *Monachus schauinslandi*) that have highly restricted ranges. If a formerly wide-ranging species is now limited to a small area, its distribution is considered relict.

There are distributions that are described as pan-tropical (or pan-tropical/temperate), exhibited by some delphinids (many species), ziphiids (e.g., Blainville's beaked whale, *Mesoplodon densirostris*), kogiids (e.g., the pygmy sperm whale, *Kogia breviceps*), and balaenopterids (e.g., Bryde's whale, *Balaenoptera edeni*). A few species and species pairs occur at higher latitudes in both hemispheres but are absent from tropical waters, the so-called antitropical species and species pairs. These are seen in the families Delphinidae (e.g., the right whale dolphins, *Lissodelphis* spp.), Ziphiidae (e.g., the bottlenose whales, *Hyperoodon* spp.), Phocoenidae (e.g., *Phocoena sinus* and Burmeister's porpoise, *P. spinipinnis*), Phocidae (e.g., the elephant seals, *Mirounga* spp.), and Otariidae (e.g., the Guadalupe fur seal, *Arctocephalus townsendi*, and Juan Fernandez fur seal, *A. philippii*).

II. Ecology and History Determine Distribution

Beyond these descriptive aspects of biogeography are the factors that determine a given species' distribution. Generally, distributions are determined by the ecology and the history of the species. In some cases, distribution is limited because a species may not be adapted for living in certain environments.

For example, tropical delphinids may not range into higher latitudes due to limitations on their abilities to thermoregulate in colder water or find food in different habitats. Tied into this is competition, either from closely related species or from ecologically similar species, which may exclude a species from a particular region in which it could otherwise survive. In the case of South American manatees, it is reasonable to surmise that competition places at least one boundary on species' ranges. Throughout most of its range, the Caribbean manatee (*Trichechus manatus*) occurs in both coastal and riverine habitats. However, it does not range into the Amazon River, where the exclusively freshwater Amazonian manatee (*T. inunguis*) occurs, although it occupies the coastal areas on either side of the river mouth. Here, the two species are parapatric, and competitive exclusion is likely at work.

The role that history plays in biogeographic patterns should not be overlooked, but it is not always evident from contemporary distributions. The dispersal abilities of organisms may partly explain why species occur in some areas and not in others. For example, the lack of otariids in the North Atlantic is probably not due to the lack of suitable habitat, but rather lies in the inability of any North Pacific or South Atlantic species to get there. Of course, one could also tie this into their ecological requirements, in that dispersal to the North Atlantic would be more likely if North Pacific species ranged far enough north for animals to disperse via the Arctic Ocean across northern North America or Eurasia. For some species that have widely separated allopatric populations (e.g., Commerson's dolphin, *Cephalorhynchus commersonii*), dispersal from one region to the other is a likely explanation for their distribution. In other cases, vicariance events can explain allopatric distributions. For example, the two subspecies of the Indian river dolphin (*Platanista gangetica*) occur in different river systems: the Indus and Ganges-Brahmaputra River. Although the two forms are not presently in contact, these rivers were all part of a single system until the late Pliocene and probably had sporadic connections through stream capture even until historical times. Therefore, the geographic separation of the populations is from a rather recent vicariance event.

Large-scale changes in the environment can have dramatic influences on species' distributions. For example, in times of global cooling, cold boundary currents in the ocean basins may have extended further toward the equator. This, in turn, could have enabled temperate species to disperse across the equator to similar habitats in a different hemisphere, giving rise to the antitropical species. Among the antitropical species and species pairs, some tendencies in their distributions are apparent. For example, for only one group (*Eubalaena* spp.) does the northern counterpart occur in both the North Atlantic and the North Pacific. Although the long-finned pilot whale, *Globicephala melas*, has only been recorded from the North Atlantic and the Southern Hemisphere, 1000+-year-old skulls of this species have been unearthed in Japan. For the rest of the eight or so recognized antitropical species and species pairs or trios, all except *Hyperoodon* have their northern members limited to the North Pacific. Perhaps the oceanographic and climatic conditions that allow transequatorial dispersal for temperate species occur more frequently or become more developed in the Pacific basin than in the Atlantic. These comparisons do not include the latitudinal migrant species, such as many of the species of balaenopterids. For these, their seasonal occurrence at low latitudes greatly facilitates transequatorial dispersal and would not likely require any significant change in oceanographic or climatic conditions.

Beyond the consideration of the underlying mechanisms of a single species' distribution, it is possible to make inferences about the origins of entire ecological communities. Vicariance biogeographers look for congruence between the phylogenetic relationships among species and their geographical distributions. Species distributions can be superimposed on phylogenetic trees to create what are called area cladograms (Fig. 1). If the area cladograms of several unrelated but geographically similar higher taxa are congruent, it is good evidence that a specific sequence of vicariance events operated on all of those taxa as SPECIATION mechanisms. Furthermore, it may allow the researcher to make inferences about the centers of origin for the higher taxa being considered.

Finally, one should try to incorporate the fossil and geologic record when inferring historical mechanisms in biogeography, especially among distantly related taxa. A case in point can be seen in the river dolphins. Among the river dolphins, the Amazon *Inia geoffrensis* and the franciscana *Pontoporia blainvillei* appear to be the closest (albeit very distant) relatives among the extant species, with the former occupying several South American rivers that flow into the Atlantic and the latter occurring along the Atlantic coast of South America. However, the closest (albeit even more distant) living relative of this pair is probably the baiji (*Lipotes vexillifer*), which is only found in the Yangtze River in China. Considering their freshwater and nearshore habits, it is not obvious from their contemporary distributions how they came to occupy areas a world apart. However, the fossil record has yielded intermediate species from various localities across the North Pacific. Furthermore, the geologic record shows that in the late Pliocene, the major river system in northern South America flowed westward, into what is now the Gulf of Guayaquil in Ecuador. It is thought that the ancestors of *Inia* entered this system from the Pacific. With the uplift of the Andes, much of the river reversed direction and flowed eastward, eventually becoming rivers such as the Amazon and Orinoco. With the North Pacific intermediate forms dying off and the *Inia* lineage splitting to give rise to the ancestors of *Pontoporia* along the coast, one can see how the present-day species distributions came to be. It should be kept in mind, however, that determining the distributions of fossil taxa is notoriously difficult, especially for offshore species that are poorly represented in accessible deposits.

III. Taxonomic Patterns

As mentioned earlier, species within higher taxa share characteristics of their distributions to some degree. It is therefore possible to characterize the distributions of the different groups of marine mammals. The sirenians are primarily a tropical group, with mostly allopatric species occurring in warm coastal waters and some rivers of the Indo-West Pacific and both sides of the Atlantic. The trichechids are represented by two species

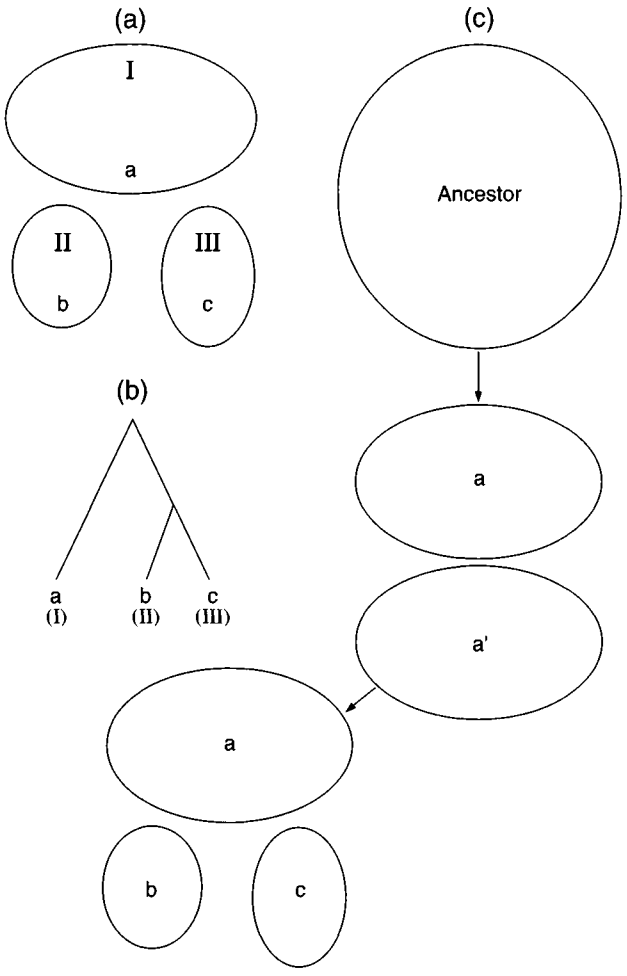

Figure 1 *In vicariance biogeography, speciation patterns are determined by vicariance events. The analysis attempts to reconstruct the sequence of vicariance events using the pattern of evolutionary relationships within a group of related species with allopatric distributions. (a) Species "a," "b," and "c" occupy ranges I, II, and III, respectively. (b) If a phylogenetic analysis determines that "b" and "c" are sister species to the exclusion of "a," this pattern of relationships is applied to their respective geographic ranges in an area cladogram. (c) Under this scenario, the range of the ancestral species is first divided by a vicariance event into a northern and a southern half. Populations in these two areas speciate into species "a" and "a'." Species "a'" is the inferred immediate common ancestor to "b" and "c." A later vicariance event divides the range of "a'" into eastern and western halves, giving rise to species "b" and "c." If unrelated species groups occupying these areas show congruent area cladograms, the support for this sequence of vicariance events is strengthened.*

in the new world (*Trichechus manatus* and *T. inunguis*) and a single congener, the African manatee (*T. senegalensis*), in western Africa, indicating the occurrence of a past trans-Atlantic dispersal event within that lineage. The family Dugongidae, formerly more diverse and widespread, now has only one extant species, the dugong (*Dugong dugon*), that occurs in the Indian and west Pacific Oceans. One recently extinct species of dugongid, Steller's sea cow (*Hydrodamalis gigas*), had a restricted range in the Commander Islands of the North Pacific, an anomalously cool habitat for a sirenian.

The majority of phocid species inhabit cold temperate and polar regions. Although no species occurs in both Northern and Southern Hemispheres, there are numerous species that are circumpolar either in the Arctic (e.g., the bearded seal, *Erignathus barbatus*) or in the Antarctic (e.g., the crabeater seal, *Lobodon carcinophagus*). In fact, all of the southern phocid species have very broad distributions; their range expansions were probably assisted by the oceanic currents that traverse all longitudes in the Southern Ocean. In the Northern Hemisphere, however, the habitats and ocean currents are much more fragmented by the continental land masses. In addition to the circumpolar species, there are northern species that have more restricted ranges, either endemic to a single ocean basin (e.g., the gray seal, *Halichoerus grypus*), or limited to landlocked bodies of water (e.g., the Caspian seal, *Pusa caspica*). In contrast to the rest of the family, the three recent (two extant) species of monk seals (*Monachus* spp.) inhabit(ed) warmer waters of the Mediterranean and eastern Atlantic, Caribbean, and Hawaii. The spread of monk seals to Hawaii must have occurred prior to the rising of the Isthmus of Panama, which has separated the Caribbean and Pacific basins for the past 3 million years.

As a group, the otariids are similar to the phocids in their distribution, although they are less well represented at very high latitudes (near the pack ice) and do not occur in the North Atlantic at all. Also, individual species tend to have more restricted ranges that are widely allopatric from their congeners. For example, the fur seal genus *Arctocephalus* is very widespread in the Southern Hemisphere, represented by six species (with an additional species endemic to the Galapagos Islands and another to the eastern North Pacific). However, there are only a handful of localities where more than one species occurs together; for the most part, the species are allopatric. It appears then that the dispersal abilities of fur seals have allowed them to colonize many areas in the Southern Hemisphere but have not prevented the resulting disjunct populations from speciating. Odobenids are represented by a single circumpolar Arctic species, the walrus (*Odobenus rosmarus*).

Cetacean species exhibit a wide range of distribution patterns. The family Balaenidae includes one circumpolar Arctic species (*B. mysticetus*) and a trio of very closely related species distributed in the North Atlantic, North Pacific, and Southern Hemisphere (*Eubalaena* spp.); until recently, these were thought to comprise a single species. The gray whale (*Eschrichtius robustus*) and the various species of balaenopterids are mostly latitudinal migrants in both hemispheres, although two species (the Bryde's whales, *Balaenoptera brydei* and *B. edeni*) are restricted to tropical and warm temperate waters, and some primarily migratory species include isolated populations that may be nonmigratory (e.g., the humpback whale, *Megaptera novaeangliae*, in the northern Indian Ocean). In addition to the widespread species of minke whale (*Balaenoptera acutorostrata*), the Southern Hemisphere also contains an

endemic species of minke whale (*B. bonaerensis*). Similarly, the Southern Hemisphere is also home to two distinct forms (considered subspecies at present) of blue whale (*B. musculus*). In both of these cases, it is not known if the two southern forms represent divergent lineages that arose within the southern ocean or if they were the result of independent dispersal events across the equator.

Sperm whales are virtually cosmopolitan, and the kogiids (*Kogia sima* and *K. breviceps*) are worldwide in tropical and warm temperate waters. Beaked whales show a variety of distribution patterns, including pan-tropical species (e.g., *Mesoplodon densirostris*), antitropical species pairs (*Berardius* spp.), and ocean basin endemics (e.g., Sowerby's beaked whale, *M. bidens*). Some (e.g., the pygmy beaked whale, *M. peruvianus*) are only known from a few strandings within limited geographic areas. For most species of sperm whales and beaked whales, so little is known about their habits and ecological needs that it is difficult to hypothesize about the mechanisms that have led to their present distributions.

Three of the four species of river dolphins (*Inia geoffrensis, Lipotes vexillifer,* and *Platanista gangetica*) are strictly freshwater in specific tropical river systems, with the fourth species (*Pontoporia blainvillei*) having a restricted marine coastal range. The two species of monodontids (the narwhal, *Monodon monoceros,* and the beluga, *Delphinapterus leucas*) are circumpolar in the north and are among the few resident polar cetaceans, although fossil species of this family occurred as far south as San Diego, California.

Apart from a single Indo-West Pacific coastal species that also ranges into freshwater (the finless porpoise, *Neophocaena phocaenoides*), the phocoenids are strictly marine and cold temperate to warm temperate in distribution, some with very restricted ranges (e.g., *Phocoena sinus*). Only one phocoenid, the harbor porpoise (*P. phocoena*), has invaded the North Atlantic, becoming very widespread in both oceans of the Northern Hemisphere and even establishing isolated populations in the Black Sea and off West Africa.

The most speciose family of marine mammals, the delphinids, shows a wide variety of distributions, from pan-tropical species (e.g., the pantropical spotted dolphin, *Stenella attenuata*) to ocean basin endemics (e.g., the white-beaked dolphin, *Lagenorhynchus albirostris*) to species with wide-ranging but disjunct populations (e.g., the long-beaked common dolphin, *Delphinus capensis*). Many delphinids are pelagic, although some inhabit coastal waters (e.g., *Cephalorhynchus* spp.) and some even invade freshwater (e.g., the tucuxi, *Sotalia fluviatilis*). Only one, *Orcinus orca*, seems to regularly range to the pack ice in the far north and south. For the many pan-tropical/warm temperate species, the continental land masses effectively separate the populations inhabiting the Indian and Pacific Oceans from those inhabiting the Atlantic Ocean, raising the question of how they came to inhabit all the ocean basins. It has been hypothesized that during warm climatic periods, warm water extended far enough south to allow interchange and range expansion around the Cape of Good Hope. This would enable some species to become pan-tropical in their distribution, and the subsequent retreat of the warm weather and isolation of populations could provide a speciation mechanism for the establishment of the tropical species endemic to the Atlantic Ocean (the Atlantic spotted dolphin, *S. frontalis*, and *S. clymene*).

IV. Conclusion

Why do species live where they do? Answering such a simple question requires the examination of clues from the past as well as the present. Biogeography involves such diverse disciplines as geology, paleontology, ecology, physiology, behavior, and systematics. For marine mammals, studying biogeographic patterns presents real challenges. There is a paucity of information about past distributions and habitats, gaps in our knowledge of contemporary and recent distributions, uncertainties about evolutionary relationships, and a tremendous amount to learn about the basic ecology and physiology of many marine mammals.

Bioluminescence

Gregory K. Silber
National Marine Fisheries Service, Silver Spring, Maryland

I. Description

Bioluminescence is the ability of certain organisms to generate visible light as a result of a chemical reaction.

Although different animals use different chemicals, these are all variants of two chemicals: the substrate is called luciferin and the enzyme is luciferase. The chemical production of light is very efficient and does not generate heat like all other light sources.

Bioluminescence has a number of important biological and ecological functions. Light emission is used to avoid or confuse predators (e.g., shrimp and squid), attract prey (e.g., angler and flashlight fishes), and help attract mates (e.g., lanternfish and sea firefleas). Many organisms use bioluminescence for predator avoidance using a mechanism called counterillumination, in which the color and intensity of sunlight or moonlight entering the water column is matched to reduce the animal's silhouette as it appears from below.

II. Occurrence of Bioluminescence

Although rare on land, bioluminescence is extremely widespread in the marine environment and it would be difficult to find a location where it does not exist. It occurs in all oceans, all latitudes, and at all depths. Bioluminescent systems are believed to have evolved independently at least 30 different times.

In the sea, the photic zone occurs, in ideal conditions, only tens to hundreds of meters into the water column. Therefore, light that occurs below the photic zone is generated by the organisms themselves. In fact, most bioluminescence occurs in the very deep ocean, and more than 90% of marine organisms from 300 to 3000 feet glow—a tribute to the importance of bioluminescence to a wide variety of organisms that inhabit waters where sunlight does not penetrate. However, a number of invertebrate species that occur within the photic zone also exhibit bioluminescence.

Among the thousands of bioluminescent marine organisms, the majority are planktonic. There are also enormous numbers of other species, including lanternfish (Myctophidae), squid, decapod shrimp (e.g., the oplophorids and sergestids), krill, copepods, ostracods, amphipods, and gelatinous zooplankton. The benttooth bristlemouth (*Cylcothone* spp.) bioluminesces and may be one of the most abundant vertebrates on earth. These creatures are vastly important components of marine ecosystems and help form the basis of many marine food webs.

Near the surface, bioluminescence is often caused by dinoflagellates, single-celled algae. The bioluminescent flash this alga produces when physically agitated is probably related to predator avoidance. The flash may cause flight in copepod predators because the flash may have attracted the attention of something larger that might eat the copepod. Frequently found in vast groups, these organisms glow in the wake of swimming fish or dolphins (see later) or passing ships.

III. Bioluminescence and Marine Mammals

There is no known example of marine mammals emitting true bioluminescence. Nonetheless, it is undoubtedly a common part of the marine mammal ecosystem and it may be used by some species to locate prey. Much of the information about marine mammals and bioluminescence is anecdotal.

As noted earlier, many squid species bioluminesce. Inasmuch as squid are the basis of the diet for many marine mammals, bioluminescing prey may be an important cue for locating prey. Sperm whales (*Physeter macrocephalus*) dive to great depths and are known to feed on a variety of species, including many deep-water species and giant squid. Thus, sperm whales may be aided in locating prey that are bioluminescent, although the species' echolocation capabilities are almost certainly the primary means of locating its prey. A number of deep-diving marine mammals [e.g., elephant seals (*Mirounga* spp.), beaked whales, and other odontocete cetaceans] probably key on bioluminescing organisms when searching for prey. This raises the question, however, of bioluminesce being maladaptive if it increases the chances that an organism will fall victim to predation. The social and ecological significance of bioluminescence must outweigh the cost of announcing an organism's presence to a predator.

Some copepod species are among those that bioluminesce, including some that are preyed upon by skim-feeding large whale species, such as right whales (*Eubalaena* spp.). Some scientists believe that this attribute is an important visual cue to prey location for foraging right whales.

Vast swarms of dinoflagellates that bioluminesce when agitated are well known to all mariners and are occasionally seen by divers and beachgoers. These organisms bioluminesce when stirred by the mechanical action of a boat hull passing through them or by wave action. The same phenomenon has been seen when dolphins, riding on the pressure wave in front of a boat, for example, swim through the dinoflagellate swarms.

Vision, and therefore light, is vital to prey capture in many marine mammal species. While not true bioluminescence, cetaceans may use reflected ambient light in the capture of prey. For example, the inside surfaces of the mouth and the lower jaw of some sperm whales often have light-colored pigment. Some scientists believe that the reflective surface may be attractive to some prey, e.g., squid, and that prey actually move toward the reflective surface. This reflectivity may be enhanced by bioluminescence occurring on the white lower jaws of sperm whales who have been feeding on bioluminescent squid, a suggestion made because sperm whale jaws on whaling ships have been seen to "glow." Also, several authors have suggested that the asymmetric (i.e., present on the left side, but absent on the right) coloration patterns on the jaw and head of fin whales (*Balaenoptera physalus*) may serve as a light-colored backdrop by which small schooling fish are corralled. These are intriguing hypotheses that have not been tested. Of course, epidermal pigmentation patterns also play important social signaling roles for marine mammals that live in groups.

Biomagnetism

MICHAEL M. WALKER
University of Auckland, New Zealand

Biomagnetism is the study of the magnetic mineral, magnetite, in living organisms (Kirschvink *et al.*, 1985) and is extended here to include the hypothesis that magnetite is used for magnetic field detection. The earth's magnetic field may well be the only reliable source of navigational information in the open ocean through which cetacean and pinniped mammals often travel large distances (tens to thousands of kilometers). There has naturally been widespread interest in the hypothesis that marine mammals navigate magnetically, but there is as yet no direct experimental evidence for a magnetic sense in any cetacean or pinniped species. Studies of any kind have only been done on cetaceans, which are difficult to study experimentally because of their large size. In recent years, however, much has been learned from experimental studies of other vertebrates and it is reasonable to guess that the findings for other vertebrates will also largely apply to marine mammals.

I. Association of Mass-Stranding Sites with Magnetic Field Features

The locations where whales mass strand have been correlated with variations in the intensity of the earth's magnetic field. Klinowska (1985) proposed the hypothesis that otherwise healthy whales that strand themselves alive have made a serious navigational mistake and that examination of the circumstances surrounding stranding sites should provide clues as to the sensory system(s) responsible for the error. Klinowska (1985), Kirschvink *et al.*, (1986), and Kirschvink (1990) found that whales tended to strand at magnetic intensity "valleys," or minima, along the coastlines of Great Britain and the United States. Although similar studies in other areas could not extend these results (e.g., Brabyn and McLean, 1992), strandings have thus provided the first tantalizing evidence that whales use the earth's magnetic field for navigation.

II. Response by Migrating Fin Whales to the Earth's Magnetic Field

An approach derived from that used to investigate strandings has also shown that fin whales (*Balaenoptera physalus*) apparently respond to variations in the intensity of the earth's magnetic field during migration. Sighting positions off the eastern coast of the United States for fin whales, as well as for sharks, turtles, and other whales, were recorded by the Cetacean and Turtle Assessment Program (CETAP) during the late 1970s and early 1908s. During the spring and autumn migration seasons, sighting positions for fin whales were preferentially associated with areas of low magnetic intensity and intensity gradient (Walker *et al.*, 1992), much like the intensity valleys or minima with which strandings were associated. Exclusion of whales that were engaged in feeding behavior when sighted increased the strength of the association with areas of low magnetic intensity and intensity gradient. These results suggested that the fin whales responded to the earth's magnetic field during active migration but not necessarily at other times.

III. Experimental Studies of the Magnetic Sense

Although the just-described findings are consistent with the existence of a magnetic sense in whales, whether whales or pinnipeds actually have a magnetic sense will require experimental demonstration of at least behavioral responses to magnetic fields. Large size and constraints on experimentation have severely restricted laboratory studies on the magnetic sense of cetaceans. Thus Bauer *et al.* (1985) unsuccessfully tested Atlantic bottlenose dolphins (*Tursiops truncatus*) for sensitivity to magnetic fields in a series of conditioning experiments. It is probably premature, however, to conclude that cetaceans do not have a magnetic sense as only a single species has been tested under a limited range of experimental conditions.

The search for evidence of a magnetic field detection mechanism in whales is complicated again by their large size and the fact that the sensory cells responsible for detecting magnetic fields may be relatively small in number and need not be organized into a sense organ. Searches for the detector cells in whales have concentrated on locating deposits of the magnetic mineral, magnetite, in the heads of four odontocete and one mysticete species. The crystals of magnetite that are most suitable for use in magnetic field detection are extremely small (<100 nm) and searching for them in the bodies of whales truly is a search for a needle in a haystack. Bauer *et al.* (1985) did find, however, that magnetic material is consistently located in the dura mater, the tissue that surrounds the brain. At least some of this magnetic material is consistent with the very small magnetite particles that will be most useful for magnetic field detection. What has not been possible so far is the unique identification of magnetite in the dura mater tissue and demonstration that it is associated with magnetic field detection in any way.

IV. Evidence from Studies of Other Vertebrates

In the last decade, a good deal has been learned about detection and use of the earth's magnetic field by other vertebrates, much of which is also likely to apply to marine mammals. Turtles, fish, and birds are all known to respond to both the intensity and the direction of magnetic fields in laboratory or field experiments, and a variety of magnetic effects have been demonstrated on the navigation of homing pigeons (e.g., Lohmann and Lohmann, 1996; Semm and Beason, 1990; Walker *et al.*, 1997; Wiltschko and Wiltschko, 1995). In addition, candidate magnetite-based magnetoreceptor cells have been identified in the rainbow trout (Walker *et al.*, 1997). A magnetic sense thus appears to be widespread among homing and migratory vertebrates, and it seems

likely from the evidence available so far that marine mammals also have a magnetic sense that they use to navigate.

V. Outlook

Given the difficulties encountered so far, it is worth considering how to make better progress toward the understanding of biomagnetism in marine mammals. What is required in the first instance is the careful selection of subject animals and robust experimental techniques to demonstrate and characterize the magnetic sense. Although research has in the past focused on cetaceans, the results that have been obtained with other vertebrates suggest that pinnipeds are also likely to have a magnetic sense. The opportunity therefore exists for investigation of an important vertebrate group that behaves well in experimental situations and that may in fact be easier to study than the cetaceans. If biomagnetism is used by marine mammals as a part of a system of navigation, it may be used more regularly by open-ocean migrators such as pelagic whales and dolphins than by nearshore bottlenose and other dolphins.

Blowing

JAMES L. SUMICH
Grossmont College, El Cajon, California

blow is one of the most visible behaviors of whales when they are observed at the sea surface. Whale blows represent the rapid emptying, or expiration, of whales' lungs through their blowholes in preparation for the next inspiration. The visibility of a blow is due to a mixture of vapor and sea water entrained into the exhaled column of air at the sea surface (Fig. 1). When a blow occurs below the sea surface, as it sometimes does, such as bubble blasts in gray whales (*Eschrichtius robustus*) or bubble trains in humpback whales (*Megaptera novaeangliae*), it may be intended as a signaling function to other nearby whales.

A complete BREATHING cycle typically consists of a very rapid expiration (the blow) immediately followed by a slightly longer and much less obvious inspiration and then an extended yet variable

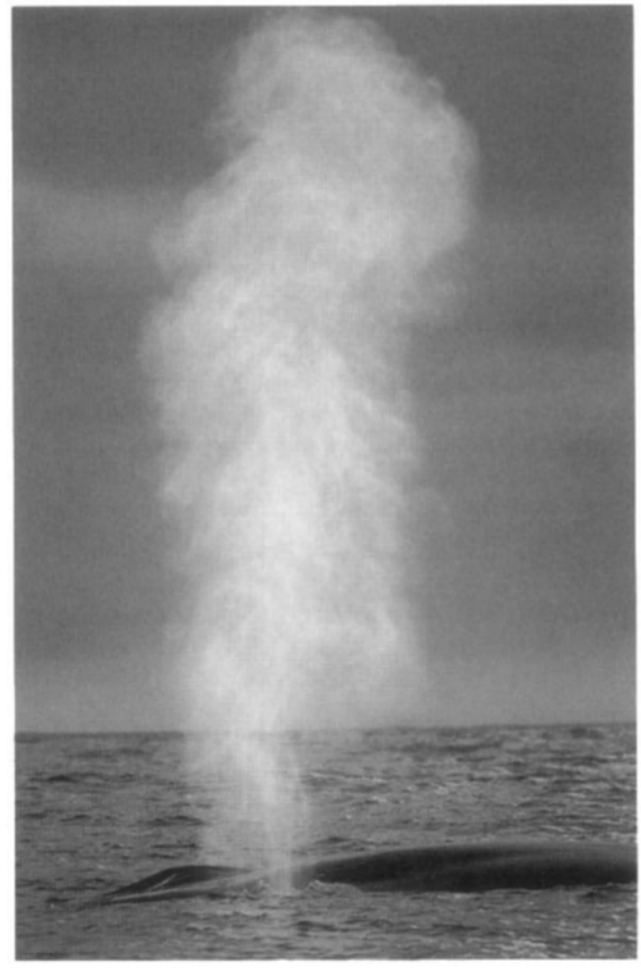

Figure 1 *Towering blow of a blue whale. Courtesy of Phil Colla.*

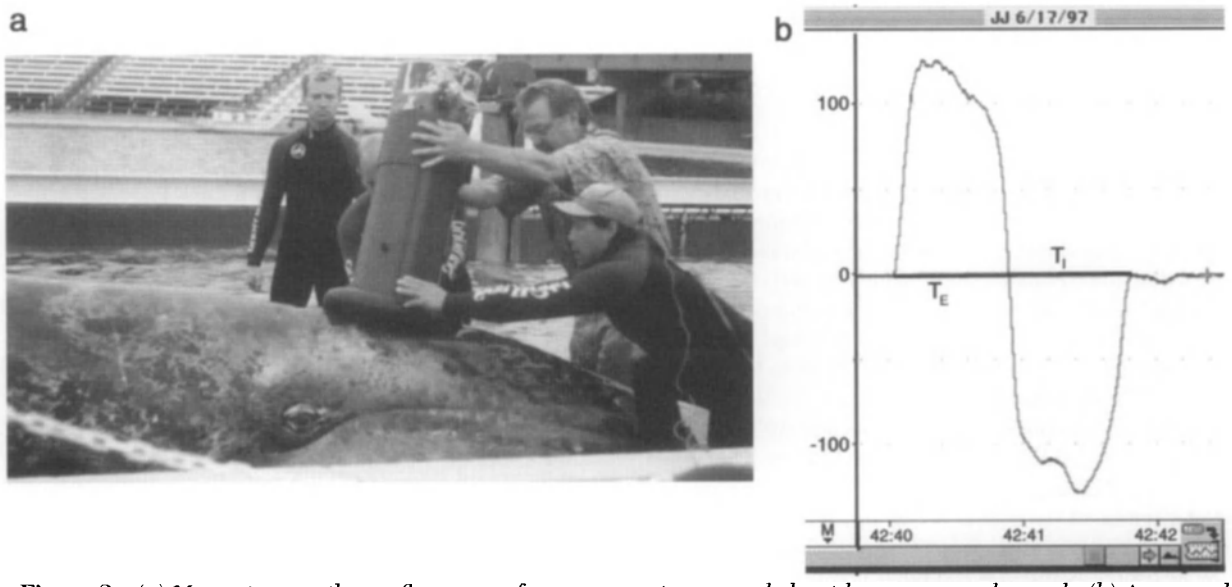

Figure 2 *(a) Measuring ventilatory flow rates of a young captive gray whale with a pneumotachograph. (b) An example of a single expiratory/inspiratory event (vertical scale = flow rate, l/sec; horizontal scale = time, min, sec).*

period of breath holding, or apnea. The rapid expiration of a typical whale blow (from as little as 0.3 sec in small dolphins and porpoises to 1–2 sec in large baleen whales) provides more time to complete the next inspiration as the blowhole of a swimming animal breaks through the sea surface and results in little delay before submerging again (Kooyman and Cornell, 1981).

The rapidity of the blow is accomplished by maintaining high flow rates throughout almost the entire expiration, which is in strong contrast to humans and other land mammals. The high expiratory flow rates of cetaceans are enhanced by very flexible chest walls and by cartilage reinforcement of the smallest terminal air passages of the lungs to prevent them from collapsing until the lungs are almost completely emptied.

Rates of air flow during a blow are measured with a pneumotachograph (Fig. 2), a device that measures instantaneous flow rates through the duration of the blow, which can be integrated over time to determine the volume of expired air for each blow. The largest lung volume measured in this manner was nearly 200 liters for a 10-month-old gray whale, and lung volumes approaching 5000 liters are estimated for very large blue whales (*Balaenoptera musculus*).

Blow patterns of whales vary, depending on their behaviors. In small dolphins and porpoises SWIMMING at low SPEEDS, blowhole exposure during a blow is minimal and gradually changes to porpoising above the sea surface at higher speeds. Porpoising behavior may serve to conserve energy because it is the most efficient way to breathe at high swimming speeds (Fish and Hui, 1991). When migrating, larger whales typically surface to blow several times in rapid succession and then make an extended dive of several minutes duration (Fig. 3). In this

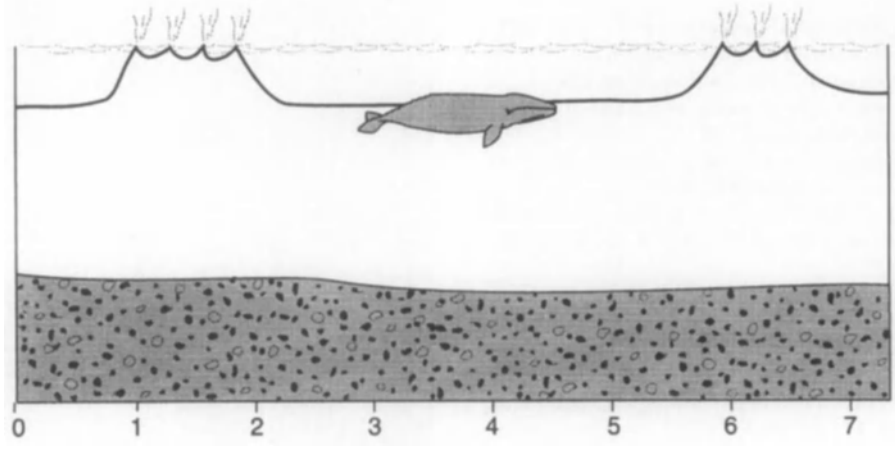

Figure 3 *Typical blowing and diving pattern of a migrating gray whale.*

manner, they reduce the amount of time they spend in the zone of high fractional drag near the sea surface. Thus, blowing in these mammals represents their best compromise in satisfying their oxygen demands while simultaneously avoiding large additional costs of energy for locomotion.

Blubber

SARA J. IVERSON
Dalhousie University, Halifax, Nova Scotia, Canada

Blubber, a dense vascularized layer of fat beneath the skin, is one of the most well-known and universal characteristics of marine mammals. Although it is not strictly present in polar bears (*Ursus maritimus*) or sea otters (*Enhydra lutris*), all cetaceans, sirenians, and pinnipeds have blubber and it may comprise up to 50% of the body mass of some species at certain life stages. Blubber has long been recognized as the primary and most important site of fat, and thus also energy, storage in marine mammals. However, blubber also has a number of other important functions. The blubber layer serves as an insulator in mammals living in often cold marine environments and is thus central to their entire process of thermoregulation. Blubber also affects buoyancy and functions as a body streamliner and elastic spring for efficient hydrodynamic locomotion. Although blubber is a dynamic tissue, which can reflect both nutritional state and life history stage of individuals, the tissue itself has likely evolved to best suit the lifestyles, stresses, and constraints of specific groups and even individual species of marine mammals. Hence, the study of blubber can provide unique insights not only into phylogenetic relationships and environmental adaptations, but also into aspects of individual feeding habits, foraging ecology, species DISTRIBUTION and demography that are otherwise difficult to study.

I. Structure of Blubber

A. Tissue Characteristics

Blubber is a specialized subcutaneous layer of fat found only in marine mammals and is different from other types of adipose tissue in that it is anatomically and biochemically adapted to serve as an efficient and adjustable thermal insulator. The blubber layer is almost continuous across the body of marine mammals, lying over (but not tightly fixed to) the underlying musculature but absent on appendages. Although nearly continuous, the thickness, structure, and biochemical composition of the blubber can vary greatly over the body of an individual in some species, and these differences are likely associated with localized differences in function. Consistent with its role as an insulator, there also usually exists a thermal, as well as biochemical, gradient through the depth of the blubber layer. The outer layer (nearest the skin) is usually cooler than the inner layer (nearest the muscle or body core) and activities of individual enzymes in each of these locations may be adapted to function at the different respective temperatures. The polar bear also deposits huge quantities of fat subcutaneously, which likely provides some degree of insulation. However, this superficial adipose tissue does not appear to be a specific anatomical adaptation for that purpose as it does not differ in structure from the superficial fat depots of other large terrestrial carnivores (Pond *et al.*, 1992).

Blubber, like other adipose tissue, is composed of numerous fat cells called adipocytes. Adipocytes develop prior to filling with fat and are composed, like other cells, of mostly protein and water. Once developed, adipocytes can alternately fill and empty with lipid and thus can change greatly in size. Mature adipocytes are generally large and spherical and packed densely into adipose tissue. The cells are surrounded and held in place by a mesh of structural collagen fibers. While most other types of adipose tissue contain small to moderate amounts of collagen, blubber is distinct in being greatly enriched in collagen and elastic fibers. This gives blubber a firm, tough, and fibrous character from which it derives much of its mechanical and functional properties. The histological structure of the blubber in pinnipeds is relatively uniform throughout its depth. However, in some cetaceans, there is a distinct stratification of the tissue into an inner, middle, and outer layer based on the size, shape, and metabolic characteristics of adipocytes, as well as on the lipid and collagen content of the tissue. Blubber also contains numerous blood vessels and specialized shunts called arterio-venous anastomoses (AVAs), which allow larger and swifter blood flow than would be possible through capillaries alone and are important to the thermoregulation process. The blubber of manatees is unusual in that a layer of muscle is imbedded in the middle of the ventral blubber layer; however, a possible functional significance for this arrangement is not known.

B. Variation in Thickness and Proximate Composition

The thickness of the blubber layer varies among species. In general, because body volume increases more rapidly than body surface area, larger species tend to have greater maximum blubber thickness. Thus, the depth of the blubber layer can be commonly 7–10 cm in adult pinnipeds, 20–30 cm in fin whales (*Balaenoptera physalus*), and up to 50 cm in the bowhead whale (*Balaena mysticetus*). In contrast, in one of the smallest odontocetes, the harbor porpoise (*Phocoena phocoena*), blubber depth generally reaches only 2.5–3.0 cm.

Beyond general species characteristics, the amount, depth, and chemical composition of the blubber also vary with age, nutrition, and reproductive status. The adipose tissue of many newborn mammals is empty of lipid, filling quickly after birth during the lactation period. Proliferation of fat depots in immature mammals is due to an increase in both adipocyte numbers and size. However, in adults, changes in the size of fat depots are primarily due to filling or emptying of adipocytes. The same appears largely true in the case of blubber. Although neonates of large baleen whales are born with a blubber layer that is several centimeters thick, most pinniped neonates are born with very little blubber, at less than 3 mm in depth in some otariids and accounting for less than 5–6% of body mass in most phocids. Most newborn pinnipeds rely instead primarily on fur and delayed entry into the water. For instance, in newborn harp seals (*Pagophilus groenlandicus*), blubber represents less than 6% of body mass and contains only 20% lipid (Worthy and Lavigne, 1983). This changes rapidly during the 12-day lactation period, such that the blubber of a newly weaned harp seal can comprise up to 50% of body mass and contains greater than 90% lipid, representing abundant and replete fat cells. In contrast, during reduced food intake or fasting, lipid is mobilized rapidly from adipocytes and hence undernourished marine mammals are characterized by greatly reduced blubber thickness and lipid content. Likewise, during annual events associated with fasting, such as lactation or molting in some species, blubber is also reduced in depth and lipid content with fat mobilization. For instance, the sternal blubber of female harbor seals (*Phoca vitulina*) changes during the 24-day lactation period from 3.8 to 1.4 cm in depth and from 92.3% lipid, 2.2% protein, and 5.5% water to 76.9% lipid, 5.9% protein, and 17.2% water (Bowen *et al.*, 1992); i.e., the increases in protein and water content reflect the larger proportion of "emptier" fat cells.

C. Lipids in Blubber

Depot lipid in animals is stored predominantly as triacylglycerols, which consist of three fatty acids esterified (i.e., linked by an ester bond) to a glycerol (three-carbon alcohol) molecule. The synthesis, storage, and catabolism of fatty acids are the components of lipid energy metabolism. Fatty acids in the marine food web are exceptionally complex and are characterized by high levels of long-chain polyunsaturated fatty acids (PUFA). During digestion of triacylglycerols by mammals, fatty acids are released from the glycerol backbone but not degraded and they are carried in the bloodstream and taken up by tissues the same way. These fatty acids are then either used for energy or stored as triacylglycerols in adipose tissue. Thus, fatty acids travel up the food chain intact, and because the kinds of fatty acids that can be biosynthesized or modified in mammals are quite limited, most fatty acids found in marine mammal blubber arise from the dietary intake of fish and other prey lipids. Hence, marine mammal blubber lipid is usually characterized by high levels of long-chain PUFA as well as unique fatty acids produced at lower trophic levels of the marine ecosystem.

Marine mammals, like other mammals, can also synthesize some of their own fatty acids from sources such as dietary amino acids consumed in excess of body needs (glucose would be another source but is scarce in diets of marine mammals). These synthesized fatty acids are usually restricted to those with 16 or 18 carbon atoms and usually, at most, one double bond (i.e., 16:0, 16:1n-7, 18:0, and 18:1n-9). Although these fatty acids are also common in all prey items of marine mammals, some are undoubtedly deposited in marine mammal blubber from biosynthesis.

The are several exceptions to the general characteristics of marine mammal blubber lipids described earlier. In addition to the usual fatty acids that are synthesized by all mammals, one very unusual fatty acid, isovaleric acid, is also found in the blubber of some species of toothed whales (odontocetes), which can arise only from biosynthesis. Isovaleric acid is unusual in that it is both very short (5 carbons) and branched. When present, it is found in highest concentrations in the outermost layer (nearest the skin) of blubber (Koopman *et al.*, 1996). Additionally, besides the most common form of storage lipid, triacylglycerols, some marine mammals (primarily some of the odontocetes) store some or all of their fatty acids in blubber as wax esters. A wax ester is a single fatty acid esterified to a long chain (22–34 carbon) alcohol. In general, wax esters are firm, stable, and resistant to degradation. This is why sperm whale (*Physeter macrocephalus*) oil was popular as an illuminant in the last century.

II. Role of Blubber in Temperature Regulation: Heat Conservation and Dissipation

As a whole body envelope of insulation, blubber is central to thermoregulation in marine mammals. Marine mammals, like all mammals, are homeothermic endotherms and hence need to maintain a stable body core temperature of about 37°C in cooler (usually <25°C) and often much colder (−1–5°C) fluid environments. Additionally, heat is always lost far more rapidly to water than to air because the thermal conductivity of water is 25 times that of air. There are several ways marine mammals have dealt with this problem. One is to increase body size, which decreases the surface-to-volume ratio and thus provides less surface area per unit volume over which to lose heat. Even the smallest marine mammals are considered large mammals, being one to two orders of magnitude larger than small terrestrial mammals such as rodents and insectivores. Additionally, and perhaps more importantly, large body size generally allows for thicker insulation (be it fur or blubber), which further decreases heat conductance.

Although fur is a far more effective insulator than blubber in air (and is used as the sole means of insulation by sea otters), fur acts by trapping pockets of air (a poor thermal conductor) among hairs, which then forms the effective insulative layer. Thus potentially when fur is wetted, but more significantly when diving under pressure (as most marine mammals do), fur gets compressed, expelling the air layer and thus losing its insulative properties. In contrast, blubber does not compress with depth and it is a good insulator because, like air, it has a lower thermal conductivity than water.

Adipose tissue is also less metabolically active than other tissues and thus requires less perfusion by blood, which would

otherwise tend to cause heat loss at the body surface. Nevertheless, because blubber is vascularized, circulatory adjustments allow both heat conservation and dissipation as necessary. An important means of regulating heat transfer in marine mammals is by restricting and diverting blood flow through the blood vessels and AVAs in blubber. Restricting blood flow to the blubber's surface (i.e., skin) conserves body heat and allows blubber to act as an effective insulator against cold. Conversely, increasing blood flow into the blubber allows sometimes massive redistribution and dumping of body heat in cases of either very warm water or air or during intense activity (e.g., Heath and Ridgway 1999).

The effectiveness of blubber as an insulative layer depends on its thickness, lipid content, and lipid composition. As an insulation layer increases in thickness, the lower critical temperature of an animal decreases and thus the animal can accommodate a broader ambient temperature range without having to increase its metabolism for heat production (i.e., to remain thermoneutral). As mentioned previously, many marine mammals, especially those of larger body size, possess a thick blubber layer, allowing them to remain thermoneutral at most of the temperatures of the world's oceans and, for some pinnipeds, even at air temperatures of −10 to −20°C on polar ice. However, smaller species are limited in the depth of blubber they can carry and also have relatively more surface area over which to lose heat. Hence most of the smallest cetaceans do not occur at high latitudes. Less insulation increases the lower critical temperature of an animal and requires increased metabolism for heat production. The harbor porpoise is the smallest cetacean species to inhabit temperate waters of the Northern Hemisphere. Although its blubber depth is only several centimeters thick, it is generally twice the thickness and contains more lipid than does a similarly sized dolphin inhabiting tropical waters. These properties appear to confer up to four times greater insulative capacity (Worthy and Edwards, 1990).

Depletion of lipid from blubber stores will decrease the insulative capacity of the tissue and may seriously compromise an individual, especially if nutritionally stressed. Thus, small species such as the harbor porpoise must feed nearly continually to maintain metabolism and to preserve their blubber's thickness and insulative capacities. In contrast, large whales can fast and mobilize blubber reserves for weeks or months, yet can remain thermoneutral due to a low surface-to-volume ratio as well as the maintenance of a still relatively thick blubber layer. Especially in cetaceans, the thickness, structure, and insulative properties of the blubber may vary across different regions of the body and thus the function of the blubber as an insulator may also vary regionally.

Variation in the lipid composition of blubber may also confer differing insulative capacities. As stated previously, the blubber of marine mammals is composed of large amounts of unsaturated fatty acids. Unsaturated fatty acids have lower melting points than saturated fatty acids. Thus even when the temperature of the outermost layer of the blubber and skin is near that of cold ambient temperatures, blubber tissue can remain fluid and an effective insulator if the melting point of its fatty acids is low. Saturated and monounsaturated fatty acids abundant in marine mammal blubber (e.g., 16:0, 16:1, 18:0, 18:1) have melting points of 13–70°C. However, nutritionally important polyunsaturated fatty acids are usually plentiful in marine mammal diets and thus in blubber, conferring an overall melting point in blubber lipid of less than −15°C. Additionally, in some small cold-water cetaceans such as the harbor porpoise, Dall's porpoise (*Phocoenoides dalli*), the bottlenose dolphin (*Tursiops truncatus*), and the beluga (*Delphinapterus leucas*), high concentrations of the very unusual branched short-chain isovaleric acid are biosynthesized and deposited in blubber (see earlier discussion). Isovaleric acid has an extremely low melting point of −37.6°C, which clearly provides fluidity to especially the outer blubber layer of these animals (e.g., Koopman *et al.*, 1996). Although the exact physiological function of isovaleric acid is not understood, its presence may contribute to the superior insulative properties observed previously in harbor porpoise blubber. In contrast to most other marine mammals, while manatees (*Trichechus* spp.) can also store large amounts of blubber, they generally do not tolerate temperatures below 20°C. As plant eaters, manatees must synthesize the majority of their blubber fatty acids, which would thus be restricted in their degree of unsaturation. However, little is known about the effectiveness of manatee blubber as an insulator in cold temperatures or the role that lipid composition might play in this ability.

III. Role of Blubber in Energy Storage and Water Balance

Blubber, as a rich energy store, is important in the lives of marine mammals because of the critical role that stored lipid plays in their ecology, reproduction, and survival. Perhaps surprisingly, even though marine mammals obviously live in the environment within which they also forage, reproduction and especially lactation are often spatially and temporally separated from their feeding grounds. For instance, the greatest areas of feeding activity for the large baleen whales are in polar regions during the high primary productivity of summers. However, they migrate in winter to warm tropical waters of low food availability to give birth and nurse their young. In phocid and otariid pinnipeds, parturition and lactation occur on land or ice and thus these activities are also separated from the feeding environment of the lactating female.

In all female mammals, lactation represents the greatest energetic cost of reproduction, requiring large amounts of nutrient transfer and elevated maternal maintenance costs. Hence, lactation is usually associated with increased maternal food consumption. However, because large energy reserves can be stored in blubber in the form of lipid, baleen whales and large phocid seals are the only mammals (besides holarctic bears) that can complete much or all of lactation without feeding. Again, because a smaller body size constrains the size of blubber stores, the smaller phocids and otariids are able to fast for only portions of lactation. All species of marine mammals produce high fat milks (usually 30–60% fat) to maximize the efficiency of fat transfer from maternal blubber into milk and the subsequent efficiency of neonatal fattening and growth. In species that fast throughout lactation, females switch almost completely to a fat-based metabolism. For instance, during a 16-day lactation period, a gray seal (*Halichoerus grypus*)

female draws 97% of the energy required for her own metabolic needs and 90% of the milk energy supplied to her pup solely from her blubber stores. Furthermore, the extent to which she can both maintain lactation and produce a fat pup depends on the size of the blubber layer she starts out with (Mellish *et al.*, 1999). Fasting female polar bears, which begin the first 3–4 months of lactation in winter dens, use their extensive subcutaneous adipose tissue in a similar manner.

Blubber deposition is equally critical to the suckling neonate, both for thermoregulation and to act as an energy reservoir. For example, most newly weaned phocid pups rely on blubber deposited during the suckling period to survive their own subsequent fast of several weeks or months after their mothers have departed the breeding grounds. The energy supplied from blubber is critical to survival of the young while they learn how to forage on their own.

Adult males of many marine mammal species also fast or greatly reduce food intake during the breeding season and during their annual molting period. During these times they rely on stored lipid in blubber as their energy source. Sirenians also use blubber during fasting. For instance, in the Amazon, manatees (*Trichechus inunguis*) face dry seasons of up to 6 months at a time, where low waters restrict them to the deep water areas of larger lakes where the aquatic plants they feed upon are unavailable. Hence food intake during these periods is nil.

Finally, besides being an important fat and energy source for marine mammals, blubber is a critical source of water that is essential to maintaining water balance during fasting. Each kilogram of lipid that is mobilized from blubber and oxidized for energy use by an animal generates a net production of 1.07 kg of metabolic water. In fact, oxidation of blubber yields enough water such that individuals usually do not require an additional external source. This is true even of lactating females that are exporting large quantities of water in milk daily. For instance, a gray seal female exports about 23 kg of water in milk over a 16-day lactation period while fasting and has no external access to water during this time (Iverson *et al.*, 1993). Thus, in most species, blubber functions to maintain both water balance and energy metabolism during periods of fasting.

IV. Role of Blubber in Locomotion

Several forces act on animals swimming in fluids, and blubber plays a significant role in the way marine mammals deal with these forces. The predominant restrictive force is drag, but the vertical forces of gravity and buoyancy also exist. Drag is the force that resists the movement of a body through a medium and is much greater in seawater than in air due to seawater's higher density and greater viscosity. The single most effective way to reduce both drag and the power required for forward motion through a fluid is to have a smooth streamlined shape. Although all marine mammals tend to be somewhat streamlined in body shape as defined by their musculoskeletal system, blubber provides their form with a smooth sculpted contour. Blubber thickness is often distributed across an animal in a nonuniform manner that ensures this. For instance, the blubber over the hind end of a seal may be thicker than would be necessary for insulative purposes. The blubber layer here instead serves to taper the animal more gradually than would be dictated by the musculoskeleton. In fact, another very important means by which to reduce drag on a body is to be spindle shaped, i.e., to have a gradually tapering tail end. This acts to reduce the wake left by the animal moving through the water and hence further reduces the forces of drag. Again, blubber creates this effect in cetaceans by a thickening and sculpting of the tailstock (Pabst *et al.*, 1999). This locomotor function may actually constrain the way in which animals utilize their blubber as energy reserves. In large baleen whales as well as the smallest harbor porpoise, blubber may be greatest in depth and fat content, even during nutritional stress, in the posterior dorsal and tail areas of the body (Lockyer, 1987; Koopman, 1998), as blubber in these areas serves important locomotory functions by both streamlining and possibly acting as a biomechanical spring, capable of temporarily storing and releasing elastic strain energy (Pabst, 1996).

Finally, blubber also plays a role in the buoyancy of marine mammals. Buoyancy is the force that acts on a body submerged in water where, if the mass of the body is greater or less than the volume of water it displaces, it will experience either a net downward or net upward force, respectively. In most marine mammals (except the sea otter), buoyancy will be determined primarily by the ratio of its adipose tissue to lean body tissue and body mass. Fat-filled adipose tissue is less dense than seawater, whereas lean tissue is more dense. Thus, the degree to which marine mammals store blubber will affect their buoyancy and thus the energy expended in moving or maintaining position in water. Although some newly weaned phocid pups may be positively buoyant at greater than 43% adipose tissue, most adult marine mammals will not be positively buoyant and thus are not likely to require any counteracting of this force when at the bottom of dives or when feeding at the benthos. However, changes in blubber stores will clearly affect the degree to which they are negatively buoyant. Only two studies of pinnipeds have directly addressed the degree to which buoyancy affects diving in marine mammals. Both studies found that seals descended faster during diving when they were more negatively buoyant than when they were less negatively buoyant, providing evidence that seals adjust their diving behavior in relation to seasonal changes in buoyancy (Webb *et al.*, 1998; Beck *et al.*, 2000).

V. Insights from the Study of Blubber

Marine mammals are widely distributed in tropical, temperate, and cold oceans of the world and show a diversity of distributional patterns and apparent physiological adaptations. However, our understanding of these patterns, as well as of the foraging ecology of most marine mammals, is hindered by the difficulties in observing free-ranging animals that spend most or all of their lives at sea. Blubber is clearly of central importance to the structure and function of marine mammals. Due to the fact that the composition and amount of blubber carried by an individual can change rapidly and yet blubber has evolved to serve complex functions, its study can provide unique insights into the lives of marine mammals as well as the ecosystems in which they live.

The ultrastructure, thickness, and proximate composition of blubber can provide insights into the feeding status of individuals as well as the functional significance of the blubber itself. As stated previously, the proximate composition, especially lipid content, of blubber changes radically in response to feeding and fasting behavior and thus, along with other nutritional indices, may be used to indicate nutritionally stressed versus robust individuals. Because many marine mammals go through predictable annual periods of fasting and fattening, the proximate composition of blubber can also be used to indicate the life cycle stage of an individual. In some cetaceans, the characteristics of blubber differ greatly across sites of the body and thus study of these properties can provide insight into the functions of blubber. For instance, the structure and composition of blubber at specific sites suggest that in some areas on the body (e.g., the thoracic–abdominal area) blubber may play a more important role in insulation and energy storage, whereas at other sites (e.g., the thick ridge posterior to the dorsal fin or at the caudal peduncle) blubber may serve more important roles in maintaining hydrodynamic shape and other locomotory functions (Koopman, 1998; Pabst *et al.*, 1999). Thus, the study of how blubber at these various sites is utilized during times of fat mobilization may provide further insight into adaptations of blubber structure. For example, the finding that blubber in the area of the caudal peduncle is rarely used and always thicker than needed for insulation, even during severe nutritional stress, lends support to the hypothesis that it may be more important in that region for structural support and locomotory functions than as an insulator or energy provider.

Blubber can also provide insight into adaptation and phylogenetic relationships. For instance, the characteristic of storing blubber lipid primarily as wax esters appears to be confined to a group of the odontocetes (i.e., beaked whales and the sperm whale). The species in which blubber consists primarily of wax esters, although all closely related, are also all deep divers. Hence the study of their blubber may provide insight into phylogenetic patterns as well as roles that wax esters may play in deep-diving animals. The presence of isovaleric acid is likewise confined to a fairly restricted group of animals, which also may be under special thermal constraints (see earlier discussion). Thus the study of isovaleric acid in blubber may provide clues to its function and potential value in insulation. Additionally, in at least one species, the presence of isovaleric in the outer layer of blubber increases in direct proportion with age, suggesting the possibility of using its level in blubber to estimate ages of unknown individuals in the same population (Koopman *et al.*, 1996).

Finally, the fatty acids in blubber can provide powerful insights into the foraging ECOLOGY and diets of both individuals and populations of marine mammals. As stated previously, fatty acids in the marine ecosystem are complex and diverse, fatty acids often travel up the food chain intact, and there are narrow limitations on their biosynthesis in marine mammals. Hence the fatty acids of marine mammal blubber arise in large part from dietary intake and therefore can be used to study aspects of diet and foraging ecology (Iverson, 1993). Given the dynamic nature of lipid mobilization and deposition in marine mammal blubber, fatty acids can provide insight into diets over both time and space. Studies on wild and captive animals demonstrate that there is direct deposition of dietary fatty acids in both marine mammals and their prey and that the influence of dietary fatty acid intake on blubber composition can be both substantial and predictable. In seals, ingested fatty acids can be deposited directly into adipose tissue, such that blubber composition may mirror that of diet when a seal is rapidly fattening on a high-fat diet (Iverson *et al.*, 1995), or blubber may reflect an integration of diet over a period of weeks or months even when not fattening (Kirsch *et al.*, 2000). Blubber fatty acids have been used to detect differences in diets both among and within populations of various pinnipeds, including the distinction of species and populations occupying freshwater vs marine habitats. For instance, in harbor seals, blubber fatty acids have been used to assess when fasting lactating females resumed feeding (Smith *et al.*, 1997) and to elucidate the use of spatial scales of foraging in Alaska populations across both large (400–800 km) and small geographical (10–50 km) scales (Iverson *et al.*, 1997).

A blubber biopsy (100–500 mg) from a free-ranging animal provides relatively noninvasive information about diet that is not dependent on prey with hard parts, nor limited to only the last meal, as are analyses of fecal or stomach contents. This is accomplished most easily in pinnipeds where, using a medical biopsy punch, one can safely obtain a complete sample through the full depth of 5–10 cm. However, in cetaceans, blubber is generally much thicker and layering of fatty acids in the blubber is more pronounced, with dietary fatty acids being most reflected in the inner and middle layers nearest the deep body core. Thus, less work has been done on live animals in these species.

In conclusion, blubber plays a number of major roles in the lives of marine mammals. Blubber can also be a powerful tool in trying to understand adaptive solutions of species living in marine environments, as well as insights into their ecology and behavior.

Blue Whale

Balaenoptera musculus

Richard Sears
Mingan Island Cetacean Study, Inc.,
Longue Pointe de Mingan, Quebec, Canada

The blue whale, *Balaenoptera musculus* (Linnaeus, 1758), is a baleen whale belonging to the family Balaenopteridae, which includes the group of cetaceans known as rorquals (Fig. 1). Common names are blue whale, sulfurbottom, Sibbald's rorqual, great blue whale, and great northern rorqual. The largest animal known to have existed on Earth, it is found worldwide, ranging into all oceans. Because of its great size and the commercial value of the products it yielded, the blue whale was hunted relentlessly beginning in the late 1800s. The greatest number of blue whales was taken from the early 1900s until the late 1930s, with the peak being in the 1930–1931 season when nearly 30,000 were killed. The height of blue whale whaling coincided with the advent of explosive harpoons, steam power vessels, and the construction of factory ships, which could process whale carcasses at sea. The blue whale was severely depleted by whaling, particularly in the Southern Hemisphere, where during the first half of the 20th century 325,000–360,000 were killed in Antarctic waters alone. A further 11,000 were taken in the North Atlantic, primarily in Icelandic waters and 9500 in the North Pacific. This unbridled hunt for blue whales, which lasted until its worldwide protection in 1966, brought the blue whale to the brink of extinction and it is still an endangered species today.

I. Diagnostic Characters

On average, Southern Hemisphere blue whales are larger than Northern Hemisphere animals, with the largest recorded at lengths of 31.7–32.6 m (104–107 feet) and 33.6 m (110 feet) for individuals caught off the South Shetlands and South Georgia. The largest blue whale recorded for the Northern Hemisphere was a 28.1-m (92 feet) female reported in whaling statistics from catches in Davis Strait. In the North Pacific female blue whales of 26.8 m (88 feet) and 27.1 m (89 feet) have been recorded. A 190-ton female was reported taken off South Georgia in 1947; however, body weights of adults generally range from 80 to 150 tons. For maximum size descriptions, female measurements are used because female baleen whales are larger than males.

Blue whales are observed most commonly alone or in pairs; however, concentrations of 50 or more can be found spread out in areas of high productivity. Blue whales project a tall (up to 10–12 m) spout, denser and broader than that of the fin whale, (*B. physalus*) which in calm conditions can help distinguish between the two species. When surfacing, the blue whale raises its massive shoulder and blowhole region out of the water more than other rorquals. The prominent fleshy ridge just forward of the blowhole, known as the "splash guard," is strikingly large in this species.

When seen from above, blue whales have a tapered elongated shape, with a huge broad, relatively flat, U-shaped head, adorned by a prominent ridge from the splash guard to the tip of the upper jaw or rostrum and massive mandibles (Fig. 2). The baleen is black, half as broad as its maximum 1-m length and 270–395 plates can be found on each side of the upper jaw (Yochem and Leatherwood, 1985). There are 60–88 throat grooves or ventral pleats running longitudinally parallel from the tip of the lower jaw to the navel, which enable the throat or ventral pouch to distend when feeding.

The dorsal fin, proportionally smaller than in other balaenopterids, yet varied in shape, ranging from a small nubbin to triangular and falcate, is positioned far back on the body.

Blue whales have long blunt-pointed flippers, slate gray, with a thin white border dorsally and white ventrally, reaching

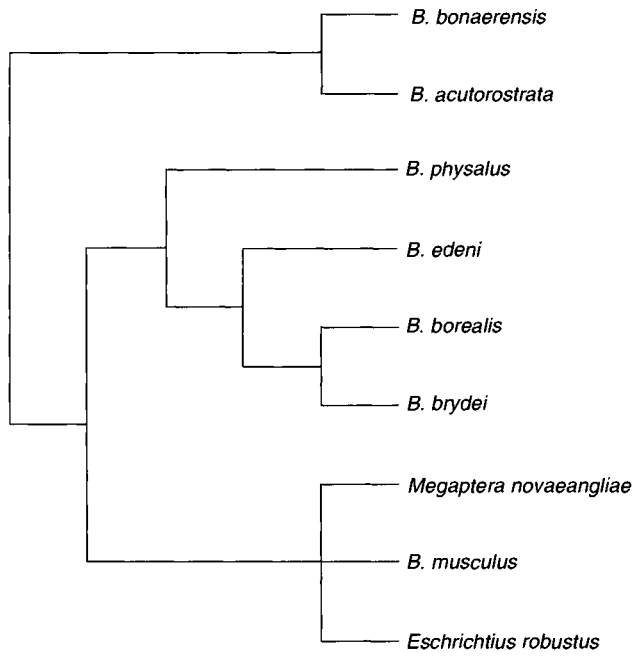

Figure 1 *Phylogenetic relationships among the species of the genera* Balaenoptera, Megaptera, *and* Eschrichtius *based on several DNA sequencing studies.*

up to 15% of their body length. In the field, particularly on bright days, blue whales generally appear much paler in coloration than all species of large whale except for the gray (*Eschrichtius robustus*), with which it should not be confused due to a great difference in size.

The characteristic mottled pigmentation of blue whales is a blend of light and dark shades of gray displayed in patches of varying sizes and densities (Fig. 3). The pigmentation is slate blue on overcast days to silvery or turquoise blue on bright sunny days depending on the clarify of the water. The mottling is found along the body dorsoventrally, occasionally on the flippers, but not on the head and tail flukes. Two prominent pigmentation configurations are found in blue whales, one where a darker, dominant background is mottled with sparser pale patches of pigmentation, while in the other there is a predominantly pale background mottled with sparser dark patches. Blue whale pigmentation can vary, however, from very sparse mottling, where the individual appears uniformly pale or dark, to densely mottled individuals, where the pigmentation is a highly contrasted variegation of spots unique to each whale. Distinct chevrons curving down and angled back from the apex on both sides of the back behind the blowholes and either pale

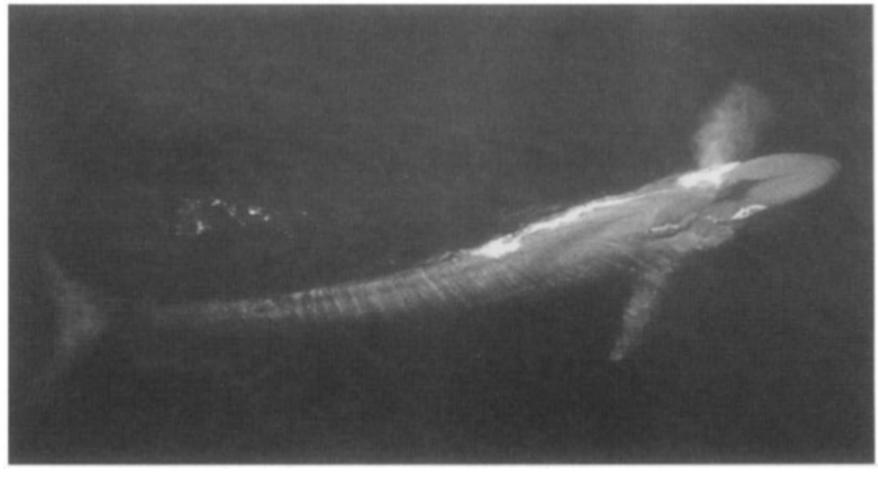

Figure 2 *Blue whale, aerial view. Richard Sears, MICS Photo.*

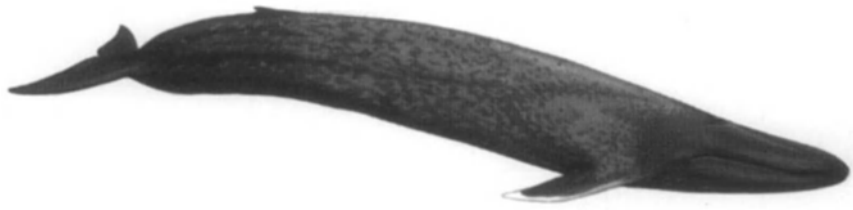

Figure 3 *Blue whale showing the characteristic mottled pigmentation of the species. Drawing by Daniel Grenier.*

or dark in tone can be found on certain blue whales. Blue whales are individually identified from the distinctive mottled pigmentation found on their back and sides.

A yellow-green to brown cast, caused by the presence of a diatom (*Cocconeis ceticola*) film, can be seen covering all or part of the body of blue whales found in cold waters. The yellowish, diatom-induced tint is the reason the "sulphur-bottom" moniker was once used for blue whales.

Although not noted for raising their flukes when diving, approximately 18% of blue whales observed in the western North Atlantic and northeast Pacific do so. This is an individual characteristic, and if the individual is relaxed it will generally raise its flukes high up in the air on each sounding dive. When disturbed, blue whales that raise their flukes when diving will often not raise their tails as high out of the water or not at all and dive more quickly from the surface. The tail flukes, sometimes striated ventrally, are predominantly gray above and below; however, some individuals do have white patches of pigmentation on the ventral surface that are used for individual identification. The trailing margin of the tail is either straight or curves very slightly from each tip to the median notch.

II. Distribution and Migration

Three subspecies have been designated: what has been considered the largest, *B. musculus intermedia*, found in Antarctic waters; *B. musculus musculus* in the Northern Hemisphere; and *B. musculus brevicauda*, from the subantartic zone of the southern Indian Ocean and south western Pacific Ocean, also colloquially known as the "pygmy" blue whale. Although the latter designation is now generally accepted, its validity still remains in question. Despite having being reduced greatly due to whaling, the blue whale remains a cosmopolitan species separated into populations from the North Atlantic, North Pacific and Southern Hemisphere (Fig. 4). In the North Atlantic, eastern and western subdivisions are recognized. Photo-identification work from eastern Canadian waters indicates that blue whales from the St. Lawrence, Newfoundland, Nova Scotia, New England, and Greenland all belong to the same stock, whereas blue whales photo-identified off Iceland and the Azores appear to be part of a separate population. The best known population in the North Atlantic is that found in the St. Lawrence from April to January, where 350 individuals have been catalogued photographically. Apart from the Icelandic and Azores sightings, few blue whales have been reported from eastern North Atlantic waters recently. North Atlantic blue whale abundance probably ranges from 600 to 1500 at this time, although more extensive photo-identification and shipboard surveys are needed for more reliable estimates.

In the North Atlantic, blue whales reach as far north as Davis Strait and Baffin Bay in the west, while to the east they travel as far north as Jan Mayen Island and Spitzbergen during summer months. Blue whales sighted recently in winter and spring off the Azores and Canary Islands could be migrating north along the mid-Atlantic ridge to Iceland, where they are seen from May to September. Other blue whales probably migrate along the European coast, far offshore and out around Ireland north to either Iceland or Norway. It is not clear where blue whales winter in the North Atlantic. Some have been observed in the St. Lawrence as late as February; however, acoustic studies have revealed that they are spread out across the North Atlantic basin, south as far as Bermuda and Florida, with concentrations south of Iceland, off Newfoundland and Nova Scotia. The southernmost observations on the eastern side of the North Atlantic are in the waters between the coast of Africa and the Cape Verde Islands (Yochem and Leatherwood, 1985).

In the North Pacific, where as many as five subpopulations were thought to exist, acoustic analysis of blue whale vocalizations now indicates there are no more than two. The best known is that from the eastern North Pacific where blue whales can be found as far north as Alaska, but are regularly observed from California in summer, south to Mexican and Costa Rican waters in winter. An abundance estimate of approximately 2000–3000 animals has been determined for this population, which has been studied extensively over a good portion of its range. From late fall to spring, blue whales can be found in the Gulf of California, Mexico, and south to offshore waters of central America. By April and May they migrate north along the West coast of North America, where a large proportion is found in California waters. From there some reach Canadian waters, and other groups may disperse north to the Gulf of Alaska or west toward the Aleutian Islands.

Few blue whales have been reported recently from the western North Pacific, including the Aleutian Islands, Kamchatka/Kurils/northern Japan, and southern Japan. In the western North Pacific, blue whales are thought to migrate to Kamchatka or the Kuril Islands and probably further northeast.

Blue whales are also found in the northern Indian Ocean; however, it is not clear whether these form a distinct population.

In the Southern Hemisphere, where the blue whale was historically most abundant, it is very rare today, with abundance estimates ranging from 710 to 1255, although reliable population assessment is poor due to limited sighting data. Al-

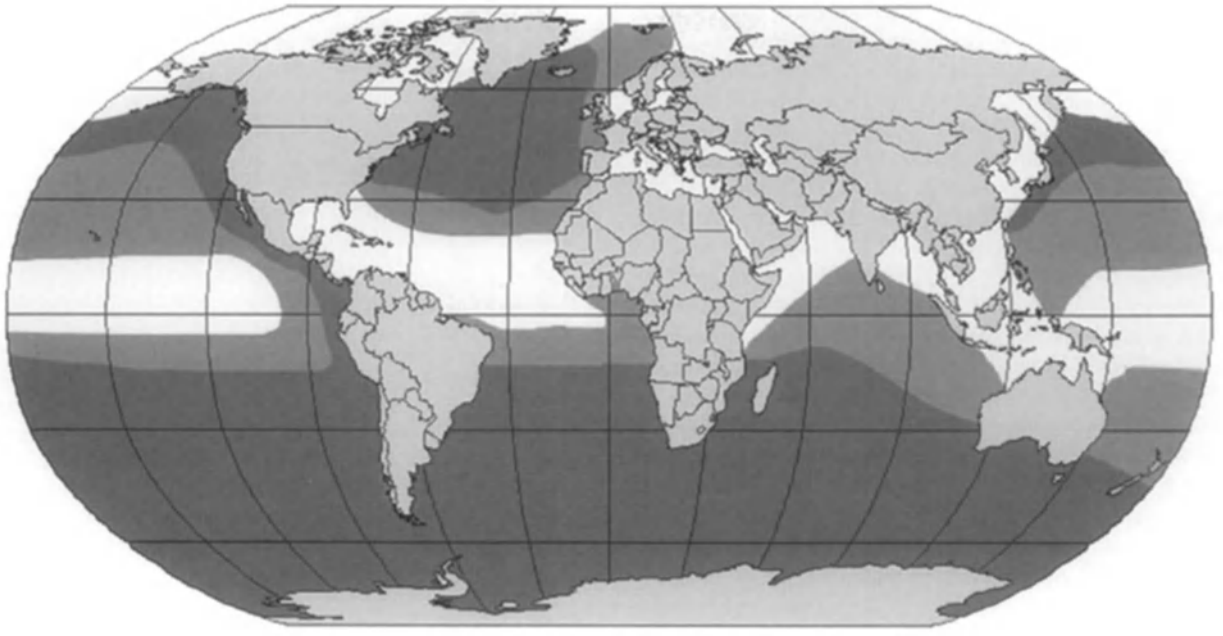

Figure 4 *Global distribution of blue whales. Darker gray indicates higher densities.*

though the general population structure in the Southern Ocean is not well understood, evidence shows discrete feeding stocks. Consistent with these feeding areas, the International Whaling Commission has assigned six stock areas for blue whales in the Southern Hemisphere.

III. Natural History and Ecology

A. Feeding

Food availability probably dictates blue whale DISTRIBUTION for most of the year. Although blue whales can be found in coastal waters of the St. Lawrence, Gulf of California, Mexico, and California, they are found predominantly offshore. Blue whales appear to feed almost exclusively on euphausiids (KRILL) worldwide in areas of cold current upwellings. When blue whales locate suitably high concentrations of euphausiids, they feed by lunging mouth wide open and gulping large mouthfuls of prey and water. The mouth is then almost completely closed and the water is expelled by muscular action of the distended ventral pouch and tongue through the still exposed baleen plates. Once the water is expelled, they swallow their prey.

When blue whales feed just a few meters below the surface, they often surface slowly, belly first, exposing the throat grooves of the ventral pouch, roll to breathe, and evacuate the water before diving to take their next mouthful. If the prey is close to the surface, blue whales lunge vigorously on their sides or lunge up vertically by projecting their cavernous lower jaws 4–6 m up through the surface. Although surface feeding has often been observed during the day, it is more usual for blue whales to dive to at least 100 m into layers of euphausiid concentrations during daylight hours and rise to feed near the surface in the evening, following the ascent of their prey in the water column. In the North Atlantic, blue whales feed on the krill species *Meganyctiphanes norvegica*, *Thysanoessa raschii*, *T. inermis*, and *T. longicaudata;* in the North Pacific, *Euphausia pacifica*, *T. inermis*, *T. longipes*, *T. spinifera*, and *Nyctiphanes symplex*. In Antarctic waters they prey on *E. superba*, *E. crystallorophias*, and *E. vallentini*.

When foraging or feeding at depth, blue whales will generally dive for 8–15 min; 20-min dives are not uncommon. The longest dive recorded was of 36 min; however, dives of more than 30 min are rare.

Blue whales generally swim at 3–6 km when feeding. When traveling, they can attain speeds of 5–30 km and when chased by boats, predators, or interacting with other blue whales, they can reach upward of 35 km.

B. Vocalization

Blue whales vocalize regularly throughout the year with peaks from midsummer into winter months. The majority of blue whale vocalizations are low frequency or infrasonic sounds of 17 to 20 Hz, lower than humans can detect. Blue whale sounds, at 188 decibels (louder than a jumbo jet at full power a few meters away), are one of the loudest and lowest made by any animal.

These calls can be heard easily for hundreds of kilometers, thousands of kilometers under optimal oceanographic conditions and may cover whole ocean basins. The low frequencies produced by blue whales are ideal for communication between individuals of a widely dispersed and nomadic species through water without much loss of information.

IV. Reproduction and Longevity

Blue whales reach sexual maturity at 5–15 years of age; however, 8–10 years appear to be more usual for both sexes. Length at sexual maturity in females from the Northern Hemisphere is

21–23 m and is 23–24 m in the Southern Hemisphere. Males reach sexual maturity at 20–21 m in the Northern Hemisphere and at 22 m in the Southern Hemisphere (Yochem and Leatherwood, 1985). Mating takes place starting in late fall and continues throughout the winter. Female blue whales give birth every 2–3 years in winter after a 10- to 12-month gestation period. The calves, which weight 2–3 tons and measure 6–7 m long at birth, are weaned when approximately 16 m long at 6–8 months. No specific breeding ground has been discovered for blue whales in any ocean, although mothers and calves are sighted regularly in the Gulf of California, Mexico, in late winter and spring. A portion of the northeast Pacific Ocean blue whale stock could be using this region as a breeding ground.

Little is known of their mating behavior; however, female/male blue whale pairings have been noted with regularity in the St. Lawrence from summer into fall, some lasting for as long as 3 weeks. When a female/male pair is approached by a third blue whale, even a fin whale, vigorous surface displays, where all three animals can be seen racing high out of the water, almost breaching, porpoising forward causing an explosive splash of a bow wave, can result. Such interactions between blue whales usually last for 5–15 min.

Blue whales are thought to live for at least 80–90 years and probably longer. What is certain, however, after extensive photo-identification fieldwork on known individuals in the St. Lawrence and northeast Pacific, is that they live for at least 31 years.

V. Mortality

Documentation of natural mortality in blue whales is rare. The blue whale's principal predator is the killer whale *Orcinus orca*, but there is little evidence of attacks on blue whales in the North Atlantic or Southern Hemisphere. However, in the Gulf of California, Mexico, 25% of the blue whales photo-identified carry rake-like killer whale teeth scars on their tails, indicating that attacks occur with some regularity but are probably rarely successful.

In the St. Lawrence, ice entrapment, where animals have been crushed, stranded, or suffocated by current and wind-driven ice floes in the late winter/early spring, has been reported.

While reports of blue whales approaching vessels are rare, at least 25% of the blue whales photo identified in the St. Lawrence carry scars that can be attributed to collisions with shipping. This type of scarring has been reported for a few northeast Pacific blue whales as well. Ship strikes in heavy shipping areas, such as the St. Lawrence and California coast, may have an impact on populations, but data are not available on this point.

Few entanglements in fishing gear have been reported, and it is thought that the size of the blue whale enables it to tear through fishing gear relatively unscathed.

Persistent contaminants accumulated over time, such as PCBs commonly found in blue whales from eastern Canadian waters, may have an impact on reproduction and limit the recovery of certain populations.

It has been shown that blue whales react strongly to approaching vessels. The degree of reaction depends on the whale's behavior, as well as the distance, speed, and direction of the vessel at the time of approach. The increasing anthropogenic noise probably has an impact on blue whales and their habitat and could also limit recovery of this species.

Bones and Teeth, Histology of

MARY C. MAAS
Northeastern Ohio Universities College of Medicine, Rootstown

The bones and teeth of marine mammals, like those of other vertebrates, consist of both organic and mineral components. Because the mineral component (mostly calcium phosphate) predominates, the constituents of bones (bone and calcified cartilage) and teeth (cementum, dentine, and enamel) are referred to as "hard tissues." Each of these hard tissues is distinguished both by its composition and by its microscopic structure. Many of the histological features of marine mammal teeth and bones are typical for mammals, and vertebrates, in general, but others are unique or unusual. Some of these may have evolved in conjunction with their shifts to marine habitats.

I. Bone

A. Bone Structure and Composition

Bone consists of highly calcified, intercellular bone matrix, and three types of cells: osteocytes, osteoblasts, and osteoclasts. The outer surface of bone is covered by periosteum, which is bound to bone by bundles of collagen fibers known as Sharpey's fibers, and the inner bone surface is lined with endosteum (Fig. 1). Periosteum is thicker than endosteum, but both consist of fibrous connective tissue lined with osteoprogenitor cells from which osteoblasts are derived. Osteoblasts are the cells that synthesize bone matrix proteins and are active in bone matrix mineralization. Bone matrix (also known as osteoid) consists of about 33% organic matter (mostly type I collagen) and 67% inorganic matter (calcium phosphate, mostly hydroxyapatite crystals). Osteoblasts occur as a simple, epithelial-like layer at the developing bone surface. As the bone matrix mineralizes, some osteoblasts become trapped in small spaces within the matrix (lacunae). These trapped osteoblasts become osteocytes, the cells responsible for maintenance of the bony matrix. Each lacuna holds only a single osteocyte but is connected with adjacent lacunae by microscopic canaliculi, which house cytoplasmic processes of the osteocytes. Osteoclasts are large, multinucleated cells that occur in shallow erosional depressions (Howship's lacunae) on the resorbing bone surface and secret enzymes that promote the local digestion of collagen and dissolution of mineral crystals.

Bone is commonly classified according to its gross appearance as cancellous bone (bone with numerous, macroscopic interconnecting cavities, or trabeculae, also known as spongy or trabecular bone) or compact bone (dense lamellar bone without trabeculae), but both types have the same basic histological structure. In a typical mammalian long bone the diaphysis (shaft) is composed predominantly of compact bone, with cancellous bone confined to the inner surface around a central, medullary cavity (Fig. 1a), whereas the epiphyses (articular ends) consist mostly of cancellous bone overlain by a thin, smooth layer of compact bone. In short bones a core of cancellous bone is completely surrounded by compact bone, and in the flat bones of the skull, inner and outer plates of compact bone are separated by the diploë, a layer of cancellous bone.

Bone also can be classified histologically, as woven (primary) bone and lamellar (secondary) bone. Woven bone, or primary bone, has an irregular structure and is usually replaced in adults by the more highly mineralized lamellar bone. Lamellar bone is organized into thin layers (lamellae), usually 3–7 μm thick, which contain parallel collagen fiber bundles. Lacunae containing osteocytes are located between lamellae. There are three types of lamellae: concentric, interstitial, and circumferential (Fig. 1b). Concentric lamellae are arranged in circular layers around a long axis, the haversian canal, which is a vascular channel containing blood vessels, nerves, and connective tissue. Adjacent vertical channels are connected by more horizontally oriented vascular

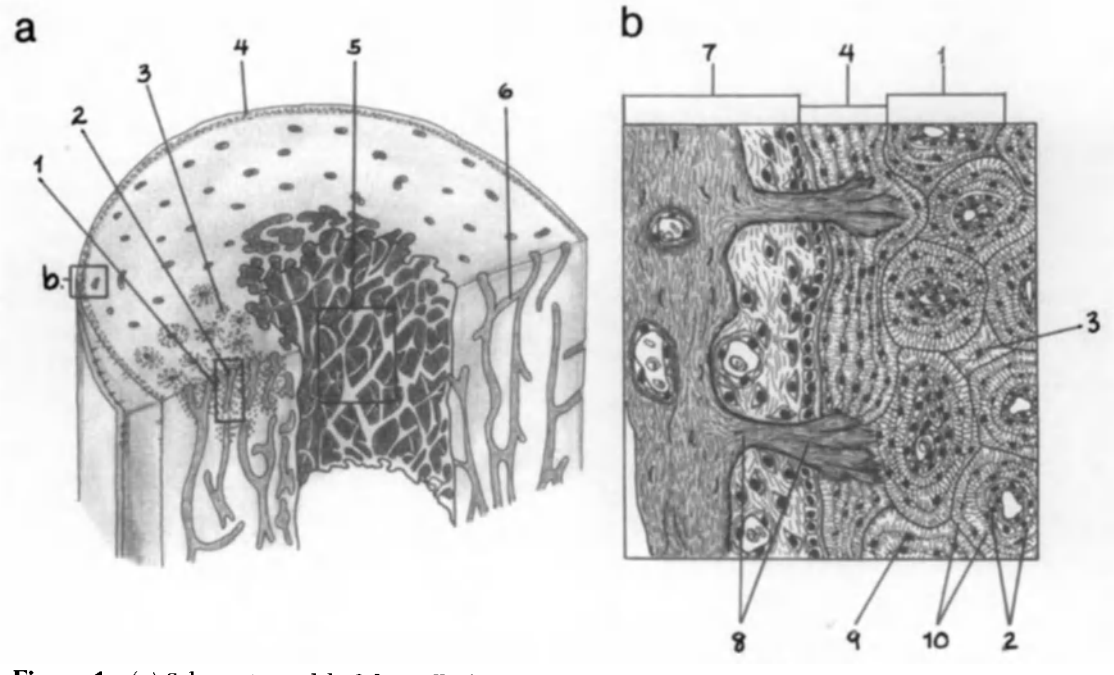

Figure 1 *(a) Schematic model of the wall of a mammalian long-bone diaphysis consisting of an outer layer of compact bone and an inner layer of cancellous bone, surrounding a central medullary cavity. Periosteum covers the outer bone surface, and endosteum covers the inner bone surface. (b) Enlarged diagram of periosteum and compact bone in (a) 1, osteon; 2, haversian canal; 3, interstitial lamellae; 4, outer circumferential lamellae; 5, cancellous bone; 6, Volkman's canal; 7, periosteum; 8, Sharpey's fibers; 9, lacuna; 10, concentric lamellae. Adapted from Ten Cate (1989).*

channels (Volkmann's canals). The entire complex, consisting of several layers of concentric lamellae around a vascular channel, is known as an osteon or haversian system. Interstitial lamellae, which appear as irregularly shaped areas between adjacent osteons, consist of lamellae that are remnants of osteons destroyed during bone remodeling. Circumferential lamellae are arranged parallel to each other and comprise the outer circumferential lamellae laid down next to the periosteum and the inner circumferential lamellae laid down next to the endosteum.

B. Bone Formation, Growth, and Remodeling

Osteogenesis (bone formation) of membrane bone (intramembranous bone, dermal bone) occurs directly by the mineralization of matrix formed by osteoblasts within condensations of mesenchyme. Osteogenesis of endochondral bone (cartilage bone) occurs indirectly by the deposition and mineralization of bone matrix on a preexisting cartilage matrix. Bone continues to grow through remodeling, as old bone is resorbed through activities stimulated by osteoclasts, and new bone is laid down through the activities of osteoblasts. Influences on bone remodeling include strain and stress imposed by movement and muscle action, hormones, and growth factors. For example, the parathyroid hormone is linked to osteoclast proliferation and activity, and calcitonin, a hormone synthesized within the thyroid, has an inhibitory effect on osteoclast activity (Marks and Popoff, 1988). Modifications of hormonal controls on bone growth and remodeling, in specific parts of the skeleton, are probably responsible for specializations in bone density patterns in some marine mammals (see later). In addition to this typical osteoblastic bone formation, osteogenesis can occur through the direct transformation of cartilage or fibrous tissue into bone (metaplastic bone). The metaplastic transformation of chondrocytes into osteoblasts may account for the formation of osseous globules found in the endosteal endochondral bone of some archaeocetes (Buffrénil *et al.*, 1990). Osseous globules are pseudolamellar bone deposited in empty lacunae that once housed chondrocytes, but their mode of origin is controversial.

Because bone growth occurs throughout life, periodic growth marks in skeletal tissue, particularly periodical deposition of periosteal bone layers, are potentially useful in mammalian age determination. Techniques of skeletal tissue age determination involve the counting of growth layer groups. Growth layer groups are sets of incremental growth lines defined by at least one change in mineral density, such as between more stained and less stained layers or dark and light layers. However, the dynamic nature of bone growth and remodeling limits the accuracy of bone growth layer group counts.

C. Marine Mammal Bone

Marine mammals show two very different trends in bone architecture and histology, reduced bone density and increased bone density, both of which are associated with their aquatic habits (Wall, 1983). Deep-diving marine mammals, especially Recent cetaceans, have bones that are less dense than homologous elements in terrestrial mammals. They efficiently overcome buoyancy at depth by the active mechanism of lung collapse, whereas at the surface their lighter bones enhance buoyancy, allowing them to float with relatively little expenditure of energy. A pattern of reduced bone density has been documented thoroughly in small to medium-sized odontocetes, some of the large-bodied cetaceans, and some phocids (notably the elephant seals, *Mirounga* spp.) and is characterized by the replacement of cortical bone (the compact bone surrounding medullary cavities) with cancellous bone, which also fills the medullary cavities. This condition is apparently caused by an imbalance between bone resorption and redeposition beginning early in ontogeny and is probably under hormonal control. An increase in cancellous bone in these mammals does not appear to be pathological—the microscopic architecture of cancellous bone in cetacean limbs is significantly more organized than that of typical osteoporotic bone.

In contrast, shallow-diving marine mammals, such as sirenians, overcome buoyancy while diving in large part by the static mechanism of *increased* bone density. Their bones are much denser than typical mammal bones. This is achieved in different ways: by osteosclerosis, by pachyostosis, or by a combination of both conditions (pachyosteosclerosis) (Domning and Buffrénil, 1991). Sirenians show pronounced pachyosteosclerosis, especially in the thoracic and occipital regions. Similarly, walruses and some seals have unusually dense limb bones.

Ongoing research in the bone histology of extinct marine mammals indicates that both increased bone density and reduced bone density have evolved independently several times in different groups of marine mammals. The earliest sirenians show pronounced pachyosteosclerosis. Likewise, in contrast to Recent cetaceans, some bones of extinct Eocene archaeocetes are osteosclerotic. In *Basilosaurus* (Basilosauridae), the osteosclerosis of ribs is very pronounced, with the total replacement of medullary trabecular bone by compact bone (Buffrénil *et al.*, 1990). Similarly, hyperostosis of the periosteal cortex and infilling of the medullary cavity with cancellous bone occur in ribs and vertebrae of *Eocetus* (Protocetidae) (Uhen, 1999) and in ribs of *Zygorhiza* (Durodontidae) (Buffrénil *et al.*, 1990). In contrast, long bones of some other durodontids show a reduced thickness of periosteal compact bone, as in modern cetaceans (Madar, 1998).

Bone of one marine mammal, the toothed whale *Mesoplodon densirostris*, exhibits unique histological features. The rostral bone of this odontocete, which is among the densest bone known among tetrapods, is characterized by hyperminerализed secondary osteons. These osteons have unusually well-aligned parallel and platy hydroxyapatite crystals and a tubular network of unusually thin collagen fibrils, and thus differ markedly from the structure of haversian systems of typical mammalian lamellae bone (Zylberberg *et al.*, 1998).

The periodic deposition of periosteal bone layers has been used in studies of age determination in mammals, although limited in use by the fact that mammalian bone undergoes remodeling throughout life (Klevezal, 1996). Bone growth layer groups have been studied in a variety of marine mammals, including sirenians, pinnipeds, and odontocetes.

II. Cementum

A. Cementum Structure and Composition

Teeth of marine mammals, like all mammals, consist of a crown, which extends above the gums, and one or more roots,

which extend below the gum line and hold the teeth in bony sockets (alveoli). The roots are covered by cementum (also known as cement), which sometimes extends to cover part of the crown, overlapping the cervical enamel. Cementum, along with the periodontal ligament, comprises the periodontium, the attachment apparatus of teeth. Cementum is similar in composition to bone. Its mineral component (65% by wet weight) consists of crystals of an impure form of hydroxyapatite similar in shape and size to those of bone. Its organic component (up to 20% of the total tissue) includes cementocytes (cementum cells), ground substance containing proteoglycans, intrinsic collagen fibers, and extrinsic collagen fibers (Sharpey's fibers). Intrinsic fibers and ground substance are the primary constituents of cementum. Intrinsic fibers, like collagen fibers of lamellar bone, are small, on the order of 1–2 μm in diameter. The extrinsic Sharpey's fibers are much larger, typically 3–12 μm in diameter. Intrinsic fibers, ground substance, and cementocytes are derived from cementoblasts, but the extrinsic fibers are derived from fibroblasts of the periodontal ligament.

Cementum is classified according to the relative proportions of the different components, although the different types are gradational. Thus, cementum can be classified as cellular or acellular depending on the relative proportions of cementocytes and ground substance, or it can be classified according to its fiber composition (Fig. 2). Extrinsic fiber cement occurs close to the alveolar bone and is dominated by well-mineralized Sharpey's fibers contained within a highly mineralized acellular ground substance. Mixed fiber cement contains intrinsic collagen fibers as well as Sharpey's fibers and ground substance and may contain cementocytes. Intrinsic fiber cement, which contains only intrinsic collagen fibers, ground substance, and cementocytes, occurs close to roots. In cellular mixed fiber cement and intrinsic fiber cement, cementocytes are contained in lacunae of variable shape that form within the mineralizing ground substance.

Incremental growth layers known as cementing lines or resting lines are sometimes a prominent histological feature of both cellular and acellular cementum. Cementing lines, like the incremental growth layers found in bone, dentine, and enamel, are distinct layers that parallel the developing surface. Due to periodic variation in mineralization during development, they contrast with adjacent layers. Cementum growth layer groups, like those of bone and dentine, can be defined empirically by at least one change in mineral density, such as between translucent and opaque layers, dark and light layers, ridge and groove, or more stained and less stained layers. Empirical studies have shown that cementum growth layer groups record the periodicity of tissue formation and thus are useful in age determination.

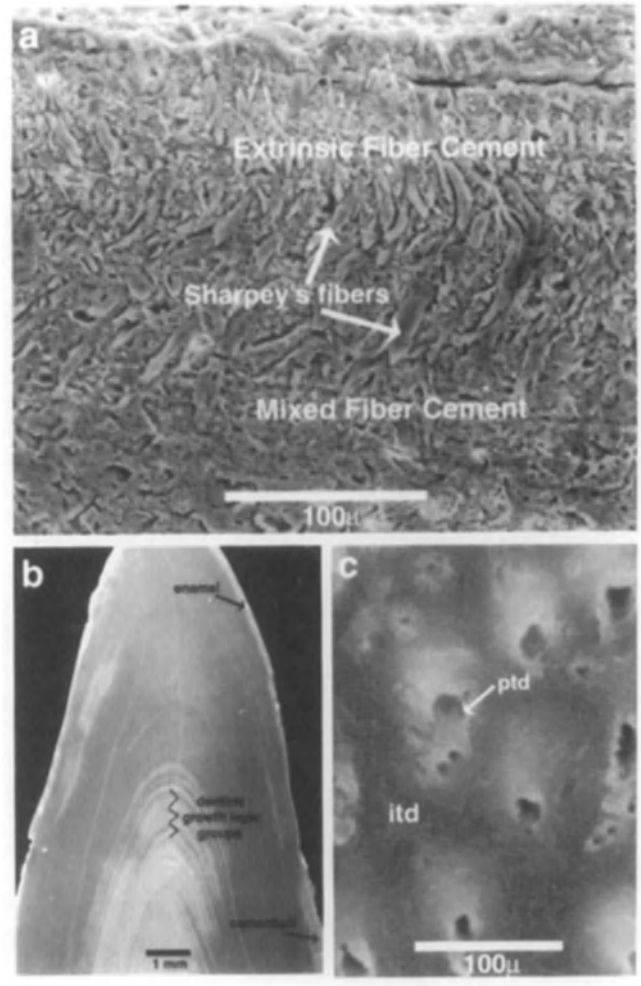

Figure 2 *Scanning electron micrographs of an isolated tooth of an unidentified delphinoid cetacean (Yorktown Formation, Pliocene, from the Lee Creek Mines, North Carolina). The specimen has been sectioned longitudinally, polished, and etched with dilute HCl. (a) High magnification view of cementum, which grades from extrinsic fiber cement on the outer periphery (top) to mixed fiber cement closer to the cementum–dentine junction (bottom). Classification of cementum depends on the proportion of Sharpey's fibers contained within the matrix. (b) Thin layers of enamel and cementum lie peripheral to dentine of the crown and root. Dentine growth layer groups appear as pairs of dark/light bands. (c) High magnification view of dentine. The walls of cross-sectioned dentine tubules contain hypermineralized peritubular dentine (ptd). Less mineralized intertubular dentine (itd) occurs between tubules.*

B. Marine Mammal Cementum

Cementum in marine mammals is, for the most part, structurally similar to that of other mammals. Cementum growth layer groups are used in conjunction with dentine and bone growth layer groups to estimate age in marine mammals, although their relative clarity varies among species. In some species, cementum formation continues beyond that of dentine, which is an advantage in age determination. In ziphiid whales, where the cementum typically extends over most of the crown and may comprise the bulk of the tooth, cementum growth layer groups are distinguishable without magnification. Ziphiids also have been reported to have an unusual, possibly vascular cementum (Boyde, 1980).

III. Dentine

A. Dentine Structure and Composition

Dentine comprises the bulk of the volume of teeth of most mammals. In the crown, dentine is covered by enamel, whereas in the root it is covered by cementum. Circumpulpal dentine surrounds the pulp cavity, which contains connective tissue, nerves, and blood vessels. Circumpulpal dentine is distinguishable histologically from a thin outer layer known as mantle dentine (in the tooth crown) or hyaline dentine (in the root). Dentine tubules, which radiate out from the pulp to the outer dentine surface, are distinctive features of dentine. They are narrow (1–4 μm diameter) tubular structures that form during dentine development around odontoblast (dentine-forming cells) cell processes. In adult teeth, tubules contain mostly fluid and amorphous cell debris.

The organic component of dentine consists mainly of very small (on the order of 50 nm in diameter) collagen fibrils. The collagen fibrils in circumpulpal dentine are laid down parallel to the developing dentine surface and perpendicular to the dentine tubules, but the mantle dentine contains some large (more than one micron in diameter) collagen fiber bundles known as von Korff fibers. Von Korff fibers are oriented parallel to tubules.

Dentine is 75% mineral (hydroxyapatite). Most of the small (2–3 nm in thickness and probably 20–100 nm in length) hydroxyapatite crystals are aligned parallel to each other and to the small collagen fibrils, but others are oriented radially and form spherical or semispherical structures known as calcospherites. Calcospherites are difficult to distinguish histologically because they typically fuse together. Areas where mineralization is incomplete and calcospherites have not fused are called interglobular dentine. Most mineralization of dentine takes place along the developing dentine front, but dentine deposited in tubule walls (peritubular dentine) undergoes further mineralization (Fig. 2c). In some cases, tubules become occluded by mineralization, forming sclerotic dentine. Denticles (smooth-surfaced, spherical mineralized bodies with a laminar structure) sometimes form by the mineralization of collagen fibers within the pulp cavity. These denticles may become attached to the inner surface of the dentine or become embedded in it during continued dentine formation.

B. Marine Mammal Dentine

The dentine of most marine mammals is structurally similar to that of other mammals, but there are some exceptions. In some, notably the narwhal (*Monodon monoceros*) and sperm whale (*Physeter macrocephalus*), the large von Korff fibers are not restricted to the mantle dentine but extend throughout the thickness of dentine, where they are located in the walls of dentine tubules. Denticles have been reported in some odontocetes and sclerotic dentine is found in some marine mammals, especially in seals.

Marine mammal dentine is characterized by prominent incremental growth layers (Fig. 2b) that lie at angles to dentine tubules and vary in their intensity, both within and among individuals. The finest scale layers are the incremental von Ebner lines, which probably reflect diurnal variation in matrix fiber arrangement. Von Ebner lines appear as alternating dark and light lines in ground sections under polarized light. Other larger-scale incremental growth layers reflect changes in density due to differences in mineralization. These include the neonatal line, a very prominent growth layer that marks physiological disturbance associated with birth, and other less distinct and consistent growth layers whose physiological bases are uncertain. In some seals, the growth layer groups are accentuated by layers of interglobular dentine. Whatever their origins, there is a regular repetition to growth layer groups that seems to reflect annual or semiannual growth cycles, and counting of dentinal growth layer groups is a primary basis of age determination in pinnipeds, sirenians, and odontocetes.

IV. Enamel

A. Enamel Structure and Composition

Enamel covers the tooth crown in most mammals. It is the most highly mineralized tissue in the body, consisting almost entirely (95% by weight) of highly structured arrangements of hydroxyapatite crystallites. The remaining fraction consists of water and two classes of proteins unique to enamel: enamelins, which predominate in mature (fully mineralized) enamel, and amelogenins, which predominate in developing enamel. The histological structure of enamel reflects the organization of crystallites into units of increasing scale, two of which are enamel prisms and enamel types. This structural organization is determined during enamel development. Unlike bone, cement, and dentine, enamel does not remodel after its initial deposition.

Enamel matrix is secreted by ameloblasts. The activity of these enamel-secreting cells commences at the enamel–dentine junction (EDJ) and continues as ameloblasts retreat outward, away from the EDJ. Mineral crystals precipitate and grow within the enamel matrix left by the retreating ameloblasts. The orientation and arrangement of the crystallites, and thus the structure of the mature enamel, depend on the shape of the secretory end of the ameloblast. The simplest enamel structure is formed by ameloblasts with flat secretory surfaces. In most mammal teeth, however, the bulk of the enamel is laid down by ameloblasts whose secretory ends form protrusions, called Tomes processes, surrounded by flattened areas called ameloblast shoulders. Because enamel crystallites grow perpendicular to the differently oriented secretory surfaces of the Tomes process and the ameloblast shoulder, there is a regular pattern of discontinuities in crystallites' orientations. These discontinuities define the boundaries of enamel prisms and interprismatic enamel.

Enamel prisms are cylindrical bundles of largely parallel hydroxyapatite crystals extending outward from the EDJ toward the outer tooth surface. The prism boundaries are defined by differences in orientations between prismatic crystallites and those of the adjacent enamel that fills the spaces between prisms. This enamel is called interprismatic enamel. It is compositionally identical to enamel prisms, but differs in crystallite orientation. The submicroscopic gap produced by the change in crystallite orientations at the prism–interprismatic boundary is known as the prism sheath (Fig. 3). Prism sheaths contain

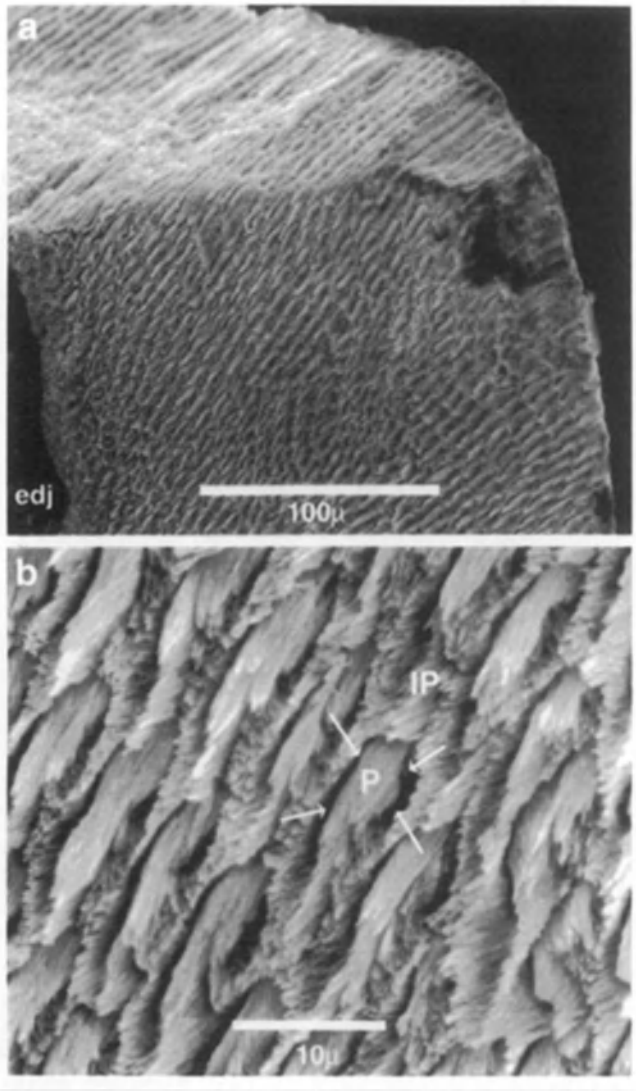

Figure 3 *(a) Scanning electron micrograph of fractured enamel near tip of tooth (unidentified Pliocene odontocete, Lee Creek Mine, North Carolina). The naturally fractured surface (at top) shows that the prisms take a straight course from the enamel–dentine junction (edj) to the outer surface, as is typical in radial enamel. (b) High magnification view showing enamel prisms (P) sectioned oblique to their long axes. Prism crystallites are parallel to each other, but not to crystallites in adjacent interprismatic enamel (IP). Arrows indicate the position of the prism sheath, which has been artificially enlarged in this acid-etched specimen.*

slightly greater concentrations of water and protein than the surrounding enamel, and thus are less dense. This allows prism patterns (the cross-sectional shapes and packing arrangement of prisms and interprismatic enamel) to be distinguished in ground sections or in acid-etched scanning electron microscope preparations. Prisms may have closed, circular cross sections or open, arc-shaped cross sections. Prism patterns have been used to distinguish among some mammalian groups, but there is considerable variation within individuals, and considerable parallelism among different groups.

Enamel types describe the organization of enamel at a scale greater than individual crystallites or prisms. Common enamel types include parallel crystallite enamel, radial enamel, and decussating enamel. Parallel crystallite enamel, a type of nonprismatic enamel, is a volume of enamel in which hydroxyapatite crystallites are parallel to each other with no discontinuities in orientation and lacking larger-scale structural features, other than incremental lines. Radial enamel refers to a volume of prismatic enamel where prism long axes are parallel to one another and directed radially outward from the EDJ. Decussating enamel is a volume of enamel characterized by layers of parallel prisms, one or more prisms in thickness, whose long axes alternate in orientation with prisms in adjacent layers. Decussating enamel, also known as Hunter–Schreger bands (HSB), includes undulating HSB, where layers of similarly oriented prisms have a gently undulating course from the EDJ to the surface, and zigzag HSB, where the layers undulate with a pronounced vertical amplitude. Differences in enamel types have a phylogenetic component, but also have different mechanical properties that can be important functionally—parallel crystallite enamel may be harder than prismatic enamel, but prismatic enamel, especially decussating enamel, is more resistant to cracks induced by chewing stress. Zigzag enamel is thought to be especially resistant to cracking. Most mammal teeth are composed of more than one enamel type.

Cross-striations, a record of the daily incremental deposition of enamel, are sometimes evident in both prismatic and nonprismatic enamel. In the scanning electron microscope, cross-striations appear as alternating constrictions and varicosities along the length of the prism, suggesting that they reflect variations in the rate of enamel secretory activity. More prominent incremental lines, known as brown striae of Retzius, also transect prisms or crystallites. They are oriented parallel to the developing enamel surface and probably reflect regular interruptions in growth, although their causes and periodicity are not clear.

B. Marine Mammal Enamel

Although the crowns of most marine mammal teeth are covered with enamel, there is considerable variation in its structural complexity among and within orders. Likewise, prism patterns vary among and without orders, although there is no compelling evidence that prism patterns are diagnostic of particular marine mammal groups.

Most extant cetaceans have thin, structurally simple enamel. In some the enamel consists of a thin layer of radial prismatic enamel with or without an outer layer of nonprismatic parallel crystallite enamel, and in many species the tooth enamel consists entirely of nonprismatic parallel crystallite enamel. In contrast, the most primitive cetacean, the fossil *Pakicetus*, had relatively thick enamel with a more complex structure consisting of parallel crystallite enamel, radial enamel, and a thick inner layer of undulating Hunter–Schreger bands. Later archaeocetes show the same arrangement of enamel types, but almost all more derived odontocetes have much less complex enamel.

This has led some workers to conclude that the enamel of most extant cetaceans is evolutionarily degenerate. Only two extant odontocetes, the Indian river dolphin *Platanista gangetica* and Amazon dolphin *Inia geoffrensis* have well-developed, undulating HSB. It is unclear whether these were acquired independently in response to functional demands of their diet or a primitive retention from archaeocete ancestors.

Extant sirenians (*Dugong dugon* and *Trichechus* spp.) are reported to have radial enamel with variably circular and arc-shaped prism cross sections. Similar enamel has been reported for some fossil sirenians, and it is likely that this is primitive for the group. Pinniped enamel has not been described in detail, but enamel of some species appears to be more complex than that of sirenians. *Phoca vitulina* has undulating HSB, and walrus (*Odobenus rosmarus*) enamel shows a transition from undulating HSB to zigzag HSB near cusp tips.

Enamel incremental lines generally are not used in the age determination of marine mammals. The thin enamel of many species makes resolution of these lines difficult and, more importantly, enamel only records the period of tooth development during which enamel is laid down, which, is most cases, is before birth.

Bottlenose Dolphins

Tursiops truncatus and *T. aduncus*

Randall S. Wells
Chicago Zoological Society, Illinois

Michael D. Scott
InterAmerican Tropical Tuna Commission, La Jolla, California

I. Genus and Species

Bottlenose dolphins are arguably the best known of all cetaceans. They figured prominently in the legends of the ancient Greeks and Romans and were described in the writings of Aristotle, Oppian, and Pliny the Elder. Several books for scientific and public audiences have focused on these species (e.g., Caldwell and Caldwell, 1972; Leatherwood and Reeves, 1990; Reynolds *et al.*, 2000), and a number of comprehensive review articles have been produced as well (Tomilin, 1957; Leatherwood and Reeves, 1982; Shane *et al.*, 1986; Wells and Scott, 1999). The name *Tursiops* can be translated as "dolphin-like," deriving from the Latin *Tursio* ("dolphin") and the Greek suffix *-ops* ("appearance"). Two species of *Tursiops*, *T. truncatus*, the "common bottlenose dolphin," and *T. aduncus*, the "Indian Ocean bottlenose dolphin," are currently recognized (Rice, 1998), pending revisions based on recent genetic information.

Bottlenose dolphins are cosmopolitan in distribution and demonstrate a great deal of GEOGRAPHICAL VARIATION in morphology. *T. truncatus* is found in most of the world's warm temperate to tropical seas, in coastal as well as offshore waters; *T. aduncus* is limited to the coastal waters of the Indian Ocean and Western Pacific Ocean, from eastern Africa to Taiwan, southeastward to Australia (Fig. 1). They are recognizable by their generalized appearance—a medium-sized, robust body, a moderately falcate dorsal fin, and dark coloration, with a sharp demarcation between the melon and the short rostrum (Figs. 2 and 3). Adult lengths range from under 2 m to about 3.8 m, varying by geographic location (Cockcroft and Ross, 1990; Mead and Potter, 1990; Wells and Scott, 1999). Body size appears to vary inversely with water temperature in many parts of the world (but not the eastern Pacific). Bottlenose dolphins are colored light gray to black dorsally and laterally, with a light belly (Fig. 3). A light blaze

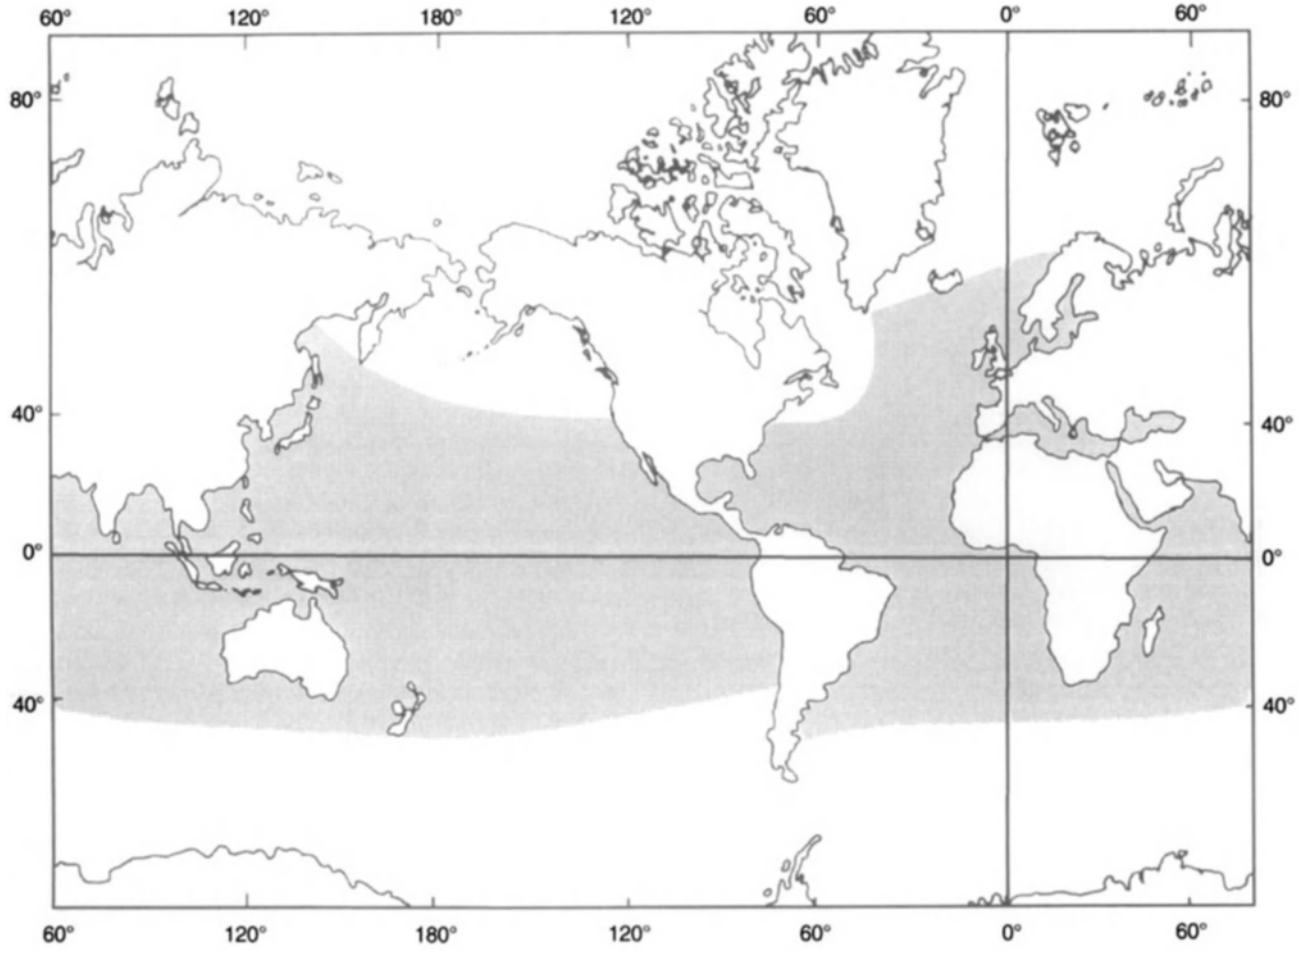

Figure 1 *Shading indicates the species range of the common bottlenose dolphin,* Tursiops truncatus. *It is not possible to be explicit regarding the range of the Indian Ocean bottlenose dolphin,* Tursiops aduncus, *because of uncertainties regarding the taxonomic status of bottlenose dolphins in the Indian Ocean, but the species generally inhabits the coastal waters of the Indian and Western Pacific Oceans, along the entire eastern coast of Africa, through the Red Sea and Persian Gulf, eastward as far as Taiwan, and southeastward to the coastal waters of Australia.*

or brush marking is sometimes observed on their sides. A distinct cape may be visible or may be obscured when the color pattern is very dark. *T. aduncus* tends to be smaller than *T. truncatus*, has a proportionately longer rostrum, and develops ventral spotting at about the time of sexual maturity (Ross and Cockcroft, 1990).

Variation in size, COLORATION, and cranial characteristics associated with feeding have led to descriptions of at least 20 nominal species of *Tursiops* (Hershkovitz, 1966, Rice, 1998). Recognition of the polymorphic nature of *Tursiops* and the existence of clinical variation had led to general agreement for many years that *Tursiops* was a single-species genus. However, recent genetic, morphologic, and physiologic studies suggest that revision of the genus may be necessary to acknowledge significant differences between forms from different oceans, as well as differences between forms in inshore vs offshore habitats within ocean basins (Hersh and Duffield, 1990; LeDuc *et al.*, 1999; Mead and Potter, 1995; Rice, 1998). Inshore bottlenose dolphins in the Atlantic and some other regions tend to be smaller, lighter in color, have proportionately larger flippers, and differ in hematologic and mitochondrial DNA features from offshore forms (Hersh and Duffield, 1990; LeDuc *et al.*, 1999); however, eastern Pacific offshore bottlenose dolphins are smaller and darker than inshore forms. The taxonomic status of *Tursiops* is made even more confusing by observations of hybridization with several other odontocete species.

Recent genetic evidence suggests that *T. aduncus* is more closely related to pelagic *Stenella* and *Delphinus* species, in particular *S. frontalis*, than to *T. truncatus* (LeDuc *et al.*, 1999). This interpretation has more than just taxonomic implications. It could change the previous focus on differences in morphology and social behavior that were thought to reflect the polymorphic nature and behavioral plasticity of a single species to a renewed exploration of the many similarities perhaps brought about by evolutionary convergence in adaptations to a coastal/estuarine environment or, alternatively, a retention of primitive characteristics (plesiomorphy).

II. Distribution and Habitat

Common bottlenose dolphins are found in the temperate and tropical marine waters of the world (Fig. 1). In the North Pacific, they are commonly found as far north as the southern Okhotsk Sea, the Kuril Islands, and central California. In the North Atlantic, they are seen inshore during summer months off New England, offshore as far north as Nova Scotia, and have been recorded off Norway and the Lofoten Islands. Bottlenose dolphins occur as far south as Tierra del Fuego, South Africa, Australia, and New Zealand. Limits to the species' range appear to be temperature related, either directly or indirectly, through distribution of prey. Off the coasts of North America they tend to inhabit waters with surface temperatures ranging from about 10 to 32°C. At the northern limit of the species' range in the western North Atlantic, they are seasonally migratory, with a more southerly DISTRIBUTION in the winter.

Figure 3 *Ventral view of a common bottlenose dolphin. Photo by R. S. Wells.*

Indian Ocean bottlenose dolphins are found in the coastal waters of eastern Africa from South Africa northward to the Red Sea and the Persian Gulf, and eastward to Taiwan and Australia (Rice, 1998), where they typically occur year-round.

Tursiops inhabits most warm temperate and tropical shorelines, adapting to a variety of marine and estuarine habitats, even ranging into rivers. Both species of bottlenose dolphins tend to be primarily coastal, but *T. truncatus* is also found in pelagic waters, near oceanic islands, and over the continental shelf, especially along the shelf break. In the Indian Ocean, *T. truncatus* tends to inhabit offshore waters, whereas *T. aduncus* is the more common coastal species.

III. Food and Feeding

The DIETS of common bottlenose dolphins have been described from many regions. A large variety of fish and/or squid forms most of the diets, although bottlenose dolphins seem to show a consistent preference for sciaenids, scombrids, and mugilids. Most fish prey are bottom dwellers, but some surface dwellers or pelagic fish are also represented in the diets. Differences in diets have been found where both inshore and offshore *Tursiops* ecotypes have been identified. In some cases, bottlenose dolphin groups feed in different areas depending on sex and size, with lactating females and their calves frequenting and feeding in the nearshore zone, adolescents feeding slightly farther offshore, and resting females and adult males feeding farther still.

Indian Ocean bottlenose dolphins also consume a variety of fish and squid (Cockcroft and Ross, 1990). Their prey includes fish with preferences for reefs or sandy bottoms and some inshore schooling fish.

IV. Predation

Sharks are probably the most important predators of bottlenose dolphins, although killer whales may also occasionally prey on them as well. Mutual tolerance during encounters between sharks and dolphins is probably typical, but as many as half of all bottlenose dolphins bear shark-bite scars as evidence of occasional encounters, depending on the region. Populations of Indian Ocean bottlenose dolphins in Australian waters are apparently subject to more frequent shark attacks than most populations of common bottlenose dolphins (Wood *et al.*, 1970; Corkeron *et al.*, 1987; Wells *et al.*, 1987; Cockcroft *et al.*, 1989a; Mead and Potter, 1990). In at least some areas, *Tursiops* appears to be a relatively minor and occasional part of the diets of sharks. Most wounds and scars from sharks tend to be found on the posterior and ventral regions of the dolphins, suggesting that the dolphins were ambushed from behind and below; some attacks may have been something other than a PREDATION

attempt (e.g., sharks defending a territory). The primary shark predators of both *T. truncatus* and *T. aduncus* are the bull shark (*Carcharhinus leucas*), tiger shark (*Galeocerdo cuvier*), great white shark (*Carcharodon carcharias*), and dusky shark (*Carcharhinus obscurus*) (Wood *et al.*, 1970; Corkeron *et al.*, 1987; Connor *et al.*, 1999). Observations of captive dolphins suggest that they may recognize certain species of sharks as potential threats.

Anecdotal accounts describe common bottlenose dolphins attacking sharks by butting them with their rostra or by striking them with their flukes (summarized by Wood *et al.*, 1970). Defense may explain the apparently high survival rate indicated by the shark-bite scars on living dolphins. The relatively infrequent occurrence of shark-bite scars on young dolphins indicates either that the calves are well protected by their mothers or that attacks on young dolphins are generally fatal.

Stingrays have also been implicated in the deaths of common bottlenose dolphins (Wells and Scott, 1999). The dolphins were wounded externally or internally from ingestion of small rays, and deaths resulted from physical trauma, infection, or toxicosis.

V. Ranging Patterns

Coastal common bottlenose dolphins exhibit a full spectrum of movements, including seasonal MIGRATIONS, year-around home ranges, periodic residency, and a combination of occasional long-range movements and repeated local residency (Shane *et al.*, 1986; Wells and Scott, 1999). Much less is known about the ranging patterns of pelagic and Indian Ocean bottlenose dolphins. In some places, coastal dolphins living at the high-latitude or cold-water extremes of the species' range may migrate seasonally, as is the case along the Atlantic coast of the United States. Long-term residency has been reported from many parts of the world and may take the form of a relatively permanent home range or repeated occurrence in a given area over many years. For example, the year-round residents of several dolphin communities along Florida's west coast have maintained relatively stable, slightly overlapping home ranges during more than 30 years of observations, and through at least four generations; seasonal changes in habitat use may occur within the ranges (Wells and Scott, 1999). Home range bounds are often demarcated by physiographic features such as passes or abrupt changes in water depth. Some common bottlenose dolphins may use seasonal home ranges joined by a traveling range. At Shark Bay, Western Australia, a group of Indian Ocean bottlenose dolphins has returned to the same beach for more than 20 years to interact with humans (Connor *et al.*, 1999).

Longer-distance movements have been reported for some coastal common bottlenose dolphins, including range shifts of several hundred kilometers in an apparent response to environmental changes such as an El Niño warm-water event and a 600-km roundtrip for several identifiable dolphins in Argentina. Average daily movements of 33–89 km, monitored through travel distances of as much as 4200 km, have been reported for bottlenose dolphins in offshore waters (Wells *et al.*, 1999).

VI. Social Behavior

Common bottlenose dolphins are typically found in groups of 2–15 individuals, although groups of more than 1000 have been reported. In general, bottlenose dolphins in bays and estuaries tend to form smaller groups then those in offshore waters, but the trend does not continue linearly with increasing distance from shore (Wells *et al.*, 1999). Group composition tends to be dynamic, with sex, age, reproductive condition, familial relationships, and affiliation histories apparently being the most important determining factors. Subgroupings may be stable or repeated over periods of years. Basic social units include nursery groups, mixed-sex groups of juveniles, and adult males as individuals or strongly bonded pairs or trios.

Indian Ocean bottlenose dolphins are also found in groups of variable size. Numbers observed off South Africa range from 3 to 1000, around a mean of 140, whereas off Australia, groups average about 10 individuals in Moreton Bay, and average about 5, ranging up to 22, in Shark Bay (Connor *et al.*, 1999; Corkeron, 1990).

Dominance hierarchies have been observed for both common and Indian Ocean bottlenose dolphins in captivity, with large adult males dominating all other pool mates, females forming a less-rigid hierarchy, and with the largest females dominant over smaller animals. Aggressive behaviors, including contact and posturing, are used to establish and maintain hierarchies. In Shark Bay, Australia, coalitions of male *T. aduncus* fight with other male coalitions and aggressively herd females (Connor *et al.*, 1999).

VII. Activity Patterns

Common bottlenose dolphins in the wild appear to be active both during the day and night, interspersing bouts of feeding, traveling, socializing, and idling or resting (Shane *et al.*, 1986; Wells *et al.*, 1999). The duration and frequency of activities are influenced by such environmental factors as season, habitat, time of day, and tidal state and by physiological factors such as reproductive seasonality. Bottlenose dolphins feed in a large variety of ways, primarily as individuals, but cooperative herding of schools of prey fish also occurs. Individual prey capture involves behaviors as diverse as high-speed chases with a pin-wheeling capture at the surface, "fish whacking" in which a fleeing fish is struck with the dolphin's flukes and often knocked clear of the water, pushing fish onto shore and then partially beaching to capture them, and herding and perhaps disorienting fish with percussive leaps and tail lobs referred to as "kerplunking." Many of these same activities and behaviors have been observed for *T. aduncus* as well.

VIII. Life History

More detailed life history information is available for *T. truncatus* than for *T. aduncus*. Analyses of dentinal and cemental growth layer groups in teeth (Hohn *et al.*, 1989) have shown that female common bottlenose dolphins can live to more than 50 years, and some males have reached 40–45 years of age (Wells and Scott, 1999). Calves achieve most of their growth during the

period of suckling, i.e., the first 1.5–2 years of life. Females typically reach sexual and physical maturity before males, leading to sexual dimorphism in some regions. Age at sexual maturity varies by region, but females usually reach sexual maturity at 5–13 years. Sexual maturity for males tends to occur at 9–14 years, often many years before they reach physical maturity (late teens) and achieve breeding status. Most breeding males in captivity are at least 20 years old (Wells *et al.*, 1999).

Indian Ocean bottlenose dolphins often develop ventral spotting at sexual maturity, when males are >235 cm in length and females are >230 cm (Ross and Cockcroft, 1990). Sexual maturity may be attained at an older age for *T. aduncus* than for *T. truncatus*, with females producing their first calf at age 12 or older (Connor *et al.*, 1999).

IX. Reproduction

Although births have been reported from all seasons, calving tends to be diffusely seasonal for both *T. truncatus* and *T. aduncus*, with peaks during warmer months (Connor *et al.*, 1999). Hormonal monitoring of captive common bottlenose dolphins indicates that females are spontaneous sporadic ovulators, ovulating repeatedly during a given season, whereas males may be active throughout the year with a prolonged elevation of testosterone concentrations over the months that different females may be ovulating. The reproductive life span for *T. truncatus* is prolonged; females up to 48 years of age have successfully given birth and raised young (Wells and Scott, 1999). Calves are born after a gestation period of about 1 year and range in length from about 84 to 140 cm depending on the geographic region. Calving intervals of 3–6 years are common for *T. truncatus*, whereas 4- to 6-year intervals are more common for *T. aduncus* (Connor *et al.*, 1999).

Lactation is the primary source of nutrition for the first year of life and may continue for several more years. Solid food has been found along with milk in the stomachs of calves as young as 4 months old. Maternal investment for free-ranging *T. truncatus* calves typically extends for about 3–6 years, with separation often coinciding with the birth of the next calf. *T. aduncus* calves in Shark Bay, Australia, typically attempt to nurse for 3–5 years (Connor *et al.*, 1999). Simultaneously pregnant and lactating females have been noted on occasion for both species.

X. Sound Production

Most of what is known about bottlenose dolphin SOUND PRODUCTION has resulted from detailed studies of *T. truncatus*, but it is reasonable to assume that *T. aduncus* acoustic patterns are comparable. Bottlenose dolphins produce these categories of sounds: whistles, echolocation clicks, and burst-pulse sounds. Dolphins produce a large variety of whistles, including largely stereotypic "signature whistles" that are individually specific, hypothesized to be used to communicate identity, location, and emotional state (Caldwell *et al.*, 1990). Once the signature whistle develops in neonates, it remains stable for at least many years, and probably for life. The signature whistles of many male calves are similar to the whistles of their mothers, whereas those of female calves are not. Dolphin echolocation involves the production of "clicks," with peak frequencies of about 40–130 kHz (Au, 1993). Echolocation is hypothesized to be used in navigation, foraging, and predator detection, among other possible functions. Burst pulses ("squawks") tend to be produced during social interactions.

XI. Fossil Record

Although no conclusive fossil evidence of the origin of *Tursiops* exists, FOSSIL RECORDS extend back several million years (Barnes, 1990). The geographic distribution of fossils falls within the range of modern animals. Anatomic features suggest that *Tursiops* evolved from some ancestral group of extinct fossil Delphininae, perhaps related to the subfamily Stenoninae, which might have evolved from the Kentriodontidae.

XII. Human Interactions

Common bottlenose dolphins take advantage of human activities in order to facilitate prey capture in a variety of ways. In Mauritania and Brazil, dolphins regularly drive schools of mullet toward fishermen wading with nets in shallow water, and in many parts of the world dolphins collect discarded fish from behind shrimp trawls and small purse seines or steal fish from various types of fishing gears.

A. Live Maintenance

The first *Tursiops* were publicly displayed at the Brighton Aquarium in 1883, at the New York Aquarium in 1914, and have been a regular attraction at Marineland of Florida since 1938. Common bottlenose dolphins continue to be the most common dolphins maintained in CAPTIVITY throughout the world. According to a May 2000 National Marine Fisheries Service inventory, 35 U.S. facilities held 392 common bottlenose dolphins. In addition, several hundred bottlenose dolphins, mostly *T. truncatus* but also including some *T. aduncus*, were held in at least 16 other countries. Within the United States, approximately 70% of the dolphins are held primarily for public display, whereas the remainder are used primarily for research or military purposes. Improved facilities and increased knowledge about the requirements for the care of dolphins have led to increasing success in the long-term maintenance of the animals, to the point where birth and survivorship rates at the better facilities approach and, possibly in a few cases, surpass those of wild populations (Wells and Scott, 1999).

B. Directed Fisheries

The largest of the historical FISHERIES for common bottlenose dolphins involved several countries surrounding the Black Sea, where dolphins were caught for oil, meat, and leather. Because of declines in dolphin populations, these countries have since outlawed the fishery. Directed takes still occur in other parts of the world, such as Peru, Sri Lanka, and Japan, for human consumption, to reduce the perceived competition with commercial fisheries, or for bait. Live-capture fisheries for dolphins for public display have existed for more than 100 years. More than 1500 *Tursiops* were removed from the waters of the United States, Mexico, and the Bahamas by 1980 for display, research, or military applications in many parts of the world (Leatherwood and Reeves, 1982). Although no bottlenose dolphins have

been collected in U.S. waters since 1989, some small-scale, live-capture fisheries for *T. truncatus* continue in other countries such as Mexico, Cuba, and Japan, and some *T. aduncus* have been captured in recent years in Taiwan.

C. Incidental Fisheries

Incidental catches of small numbers of *T. truncatus* have been reported for several fisheries, including purse-seine fisheries for tunas, sardines, and anchovetas (Wells and Scott, 1999). In some cases, dolphins have been killed by fishermen to prevent damage to their fishing gear or stealing of the catch or bait by the dolphins (Leatherwood and Reeves, 1982). A large incidental take of *T. aduncus* has apparently occurred in the Taiwanese gill-net fishery off Australia, with an annual mortality perhaps exceeding 2000 animals (Northridge, 1991). Large numbers of Indian Ocean bottlenose dolphins have also been killed in nets set for sharks off the swimming beaches of South Africa and Australia. In the United States, entanglement in or ingestion of recreational fishing gear has resulted in dolphin mortality.

D. Habitat Alteration, Pollution, and Vessel Impacts

Although the impact of habitat alteration and POLLUTION on dolphins has not been studied systematically, anecdotal accounts suggest that human-caused degradation may have led to declines in some dolphin populations (Wells and Scott, 1999). Extremely high concentrations of chlorinated hydrocarbon residues have been found in the tissues of *Tursiops* in many parts of the world, with males accumulating higher concentrations than females with age (O'Shea, 1999). Cockcroft *et al.* (1989b) reported that first-born calves of South African bottlenose dolphins (identified by the authors as *T. truncatus*) received 80% of their mother's body burden of contaminant residues (polychlorinated biphenyls and dieldrin), perhaps leading to increased neonatal mortality, but also reducing levels of contaminants in the mothers. The accumulation of contaminants in tissues of males has reached levels that theoretically could impair testosterone production, and thus reduce reproductive ability. Preliminary findings suggest that even relatively low levels of PCBs and DDT metabolites can result in a decline in bottlenose dolphin immune system function. Responses to other human use of dolphin habitat through boating, dolphin feeding, and swimming with dolphins are receiving much current research attention, but it is clear that common bottlenose dolphins suffer mortality and serious injury from collisions with boats and that their behaviors change in the presence of vessels.

Bottlenose Whales

Hyperoodon ampullatus and *H. planifrons*

SHANNON GOWANS
Dalhousie University, Halifax, Nova Scotia, Canada

Bottlenose whales are relatively large beaked whales (6–9 m), found in deep waters of the North Atlantic and southern ocean. They are excellent divers, capable of diving for over an hour, and routinely dive deeper than 800 m. Their primary prey is deep-water squid of the genus *Gonatus*, although some fish and benthic organisms are also consumed. Northern bottlenose whales are the best-studied beaked whale, with data from whaling records and a long-term study on live animals concentrated in a submarine canyon known as the Gully off Nova Scotia, Canada. Relatively little is known about the southern bottlenose whale. Individuals are found in small groups, ranging from 1 to 20. In the Gully population, males form long-term bonds, whereas females live in a loose network of associates. Northern bottlenose whales were heavily whaled from the 1850s to the 1970s and numbers are believed to be reduced throughout their range. Only a few southern bottlenose whales were harvested.

I. Description and Diagnostic Characteristics

Bottlenose or bottle-nosed whales are large, robust-beaked whales distinguished by their large bulbous forehead and short dolphin-like beak (Fig. 1). They are chocolate brown to yellow in color, being lighter on the flanks and belly. This COLORATION is believed to be caused by a thin diatom layer. Newborns are gray in color with dark eye patches and a light-colored forehead.

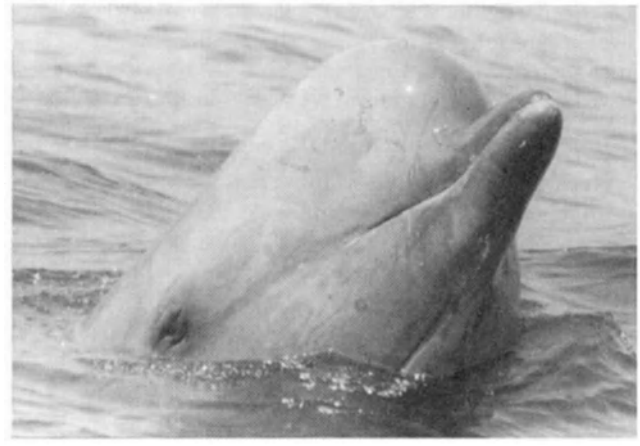

Figure 1 *Spyhop of a northern bottlenose whale showing prominent beak and V-shaped throat grooves.*

The maxillary crests of males become larger and heavier with age, leading to a change in the shape of the forehead, with mature males having a flat, squared-off forehead whereas female/immature males have a smooth-rounded forehead. The dense bone in the males forehead may be used for male–male competition, as males head butt one another. Males possess a single pair of conical TEETH at the tip of the lower jaw; however, these teeth are rarely visible in live animals.

II. Distribution and Range

Northern bottlenose whales are found in cold and temperate waters of the North Atlantic, from the ice edge to the Azores, almost always in waters deeper than 500 m. They concentrate in submarine canyons, the shelf edge, and other areas of high relief. A resident year-round population is found in the Gully, a large submarine canyon off the coast of Nova Scotia, Canada. Whales found in different areas have different length distributions, indicating that there may be geographic isolation between the different whaling grounds. Preliminary analysis of mitochondrial DNA suggests that there may be reproductive isolation between bottlenose whales off Labrador and in the Gully.

Southern bottlenose whales are found throughout the southern hemisphere, from the ice edge to 30°S. There are no known areas of concentration, although relatively little effort has been made to identify these animals. Recent molecular work on southern bottlenose whales indicates that there may be more than one species (Dalebout *et al.*, 1998). Many sightings of a large beaked whale in the tropical Pacific have been identified as a bottlenose whale and may represent a more tropical DISTRIBUTION of *H. planifrons*, or a third undescribed *Hyperoodon* species. Pitman *et al.* (1999) suggested that the tropical bottlenose whale is actually Longman's beaked whale *Indopacetus pacificus*, known hitherto only from skeletal remains.

III. Ecology

Bottlenose whales are deep divers feeding predominantly on squid of the genus *Gonatus*, although other species of squid are eaten. Adult *Gonatus* are primarily benthic, although juve-

niles may inhabit the water column. Fish (including herring and redfish) and benthic invertebrates such as starfish and sea cucumbers are occasionally consumed. Time-depth recorders on two northern bottlenose whales in the Gully indicated that these whales were routinely diving to or near the sea floor, over 1400 m below the surface.

Evidence from whaling suggests that northern bottlenose whales migrate north in spring and south in the fall; however, evidence for this is weak and this migration may actually represent a migration of whaling vessels. Stomach contents of stranded animals indicate that both northern and southern bottlenose whales travel over long distances (ca. 1000 km), although it is not known if these movements are routine. Individuals routinely return to the Gully after spending time outside the canyon, and bottlenose whales are found in the Gully year round.

IV. Social Organization

Both northern and southern bottlenose whales are typically found in small groups (one to four individuals), although groups of up to 20 have been observed. Nothing is known about the social organization of southern bottlenose whales, and only the Gully population of northern bottlenose whales has been studied. In the Gully, individuals live in fision–fussion groups and most associations are brief (on the order of minutes to a few days). Females form a loose network of associates with most members of the community. However, mature males form long-term companionships with other mature males and these associations last for years. The function of these associations is unknown, but they may be linked to mating and may be similar to male coalitions in bottlenose dolphins.

V. Interactions with Humans

Northern bottlenose whales are often described as curious, as they will often approach boats. Whalers exploited this behavior to find groups of bottlenose whales, and as healthy whales would often remain near wounded individuals, the entire group was often captured.

The commercial hunt for northern bottlenose whales began in the 1850s and extended until the 1970s. Over 80,000 whales were captured during this period, and many more were harpooned but not recovered. Preexploitation numbers are estimated at 40–50,000 whales, although this number is at best a rough guess. There is no current estimate for the size of the North Atlantic population, but it is unlikely that it has fully recovered from whaling. Only 130 individuals reside in the Gully currently and this population is likely still recovering from the whaling catch of approximately 60 animals taken from the area in the 1960s.

The study in the Gully represents the first long-term study of live beaked whales. Crews from several documentary films and magazines have visited the Gully, as it is one of the few places where beaked whales can be observed routinely.

Bowhead Whale

Balaena mysticetus

DAVID J. RUGH AND KIM E. W. SHELDEN
National Marine Mammal Laboratory, Seattle, Washington

Bowhead whales (*Balaena mysticetus*), sometimes called Arctic right whales, Greenland right whales, great polar whales, or ahvik, are the only members of the family Balaenidae (suborder Mysticeti, order Cetacea) that live most of the year associated with sea ice in northern latitudes. Bowheads have never been seen in the Southern Hemisphere.

I. Description

Bowheads are readily identifiable by their large size, rotund shape, lack of a dorsal fin, dark color, white chins, triangular head (in profile), and neck (an indentation between the head and back). They are predominantly black, but most have characteristic white patterns on their chins, undersides, around their tail stocks, and/or on their flukes (Fig. 1). These patterns distinguish them from the similar-appearing right whales (*Eubalaena* spp.) and are unique to each individual. The white patterns around the tail and on the flukes increase with age. In addition, most bowheads accumulate distinctive, permanent marks on their backs, perhaps resulting from contact with sea ice. The bowed appearance of the mouth gives them their name.

These huge marine mammals are among the largest animals on earth, weighing as much as 75–100 tons. Males grow to

Figure 1 *Bowhead whales are large, black cetaceans with various amounts of white on their chins (the arched, bright white area on the left), tail stocks (the paired white spots on the far right), and ventral surfaces (out of sight in aerial photographs). Note that the whale's left eye is visible deep underwater directly below the blow (exhalation vapor). This adult bowhead was photographed in March at the start of its long migration from the Bering Sea to the Canadian Beaufort Sea for the summer. Photo by David Rugh.*

14–17 m in length and females 16–18 m, perhaps as much as 20 m. Their flukes are 2–6 m across. The heads of these whales constitute over a third of the bulk of their bodies, and their baleen may be as long as 4 m (no other whale has baleen longer than 2.8 m) with 230 to 360 plates on each side of the mouth, making their capacious mouths quite possibly the largest of any animal ever. To insulate them from the icy water, bowheads are wrapped in blubber 5.5 to 28 cm thick covered by an epidermis up to 2.5 cm thick. This combination of blubber and skin is the thickest of any whale species.

Bowheads are well adapted to the risky occupation of being air-breathing mammals in seas often covered with thick ice: they can withstand breaking through ice as much as 60 cm thick, and their diving abilities are exceptional—possibly exceeding an hour—which is critical to finding breathing holes when swimming under sea ice. The very low and very loud calls that bowheads produce may help them find mates or assist in following each other while navigating through sea ice. The only other whales commonly found as far north as bowheads are belugas (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*), which are toothed whales with some of the same characteristics seen in bowheads: smooth backs and relatively thick blubber.

II. Breeding

Bowheads probably mate in later winter or early spring, but sexual activity may occur in any season. MATING groups consist of a male–female pair or several males and a female. Acoustics probably play a vital role in reproduction as bowheads are vocally active during the mating season and can hear each other 5–10 km away. Breaching (leaping completely out of the water) and fluke slapping (where the tails smash down on the water surface) may also play a role in attracting a mate or asserting dominance. Dominance is sometimes expressed through physical contact or sperm competition. However, there is a possibility that cooperation occurs among males during mating, making it more likely that at least one of them is able to inseminate a female. Over a year after mating (13–14 months), calves are born, usually during the spring migration between April and June. Calves are about 4 m long at birth. Females have calves 3 to 4 years apart. The following spring, the young whales, now 6 to 8 m long, are weaned from their mothers. After this, growth is slow compared to other baleen whales. At roughly 15 years of age, when 12 to 14 m long, females become sexually mature, and males become sexually active when 12 to 13 m long. Bowhead whales may live longer than other mammals; ancient harpoon points collected in whales recently indicate that the whales may have lived for more than a century.

III. Feeding

Bowheads feed throughout the water column, sometimes on the surface (called "skimming") and sometimes at or near the seafloor (as evidenced by mud smeared across their heads and backs). A bowhead's huge mouth can engulf large volumes of water, including prey, and, as the tongue rises, the water is pushed out, trapping prey on the inside fringed surfaces of the baleen, which serves as a filter all the way around the mouth. The massive tongue (as much as 5 m long and 3 m wide) then sweeps the food off the baleen into a very narrow digestive tract. As many as 60 species of animals have been found in

bowhead stomachs, but their preferred prey are copepods (11 species) and euphausiids (2 species), as well as mysids and gammarid amphipods. Sometimes as many as a dozen bowheads will feed together in an echelon formation, similar to a line of migrating geese. Perhaps this coordinated effort helps the whales entrap their prey.

The only predators of bowhead whales, other than humans, are killer whales (*Orcinus orca*). Killer whale scars were found on approximately 4 to 8% of the whales taken by Alaskan Eskimos. In part, the bowheads' close association with sea ice may be a way of seeking refuge from killer whales.

IV. Distribution and Abundance

Bowhead whales may have once been a single panmictic (randomly interbreeding) population that emerged in the Northern Hemisphere during the Pliocene (roughly 8 million years ago), according to fossil records. Genetic mixing between stocks in different areas was possible during the relatively warm interglacial periods (such as in A.D. 1000–1200) when reduction in sea ice meant whales could move between the Atlantic and Pacific Basins. Bowheads could have moved freely between the Beaufort Sea and Hudson Bay until the "Little Ice Age" between 1400 and 1850. Today's temperatures are cool enough to keep ice across most of the east–west passages of the Arctic, isolating these whale stocks.

While ice may have contributed to this isolation, commercial whaling had a more profound effect. The bowhead's large size, long baleen, thick BLUBBER, slow speed, and gentle disposition have made them such a valuable commodity that whalers went to great lengths to harvest them. Commercial whalers from the 17th to 19th centuries were so efficient that they eliminated stock after stock of these whales. In fact, even a century after commercial whaling ceased, all bowhead stocks are still considered endangered.

Currently there are five stocks of bowheads defined as geographically distinct segments of the species' total population: the Bering Sea (or Bering-Chukchi-Beaufort stock around Alaska), Okhotsk Sea (eastern Russia), Davis Strait (northeastern Canada), Hudson Bay (perhaps a part of the Davis Strait stock), and Spitsbergen (North Atlantic). The largest remnant stock, the Bering Sea stock, consists of approximately 8000 whales that migrate from the Bering Sea in the winter through the Chukchi Sea to the Beaufort Sea in the summer. This is the only stock that appears to be recovering from commercial whaling, growing at an annual rate of 3%. Originally there may have been 10,000 to 23,000 whales in this stock. Currently, Native Alaskans harvest approximately 40 whales per year through quotas set by the International Whaling Commission (IWC). The Chukotka Natives of Siberia have been allotted 5 bowheads per year from the Alaska quota. Independent of the IWC quota, the Canadian government has allowed a limited hunt of bowheads in the Bering Sea stock as well as from the stocks in Hudson Bay and Davis Strait.

There is very little known about other stocks of bowheads. Available evidence indicates that most stocks are very small: only about 300–400 currently live in the Okhotsk Sea (originally more than 3000); approximately 350 (originally 11,700) are in the Davis Strait stock; roughly 270 (originally about 580) live in Hudson Bay; and the Spitsbergen stock numbers "only in the tens" where there may have been as many as 24,000.

Bow-Riding

BERND WÜRSIG
Texas A&M University, Galveston

One of the most fascinating BEHAVIORS of dolphins is when they ride the bow pressure waves of boats. Dolphins probably have been bow-riding ever since swift vessels plied the seas, propelled by oar, sail, or very recently in the

history of seafaring, motor. The Greeks wrote of bow-riding in the eastern Mediterranean and Aegean Seas by what were most likely bottlenose (*Tursiops truncatus*), common (*Delphinus delphis*), and striped dolphins (*Stenella coeruleoalba*).

Bow-riding consists of dolphins, porpoises, and other smaller toothed whales (and occasionally sea lions and fur seals) positioning themselves in such a manner as to be lifted up and pushed forward by the circulating water generated to form a bow pressure wave of an advancing vessel (Lang, 1966; Hertel, 1969). Dolphins are exquisitely good at bow-riding, able to fine-tune their body posture and position so as to be propelled along entirely by the pressure wave, often with no tail (or fluke) beats needed. Bow-riders at the periphery of the pressure wave do need to beat their flukes, and so do bow-riders of a slowly moving vessel or one with a very sharp cutting instead of pushing bow.

There is often quite a bit of jostling for position at the bow, as dominant animals of a group edge others to a less favorable position, or as one is displaced from the bow by another one approaching (Fig. 1). It is great fun for a person to lean over the bow of a vessel and watch these interanimal antics, as well as the fine-tuning of positioning, effected by slight body turns and almost imperceptible movements of the flippers. Bow-riding dolphins also tend to emit what sounds to the human listener like a cacophony of underwater whistles and "screams," sounds implicated in high levels of social activity (Brownlee and Norris, 1994). Bow-riding is probably the dolphin behavior most noted, and most enjoyed, by seafaring people the world over.

Of course, riding the bow also makes these animals susceptible to being lanced or harpooned in areas where they are taken by humans. Where this occurs nearshore and in apparent smaller populations, dolphins become shy of the bow (Norris, 1974), but on the high seas or in deeper water, probably in larger populations, dolphins often still ride the bow after tens to hundreds of years of (generally small-scale) human hunting.

While many species of dolphins, porpoises, and small toothed whale ride the bow, some do not; and in some species, certain populations do not. Bottlenose dolphins are well-known bow-riders the world over, but even they do not ride in some areas (even where they are not hunted) or on some types of vessels. For example, off the shores of Texas in the Gulf of Mexico, they generally do not approach any vessel smaller than about 20 m long to bow-ride, apparently finding the smaller bows not worth their while. Instead, they "hitch a ride" on the oil tankers and freighters that ply in and out of major harbors, at times bow-riding for 20 or more kilometers at a stretch. Dolphins ride underwater, and must leave their position to breathe, leaping forward and at an angle to the surface before falling back toward the advancing bow in a welter of foam (Fig. 1). Dolphins also ride the stern waves (or wakes) of boats, which present a different hydrodynamic challenge than bow-riding; and in some areas, dolphins that do not approach the bow will nevertheless ride in the influence of a large (or fast small) vessel's wake.

Figure 1 *Common dolphins on the bow of a vessel off Panama.*

Most oceanic dolphins ride bow waves, with notable exceptions in areas of intensive hunting, such as by tuna vessels of the eastern Tropical Pacific, where vessels chase dolphins in order to net the tuna often affiliated with a dolphin school (Perrin, 1968). However, riding the bow is also "mood dependent"; dusky dolphins (*Lagenorhynchus obscurus*), for example, will not approach vessels when they have not fed for 2 or more days. These same dolphins will race toward a boat from several kilometers during and after social/sexual activities that take place immediately after bouts of feeding on schooling anchovy (Würsig and Würsig, 1980).

Why do dolphins bow-ride? It has been proposed that it is a mechanism to efficiently travel from one place to another. However, this is unlikely, for one often sees bow-riding dolphins after some time heading back to whence they picked up the vessel. Instead, it is more likely that riding the bow is done for enjoyment, for the sport of it; in other words, play. This is of great interest to behaviorists, for there are not too many nondomesticated adult mammals that habitually engage in activities just for the fun of them, although the list is growing with detailed observations in nature.

Bow-riding was certainly not "invented" by dolphins as a sport when human-made vessels first came on the scene. Instead, it appears to have been adapted from other wave-riding forms. Dolphins ride on the lee slopes of large oceanic waves and on the curling waves (or surf) that are formed as oceanic waves touch near-shore bottom (these two "rides" are hydrodynamically quite different; Hertel, 1969). Yes, dolphins "body surf" much as do humans, but dolphins are generally much better surfers than humans. Dolphins also ride the bow waves of surging whales, such as of the larger of the baleen whales, and sperm whales (*Physeter macrocephalus*). Dolphins even "entice" whales to surge ahead by rapidly crossing back and forth a whale's eyes and snout. The whale surges forward in response (and apparent annoyance), often blowing forcefully during the surge. An abrupt bow wave is formed, and the previously heckling dolphins are all lined up in that wave, apparently enjoying its momentary pressure effect. This activity can go on with one whale for 20 min or more, until the whale tires, the bow wave becomes less distinct, and the dolphins abandon it to try with another whale or to go about other activities. They have had their fun, and we are left to wonder what is going on in that large BRAIN during these bouts of quite obvious play.

Brain

HELMUT H. A. OELSCHLÄGER AND JUTTA S. OELSCHLÄGER
Johann Wolfgang Goethe University, Frankfurt am Main, Germany

It takes a complicated brain to deal with a complicated environment. —Christopher Wills, *The Sciences,* 1993

Adaptation to the aquatic environment is a multiconvergent phenomenon seen in a number of mammals. Most fascinating is the degree of specialization in different groups that comprise the semiaquatic insectivores, otters, and pinnipeds, and the fully aquatic sirenians and cetaceans. Both the body shape and the morphology of the sensory organs and brain intimate which selective pressures may have led to exclusively aquatic life. There are some obstacles, however, in understanding brain evolution in aquatic mammals. First, we are only marginally familiar with brain morphology of a very few species, and here mainly the bottlenose dolphin (*Tursiops truncatus;* Figs. 2–3). Second, the brain itself does not fossilize; only the outer shape can be studied in natural endocasts, and these are biased by covering blood vessels, meninges, and geological artifacts. Thus, the tracing of brain evolution in fossils is difficult and should be supplemented by phylogenetic reconstruction on the basis of extant relatives. This is particularly true for the cetaceans and the lack of adequate data from their closest relatives, the ungulates (hoofed animals; Fig. 1) and the more distantly related paenungulates [hyraxes or conies, sirenians or sea cows, and proboscideans or elephants; for a survey see Berta and Sumich (1999)]. Third, although the comparative consideration of analogous developmental trends (primates) may be useful for the understanding of brain evolution in highly encephalized aquatic mammals, the paucity of data often leads to an overestimation of these analogies. Particularly the large size of the cetacean brain sometimes has led to an anthropocentric approach to these mammals, thereby resulting in inadequate questions and wrong answers. This article first focuses on the cetacean, particularly the odontocete brain, and then discusses its specifics together with those of convergent adaptive trends seen in semiaquatic and other aquatic mammals so as to provide an idea of what may have happened during the evolution of these mammals.

Among the most fascinating characteristics of cetaceans are their exceptionally large brain, both in absolute and relative terms, and their extremely convoluted neocortex. Whereas dolphins usually have a brain mass of about 200–2000 g, the maximal size is attained in killer whales (*Orcinus orca*) and sperm whales (*Physeter macrocephalus*) with nearly 10,000 g. Basically, cetacean brains show the typical mammalian bauplan and are as complicated morphologically as those of other mammalian groups. To some extent they parallel the simian and human brains. In this respect, however, it has to be kept in mind that cetaceans have been subject to profound modifications in brain morphology and physiology during 50 million years of separate evolution in the aquatic environment. Moreover, it is still very difficult to correlate the results of behavioral and physiological research on dolphins with the existing neuroanatomical data. Because invasive experimentation is not possible in cetaceans, the functional significance of such data can only be elucidated via comparison with other aquatic or terrestrial mammals.

Most studies during the last decades have focused on the morphology and physiology of the adult odontocete brain and its functional systems [for reviews, see Jansen and Jansen (1969), Pilleri and Gihr (1970), Morgane and Jacobs (1980), Glezer *et al.* (1988), and Ridgway (1986, 1990)]. Concerning the development of the cetacean brain, very few recent papers have been dedicated to the striped dolphin (*Stenella coeruleoalba;* Kamiya and Pirlot 1974), harbor porpoise (*Phocoena phocoena;* Buhl and Oelschläger 1986), pantropical spotted dolphin (*Stenella attenuata;* Wanke 1990), narwhal (*Monodon monoceros;* Holzmann (1991), and sperm whale (Oelschläger and Kemp 1998). Some studies of the morphology and ultrastructure of the cetacean cortex are by Supin *et al.* (1978) and Manger *et al.* (1998). Other relevant publications are those by Bauchot and Stephan (1966) on semiaquatic insectivores; Schwerdtfeger *et al.* (1984), Schulmeyer (1992), and Marino (1998) on the encephalization of toothed whales and the quantitative composition of their brain; and Pirlot and Kamiya (1985), Reep *et al.* (1989), and Reep and O'Shea (1990) on the brain of manatees.

I. Morphology of the Cetacean Brain

A. General Appearance of the Brain

Whereas its development in the embryonal and early fetal period is similar to that of other mammals, the brain of adult whales and dolphins is rather spherical in comparison with that

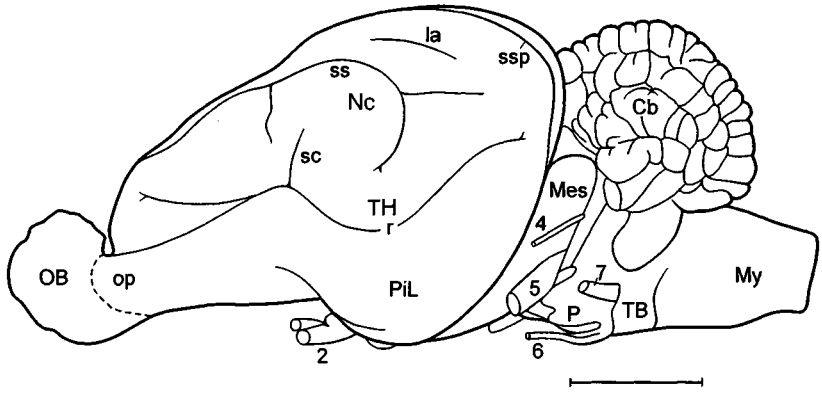

Figure 1 *Lateral aspect of the brain of a generalized land mammal, the mouse deer (*Hyemoschus aquaticus*), as a representative of the hoofed animals. Here the telencephalic hemisphere (TH) is rather flat, the neocortex (Nc) is moderately folded, and the olfactory bulb (OB) and the olfactory cortex in the piriform lobe (PiL) are large. In more advanced mammals such as cetaceans (see later), the hemispheres are much larger, the neocortex is much more extended, i.e., extensively folded, and it strongly dominates the olfactory cortex, which then is only found on the rostral basal surface of the telencephalic hemisphere. Cb, cerebellum; la, lateral sulcus; Mes, mesencephalon; My, myelencephalon; op, olfactory peduncle; P, pons; r, rhinal sulcus; sc, Sylvian cleft; ss, suprasylvian sulcus; ssp, splenial sulcus; TB, trapezoid body; 2, optic nerve; 4, trochlear nerve; 5, trigeminal nerve; 6, abducent nerve; 7, facial nerve. Scale: 1 cm. Modified after L. Sigmund (1981;* Vest Cs. Spolec. Zool. *45, 144–156).*

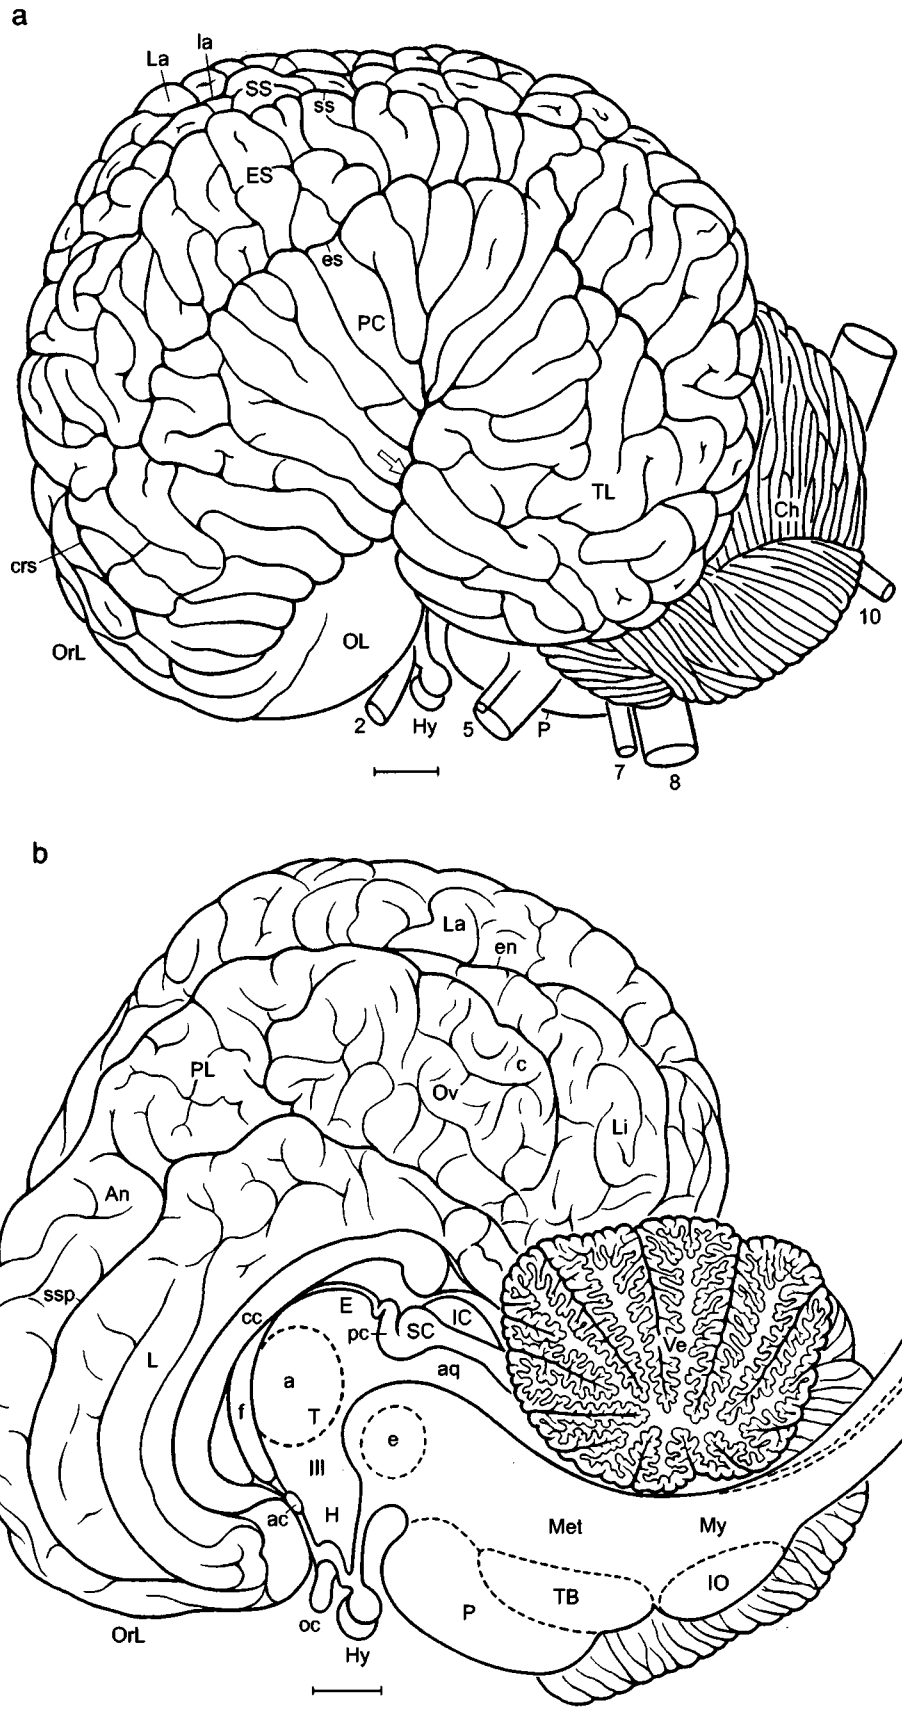

of generalized land mammals (Fig. 1) and is somehow reminiscent of a boxing glove (Fig. 2a). In correlation with the so-called "telescoping" of the skull along the beak–fluke axis, both the cranial vault and the brain are short but wide (Figs. 2–7), and more so in the toothed whales (odontocetes) than in baleen whales (mysticetes). In the bottlenose dolphin (Fig. 2), the hemispheres are rounded and high, and the anterior profile is rather steep. In ventral aspect, the contour of the odontocete forebrain is more trapezoidal, whereas in mysticetes it is more trilobar, with the area of the insula being visible as an indentation between orbital and temporal lobes (Figs. 3, 4, and 7). In comparison with hoofed animals (Fig. 1), the telencephalic hemisphere seems to be rotated rostralward and ventralward leading to a subvertical position of the corpus callosum (Figs. 2b and 6). In some odontocetes (bottlenose dolphin, sperm whale), the posterior myelencephalon and the anterior spinal cord arch around the cerebellum. Via an S-shaped transition, the spinal cord then continues straight along the body axis, thus accounting for the shortening of the cetacean neck region.

The ventricular system reflects the foreshortening of the brain in the tight coiling of the lateral ventricles, the shortness of the fronto-orbital region (anterior horn), the lack of an occipital pole of the hemisphere (no posterior horn), and the large size of the midbrain (cerebral aqueduct). Only rarely is a posterior horn of the lateral ventricle reported.

B. Telencephalon

1. Cortex In comparison with generalized tetrapod mammals (Fig. 1), the surface of the telencephalic hemispheres is extremely convoluted, particularly in toothed whales (Figs. 2–7). Gyrification in baleen whales is less extreme because of the greater width of their cortical layers. The neocortex accounts for

Figure 2 *Bottlenose dolphin brain: (a) lateral [after Langworthy (1932), modified after Morgane and Jacobs (1972) and Pilleri and Gihr (1970)] and (b) another specimen, mediosagittal aspect (after Morgane and coworkers). the large size of the telencephalon and thus the large size of the brain [percentage of the neocortex: 63% in the franciscana (La Plata dolphin or *Pontoporia blainvillei*); 87% in the sperm whale.

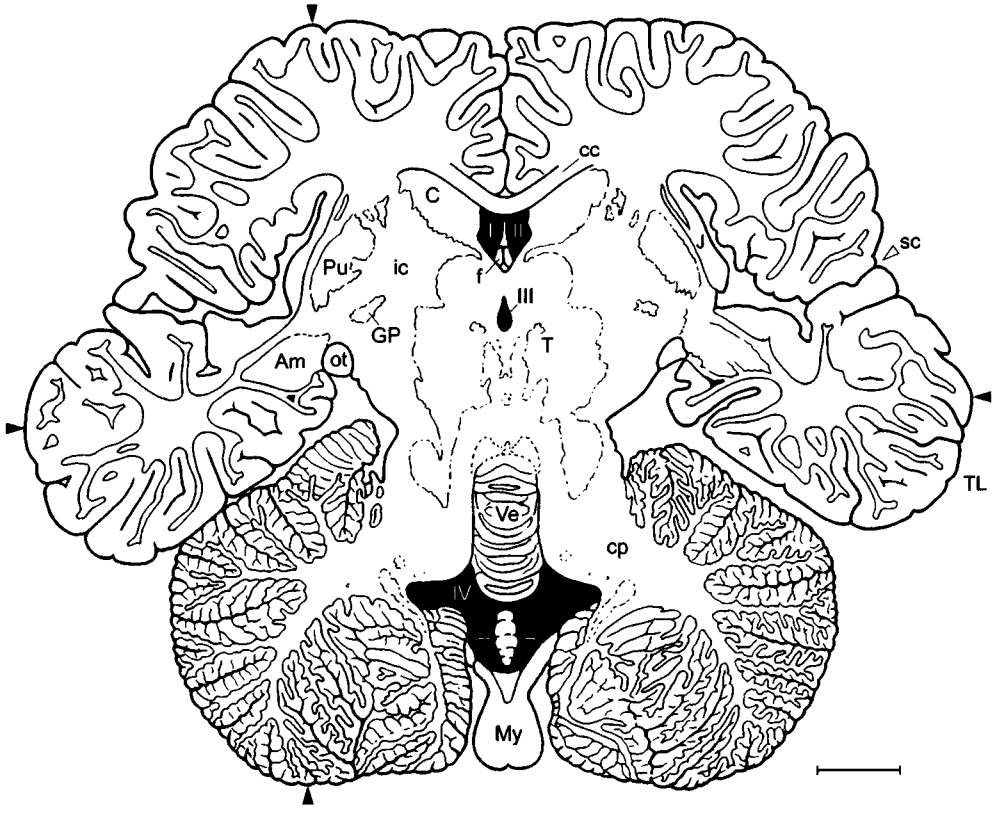
As in higher primates, the cortex of the cetacean olfactory and limbic systems (allocortex) is restricted to the rostral base of the hemisphere (paleocortex; olfactory system) or is located at the inferior horn of the lateral ventricle in the temporal lobe (archicortex: hippocampus as part of the limbic system). The archicortex in cetaceans, above all in toothed whales (Fig. 5), is much smaller than in terrestrial mammals. This correlates well with the small size of other components of the limbic system, e.g., the fornix as the main fiber tract of the hippocampus and the mammillary body as a main relay within the limbic system, whereas the cortical fields above the corpus callosum ("limbic lobe") and the entorhinal cortex on the temporal lobe are well developed. As in primates, the cortex of the cetacean limbic lobe presumably does not have an immediate relationship to olfaction. In adult baleen whales, the nose is small but obviously functional, and the same holds true for the components of the rhinencephalon. In adult toothed whales, these components are very much reduced: there is no olfactory part of the nose, olfactory bulb or tract, and the central parts of the olfactory system are small.



A. SURFACE CONFIGURATIONS. The fissural or gyral pattern of the cetacean cortex, which has been discussed in many papers in the past, bears general resemblance to that of carnivores and ungulates (Figs. 1–7 and 12). On the convex lateral surface and the vertex of the hemisphere, the main fissures (ectosylvian, suprasylvian, lateral sulcus) run at different distances around the Sylvian cleft. Thus, the ectosylvian gyrus is bordered by the ectosylvian and suprasylvian sulci, the suprasylvian gyrus by the suprasylvian and lateral sulci, and the lateral gyrus by the lateral and entolateral (paralimbic) sulci. As in other high-encephalized mammals, the insular area (Figs. 4 and 5) is covered by so-called "opercula" of the neighboring neocortex, which meet at the lateral hemispheral fossa (Sylvian cleft) and are com-

bined in the term perisylvian cortex (Fig. 2a). The medial cortex of the hemisphere (Fig. 2b) is subdivided by the suprasplenial sulcus or limbic cleft. The cruciate sulcus (Figs. 2a and 12) separates an anterior (medial) motor cortical field from a posterior (lateral) somatosensory field and is therefore a candidate for homologization with the ansate sulcus in hoofed animals as well as the central sulcus in primates. It is doubtful whether the "calcarine sulcus," which originates from the entolateral paralimbic cleft and encircles the oval lobule (Fig. 2b), is the homologue of the primate calcarine fissure that houses the primary visual field. Electrophysiological mapping experiments in dolphins have detected visually responding cortical fields in a more anterior and lateral position on the vertex of the hemisphere.

In one of the most plesiomorphic whales (Susu or Ganges river dolphin; *Platanista gangetica*), gyrification is still relatively simple. In the dorsal aspect, the main fissures are straight, smooth, and similar to the mesonychid *Synoplotherium*, a fossil terrestrial relative of the cetaceans (Geisler and Luo in Thewissen, 1998). Brain length in the latter still exceeded brain width, the formation of a temporal lobe had only just begun, and the olfactory system was well developed. Archaic fossil cetacean (archaeocete) brains are difficult to interpret morphologically because they apparently had large retia mirabilia on the surface of the brain as is seen in living baleen whales, which largely conceal the posterior (cerebellar) part. Their telencephalic hemispheres were obviously small and showed no signs of gyrification. As a result, the pattern of gyrification in cetaceans is not necessarily homologous in detail to that of their potential terrestrial relatives, the extant hoofed animals (Fig. 1).

B. LOCALIZATION OF CORTICAL AREAS. Electrophysiological cortical mapping experiments in the bottlenose dolphin located the *motor neocortical field* in the frontal (orbital) lobe rostral to the paralimbic lobe (Fig. 12). The motor cortex is characterized by the presence of giant pyramidal neurons and gives rise to the pyramidal tract. The *somatosensory field* is situated rostral to the visual and auditory fields. The position of the *visual fields* is somewhat more complicated. Although different in many aspects from other mammalian visual cortices, those of the dolphin are apparently well developed and highly differentiated. Whereas all authors place the visual cortex in the lateral gyrus, some distinguish a primary visual field near the medial border of the suprasylvian gyrus from a secondary field in the lateral gyrus. Other authors find an additional visual area in the medially adjacent part of the paralimbic lobe (Fig. 12). On the basis of histological analysis, a visual field has also been reported for the area along the supposed "calcarine" sulcus that separates the oval and lingual sublobules of the paralimbic lobe (Fig. 2b). The large *primary auditory field* lies on the vertex of the hemisphere in the suprasylvian gyrus and lateral to the visual field(s), and the *secondary auditory field* lies more laterally in the medial part of the ectosylvian gyrus.

Viewed as a whole, the topography of the motor and sensory projection fields of dolphins differs from that in other mammals. However, the primary cortical fields in cetaceans have retained the sequence found in plesiomorphic terrestrial mammals. Therefore, it seems as if the hemisphere would have been expanded to such a degree in a caudal and ventral direction (huge temporal lobe) that the auditory cortex extends as a belt along the vertex of the hemisphere and reaches further caudally in the dolphin than the visual field, which now is located more in the center of the hemisphere. In contrast to carnivores (cat, dog, seal), however, where all of the auditory cortex is located in the ectosylvian gyrus, this holds only for the secondary auditory field in toothed whales. The lateral surface of the whale hemisphere may be interpreted as a large "association cortex"

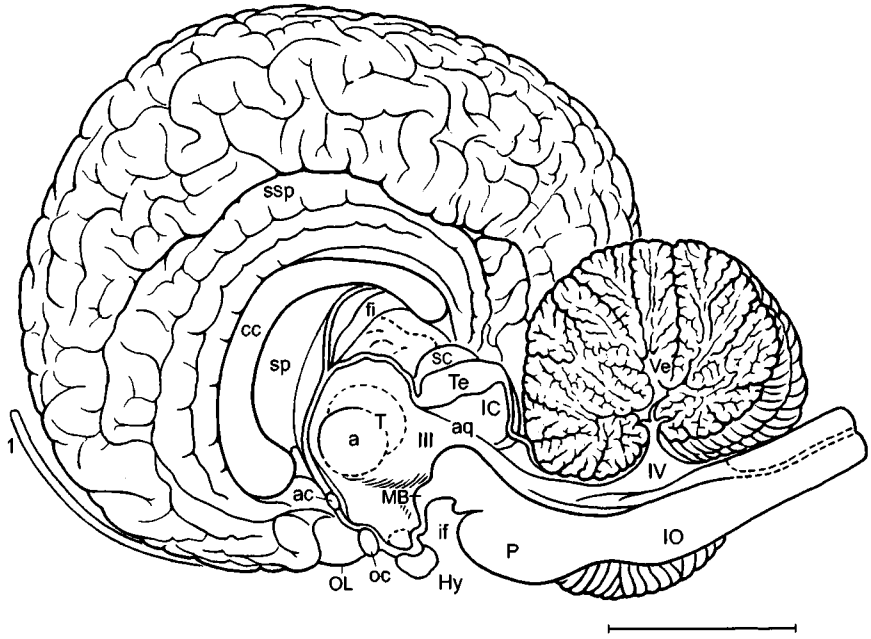

Figure 6 *Brain of humpback whale* (Megaptera novaeangliae) *in mediosagittal section. if, interpeduncular fossa; sp, septum pellucidum; Te, tectum; 1, olfactory nerve. Scale: 5 cm. After Breathnach (1955, 1960).*

connecting the auditory fields with other sensory and motor modalities.

2. *Commissures* The size of the commissural systems is specific for cetaceans and shows correlations with cortical and nuclear structures throughout the forebrain (Figs. 2b, 4–6, and 8a).

The *anterior commissure*, which links neocortical and paleocortical areas of both temporal lobes, obviously is weak due to the strong reduction of the olfactory system. The *corpus callosum* as the main link between the neocortical fields of both hemispheres is rather thin in dolphins relative to total brain mass and in comparison to the situation in other mammals. Tarpley and Ridgway (1994) have shown that in cetaceans the cross-sectional area of the corpus callosum (defined by its area in the midsagittal plane) related to brain mass generally decreases in larger-brained toothed whales (and pinnipeds), thereby suggesting that increases in brain weight are not necessarily accompanied by increases in callosal linkage between the telencephalic hemispheres. Thus, the corpora callosa of a killer whale and a human brain show the same cross-sectional area, with the killer whale brain being some five times heavier than that of the human. Furthermore, this relative reduction of the corpus callosum in larger species obviously has not been compensated by an enlargement of other commissural tracts. In conclusion, the interhemispheric connectivity seems to correlate inversely with brain weight insofar as larger brains possess a lower neocortical neuronal density with the result that relatively fewer fibers constitute the corpus callosum. An additional explanation for the regression of the corpus callosum in larger brains could be a smaller percentage of cortical neurons establishing interhemispheric connections and thus a certain independence on the part of both hemispheres. In electroencephalographic experiments, sleeping bottlenose dolphins have been reported to show signs of wakefulness (low voltage, fast activity waveforms) in one hemisphere and sleep (high voltage, slow wave) in the opposite hemisphere. The *posterior commissure* (Fig. 8a) is very well developed. Provided that its connections to other brain structures are similar to those in other mammals, the considerable size of the posterior commissure in cetaceans may suggest massive projections from the somatosensory relay nuclei of the brain stem and the cerebellum to the contralateral pretectum and thalamus.

3. *Basal Ganglia* All components of the basal ganglia as known from other mammals are present in cetaceans (corpus striatum, globus pallidus, claustrum, amygdaloid complex) and, for the most part, show the usual topographic relationships to each other and to neighboring structures (Fig. 4). Moreover, their histological organization corresponds well with that in other mammals. The caudate nucleus as the main part of the large cor-

pus striatum, which bulges distinctly in the area of the "olfactory tubercle" (olfactory lobe), together with the putamen, is largely separated from the latter by a well-developed internal capsule.

Reports regarding the size of the basal ganglia in cetaceans are contradictory. Schwerdtfeger *et al.* (1984) have shown that in the franciscana (La Plata dolphin), the corpus striatum, one of the most important centers for locomotion, is large and attains a size index between that of prosimians and anthropoids. Moreover, as in primates, a size correlation between the striatum and the neocortex seems to be valid for the dolphins as well. The structure of the amygdaloid complex resembles that of other mammals very closely. The size of the amygdala as a whole seems to have been affected only slightly by the reduction of the paleocortex in odontocetes, giving the impression that this nucleus, as in primates, is largely independent of the olfactory system. Its relative size in the franciscana seems to be larger than that in primates, presumably on account of its interconnections with the hypertrophied auditory system and the temporal lobe. However, the corticomedial group of the amygdaloid nuclei, which functionally depends largely on the olfactory system, occupies the same proportion of the entire amygdaloid complex in the harbor porpoise as in the macrosmatic sheep. The lateral amygdaloid nucleus may bear some relation to auditory function, as this nucleus is extremely well developed both in whales and in bats.

C. Diencephalon

The relative size of the diencephalon in plesiomorphic dolphins (franciscana; Ganges river dolphin) is approximately the same as that in simian monkeys, including the human. There are no reliable data for advanced, i.e., pelagial, dolphins. The predominant structure is the thalamus (Figs. 2b, 4a, 5, and 6). The shape of the diencephalon in mediosagittal aspect is often rather wedge-like in adult cetaceans, with the hypothalamus bending slightly caudalward and tapering in the direction of the hypophysis, particularly in larger toothed whales. Whereas in late embryos and early fetuses the floor of the hypothalamus is rather long, it is foreshortened rapidly in later stages during the telescoping process, especially in larger toothed whales. Thus, the transverse interpeduncular fossa between the optic chiasm and pons appears slit-like in adult toothed whales, whereas it is much wider in baleen whales (Fig. 2b, 3, 6, and 7).

1. Epithalamus The habenular complex is large and the habenular commissure well developed. The pineal organ is reduced or even lacking in cetaceans. A pineal rudiment is present between the habenular and posterior commissures in embryos and early fetuses of dolphins and the sperm whale, but not in the early fetal narwhal (Holzmann, 1991). In adult whales and dolphins, many observers found the pineal organ to be lacking; rudiments, however, have been found in the humpback whale (*Megaptera novaeangliae*) and fin whale (*Balaenoptera physalus*).

2. Thalamus Basically, the organization of the large thalamus in cetaceans corresponds well with that in a variety of terrestrial mammals, among them ungulates and primates. There are four groups of nuclei in the dorsal thalamus that constitute about 92% of the thalamus in the bottlenose dolphin: anterior, medial, ventral, and lateral. (1) The anterior group of nuclei, which is related to the cortex of the highly developed cetacean limbic lobe, is well developed, but constitutes only a small part of the total dorsal thalamus. The anteroventral nucleus, which projects to the anterior limbic cortex, dominates this group. In contrast, the mammillary body and the interconnecting mammillothalamic tract are comparatively small and thin. (2) In the medial group of the thalamus, the mediodorsal nucleus is remarkably large and merits special interest because of various connections with olfactory and limbic structures as well as a presumed phylogenetic size correlation with the frontal (orbital) lobe of the mammalian telencephalic hemisphere. (3) The ventral group consists mainly of somatosensory nuclei and constitutes a large part of the dorsal thalamus. In mammals generally, its ventral posterior nucleus (VPN) receives afferents via the medial lemniscus and the spinothalamic and trigeminothalamic tracts and dispatches a main projection to the somatosensory cortex. In the bottlenose dolphin, the ventral posterior nucleus is relatively small and projects to the neocortex anterior to the suprasylvian auditory area (Fig. 12). Compared to its lateral subnucleus, where the body region is represented, the medial subnucleus of the VPN with the head representation is relatively large. In dolphins, the limited somatosensory representation of the body is also reflected in the spinal cord (see later). (4) As in higher primates, the lateral group of thalamic nuclei in cetaceans is dominated by the massive pulvinar, the largest single complex in the thalamus of the bottlenose dolphin. The pulvinar more or less blends into both the strongly protruding medial geniculate nucleus (MG; auditory) and the large lateral geniculate nucleus (LG; visual). The main projection of the inferior pulvinar targets the suprasylvian gyrus, and that of the medial pulvinar the ectosylvian gyrus, whereas the lateral pulvinar projects to the border of the lateral and suprasylvian gyri. The MG is impressively large in cetaceans (Fig. 8) and reflects the outstanding development of the auditory system in these animals. Ventral portions of the MG project to the primary auditory area of the suprasylvian gyrus (Fig. 12) and dorsal portions to the "secondary" auditory area in the ectosylvian gyrus, as well as to the temporal operculum (perisylvian cortex). In the bottlenose dolphin, the LG is surprisingly well developed, although less so than the MG. The LG projects to the visually excitable part of the lateral gyrus (Fig. 12), but does not show the laminar organization usually associated with biretinal projection. This may be related to the fact that the fibers in the optic nerve show a complete or almost complete decussation in cetaceans.

3. Hypothalamus The basal part of the diencephalon exhibits an organization similar to that encountered in other mammals. Anterior, tuberal, and posterior hypothalamic nuclei are evident but not particularly prominent. Paraventricular and supraoptic nuclei are obvious because of their large hyperchromatic cells, with the latter nucleus being especially well formed. As in other mammals the supraoptic commissure is well developed and well organized. The small size of the mammillary bodies, which in the postnatal animal do not protrude at the brain surface, correlates with the weak development of the hippocampus, postcommissural fornix, and mammillothalamic tract.

4. Hypophysis The pituitary gland in both toothed and baleen whales is rather wide (adenohypophysis), a pars intermedia and residual lumen are lacking. The neurohypophysis, which is separated from the adenohypophysis by a meningeal septum, is slender and consists of a pars nervosa, an infundibular stalk, and a median eminence. The adenohypophysis is composed of chromophobe, basophilic, and eosinophilic cells. The hypothalamohypophysial tract was reported to be wide in the bottlenose dolphin.

D. Brain Stem and Cerebellum

The percentage of the dolphin midbrain in the total brain volume is relatively low and ranges between that of prosimian and simian primates. Nevertheless, the size index, which is related to body size and the regression line of basal insectivores (shrews, hedgehogs, tenrecs), shows a remarkable increase of this structure even in plesiomorphic "river dolphins" (franciscana; Ganges river dolphin). This may be attributable to the growth of auditory system components. The cerebellum and pons are well developed, and the myelencephalon (medulla oblongata) is very large in comparison with that of other mammals. This may be due to the considerable growth of cranial nerve nuclei and their connectivity, particularly those of the trigeminal, auditory, and motor systems.

1. Selected Nuclei The cetacean brain stem comprises nuclei known from other mammals; some of them, however, are rather exotic and their functional properties are virtually unknown. Perhaps because they have changed considerably in appearance and/or location during evolution, a few nuclei have been described as unique to cetaceans so that they cannot be homologized easily with potentially corresponding nuclei in other mammals. Many of the features, however, presented in the literature on the cetacean brain stem could be confirmed in the work of Holzmann (1991) on the fetal narwhal (Fig. 11).

The *oculomotor nucleus* is the largest eye muscle nucleus, a fact that correlates well with the diameter of the oculomotor nerve. In comparison, the trochlear and abducent nuclei and nerves are rather small and thin in most cetaceans. The *trigeminal nuclei* (motor, principal, spinal nucleus) are very well developed, reflecting the large relative size of the cetacean head and the diameter of the trigeminal nerve, which is maximal or submaximal among the cranial nerves. Within cetaceans, the motor nucleus is reported to be larger in mysticetes but subdivided much better in odontocetes. Also the sensory principal nucleus is reported to be larger in baleen than in toothed whales, with its dorsal part giving rise to the well-developed trigeminothalamic tract (Wallenberg). The *facial nucleus* is very large in cetaceans and often bulges at the ventral surface of the medulla (tuberculum faciale). The nucleus is divided into a number of cell groups that can be differentiated from each other cytologically. These cell groups are believed to be responsible for specific muscles or muscular systems, e.g., the dorsal group for muscles of the upper respiratory tract around the blowhole (epicranial complex; Cranford *et al.*, 1996), which are involved in the generation and emission of sonar signals in toothed whales. In comparison with other mammals, the *ambiguus nucleus* is large in cetaceans, which recalls to mind the situation in bats (mouse-eared bat; *Myotis myotis*). This nucleus, which is larger in mysticetes than in odontocetes, innervates the muscles of the pharynx, larynx, and the striated muscles of the esophagus via the glossopharyngeus–vagus–accessorius nerve complex. Comparable to other mammals, it should be involved in cetaceans in respiration, food processing, and sound production in the larynx. The *nucleus of the accessory nerve*, as part of the anterior horn in the spinal cord, is moderately well developed. This may be related to the extreme foreshortening of the cervical region, restrictions in head and shoulder girdle motion, and the transformation of the forelimb into a steering device (flipper). The *hypoglossal nucleus*, a derivative of the ventral horn of the spinal cord, is well developed, although the flexibility of the tongue is reported to be restricted in most cetaceans. In large baleen whales, the tongue may attain the body mass of a full-size elephant.

Nuclei related to or belonging to the extrapyramidal motor system are located in the rostral mesencephalon and in the formatio reticularis throughout the rhombencephalon. The *elliptic nucleus*, which is situated within the central gray either rostral or dorsal to the oculomotor nuclear complex, is very conspicuous and in the past was thought to be unique for the Cetacea until a similar nucleus was found in the elephant. Moreover, it was unclear whether the *nucleus of Darkschewitsch* is integrated into the elliptic nucleus or is even equivalent to this nucleus. Today, the latter opinion is the generally accepted one: In cetaceans, the elliptic nucleus projects via the medial tegmental tract to the rostral medial accessory inferior olive and correlates with a hypertrophy in cerebellar structures (see later). The *red nucleus* in cetaceans is little known. In contrast to ungulates, which possess a large rubrospinal tract and lack a spinal pyramidal tract, cetaceans have both weak rubrospinal and corticospinal tracts (see later). *Pontine nuclei* are exceptionally well developed in cetaceans, giving rise to the bilaterally ascending large brachia pontis, and the transverse pontine bundles are very numerous. The size and the caudal extent of the pons are directly related to the size of the neocortex.

The cetacean *inferior olive* is characterized by an extraordinary development of the medial accessory olive, particularly its rostral portion; in comparison, the principal olive and the dorsal accessory olive appear small. In the two cetacean suborders, there are only minor differences in the relative development of the subnuclei, and both inferior olives join each other in the midline. The rostral part of the medial accessory olive receives massive input from the elliptic nucleus via the medial tegmental tract, and its pronounced development in cetaceans seems to be related to the immense size of the posterior interposed nucleus and of the paraflocculus. In terrestrial mammals, the medial accessory olive is part of a fiber system involved in directional hearing.

2. Cerebellum The cetacean cerebellum is very large (Figs. 2–4, 6, 7, 9, and 10), its size obviously being linked phylogenetically with that of the neocortex. In older studies, the relative mass of the cerebellum in baleen whales with respect to total brain mass (average: 20%) was reported to represent a maximal development within the mammalia as a whole. A recent study has shown that in relation to body mass the cerebellum of baleen whales is not as voluminous as in larger dolphins such as the

killer whale. Concomitantly, it became obvious that the large proportion of the cerebellum in the total brain volume of baleen whales is attributable to the relatively small size of the forebrain. Indeed, in double-logarithmic regressions, baleen whales rank a little higher than sperm whales, beaked whales, and "river" dolphins but distinctly below the delphinid cetaceans. With respect to the regression line in basal insectivores (Stephan), the cerebellum of the plesiomorphic La Plata dolphin ranks higher than the averages of prosimian and simian monkeys but lower than humans. In a group of delphinid species, indices of the total brain mass and cerebellum mass relative to body mass exceeded other groups (sperm whales, river dolphins, baleen whales) by up to three times. Within cetaceans, the cerebellum of the baleen whales is much better understood due to ontogenetic histological studies by Jansen (1950). Only minor structural differences exist, however, between the cerebella of toothed and baleen whales: Thus, the mysticete cerebellum is more rounded and slightly hourglass shaped in the dorsal aspect, whereas the odontocete cerebellum is somewhat more flattened dorsoventrally as a consequence of the stronger telescoping of the brain and resultant overlapping of the cerebellum by the cerebral hemispheres.

The cerebellum consists of two large hemispheres and a comparatively narrow vermis in between (Figs. 10 and 12). Two transverse fissures separate three cerebellar lobes: the primary fissure separates the small anterior (rostral third) from the large posterior lobe (caudal two-thirds), and the posterolateral fissure the posterior lobe from the small flocculonodular lobe. These size relations between the lobes are characteristic for cetaceans. In midsagittal section (Fig. 10), the conventional subdivision of the vermis into nine lobules of the mammalian cerebellum is obvious. In cetacean cerebellar hemispheres the small size of the anterior lobe may be explained by electrophysiological findings indicating that the hemispheral parts of this lobe comprise the cortical representation of the fore- and hindlimbs (cf. Jansen, 1950) that are highly modified or even have vanished in these animals. The caudally adjacent ansiform lobule, which also receives input from the extremities, is similarly small. However, the representation of the head in the simple lobule of the posterior lobe is rather large, and the considerable size of the paramedian lobule (body representation) has been related to the enormous significance of the tail in cetaceans. The paraflocculus, situated between the parafloccular and posterolateral fissures, is exceptionally large, particularly the ventral parafloccular lobule (Fig. 3). The latter comprises about half of the surface of the cerebellar hemisphere. In mammals, generally speaking, the paraflocculus usually receives climbing fibers from the rostral part of the medial accessory inferior olive. In cetaceans, both structures are exceptionally large, which strongly indicates a functional relationship between the paraflocculus on the one hand and trunk and tail on the other (Jansen, 1950). The flocculonodular lobe as the principal terminus of primary and secondary vestibulocerebellar and visceromotor fibers ("vestibulocerebellum") is very small in cetaceans, particularly the floccular component (Fig. 10). In mammals generally, the latter is responsible for the regulation of compensatory vestibulo-ocular and optokinetic movements as well as compensatory movements of the neck in the so-called "smooth pursuit" movements of the eyes, particularly in

carnivorous animals that lure and hunt. Dolphins, however, which have a restricted neck mobility and can use their visual system only during daylight, may have to rely on their auditory system instead to follow their prey effectively.

In the ontogenesis of the cetacean cerebellar cortex, which is three layered, the fundamental mammalian pattern of transverse and longitudinal zones is discernible. These longitudinal zones obviously are related topographically to the development of the cerebellar nuclei (anterior, medial, and posterior interposed nuclei, lateral cerebellar nucleus). In cetaceans, the lateral intermediate cortical zone (C2 zone) is developed enormously, occupying about three-fourths of the cerebellar surface (paraflocculus) and correlating with the huge posterior interposed nucleus.

3. *Main Fiber Systems* *Medial lemniscus:* In cetaceans, the afferent spinal system (proprioceptive sensitivity) is moderately developed in accordance with the reduction of the hindlimbs and pelvic girdle. In these animals, the dorsal funiculi (gracile and cuneate fascicles) are strikingly small; they are thought to convey input predominantly from the flippers and the tail (sense of position). Nevertheless, cutaneous sensitivity in the trunk was reported to be high (Slijper, 1962). The medial lemniscus is weak in the caudal medulla, but becomes considerably stronger at more rostral medullary levels, presumably due to the input of afferent systems of the head (auditory, trigeminal systems).

Trigeminothalamic tract (Wallenberg): The dorsal part of the principal sensory trigeminal nucleus gives rise to the ipsilateral (uncrossed) trigeminothalamic tract. The latter terminates in the medial part of the ventral posterior thalamic nucleus as the main somatosensory thalamic nucleus. As in ungulates and the elephant where it is extremely well developed, the tract is thought to be responsible for intra- and peri-

Figure 11 *Brain stem of fetal narwhal* (Monodon monoceros) *with major nuclei (from Holzmann, 1991, modified). The physiological quality of the nuclei is indicated by different textures. Figure 12 *Neocortical motor and sensory fields in the bottlenose dolphin. A1, A2, auditory fields; crs, cruciate sulcus; M, motor field; PL, paralimbic lobe; S, somatosensory field; V, visual field. After Morgane* et al. *(1986).*

oral sensitivity in cetaceans innervating, e.g., tactile bodies on the lips of fin whales and sei whales (*Balaenoptera borealis*), and the epicranial complex (Cranford *et al.*, 1996) in toothed whales.

Medial tegmental tract: The elliptic nucleus (Figs. 2b and 11), which almost "replaces" the red nucleus in Cetacea, is developed enormously in whales and elephants and gives rise to the strong medial tegmental tract that proceeds to the rostral part of the huge medial accessory inferior olive. This nucleus also receives afferents from the spinal cord (spino-olivary tract) and projects to the lateral intermediate (C2) zone in the huge paraflocculus. The paraflocculus, which was shown to be the main target of auditory pontocerebellar projections in the rat and was estimated to receive three-fifths of the pontocerebellar fibers in the blue whale (*Balaenoptera musculus*), has a massive projection to the posterior interposed nucleus of the cerebellum. From the latter nucleus, ascending fibers run to the elliptic nucleus and other nuclei at the diencephalic/mesencephalic border, which, in turn, project to the inferior olive. Like the medial accessory olive, the paraflocculus also has been associated with mass movements of the trunk-and-tail region, the only region where the axial skeleton possesses a reasonable range of motion. The medial tegmental tract thus seems to be part of a recurrent circuit (elliptic nucleus–inferior olive–paraflocculus–posterior interposed nucleus-elliptic nucleus), which combines auditory input with locomotor activity and illustrates the dominant position of hearing among sensory systems in whales.

Pyramidal tract: The tract originates in the neocortical motor area rostral and medial to the "cruciate" sulcus (Figs. 2a and 12) and runs through the internal capsule. At mesencephalic levels, the localization of the pyramidal tract is difficult and it is very small at high medullary levels. Typical macroscopical "pyramids" as seen in terrestrial mammals are not present in cetaceans. Here, the pyramidal tracts are weak and situated lateral to the inferior olivary complex, with both inferior olives joining each other midsagittally (Figs. 3, 7, and 9). Obviously, the extremely well-developed rostral medial accessory olive, which occupies the ventromedial area in the medulla, has pushed the pyramids lateralward. Caudal to the inferior olives, the pyramidal tract disappears in baleen whales. In toothed whales, both pyramids merge with each other; their crossing (decussation) is described by most authors as indistinct and the pyramidal tract as small and hardly visible. Thus, it is likely that pyramidal (corticospinal) fibers do not descend more than a few (cervical) segments in the spinal cord. This pattern resembles much that is seen in hoofed animals and the elephant. In terrestrial mammals, an inverse relationship exists between the development of the pyramidal tract and of the rubrospinal tract. Perissodactyls and artiodactyls have small pyramidal tracts, whereas their rubrospinal tracts are large. The opposite is seen in primates whose small rubrospinal tract is coexistent with a large spinal pyramid. Such an inverse relationship is not encountered in Cetacea: Here, both the rubrospinal and corticospinal tracts are small, obviously a speciality in cetaceans.

II. The Cetacean Spinal Cord

Within the nervous system, the spinal cord (Figs. 4a and 8) is responsible for the innervation of the trunk and tail, and the

pectoral and pelvic girdles together with their appendages. Thus, the spinal cord mediates between the locomotory apparatus of the body and the brain by transmitting sensory vs motor information.

All cetaceans are characterized by (1) the subtotal reduction of the pelvic girdle and hindlimb and the transformation of the pectoral girdle and forelimb into a steering device and (2) the extraordinary development of the axial musculature, thus contributing to the spindle shape of the body required for efficient locomotion by the trunk-and-tail complex.

With respect to the sensory innervation of the body in whales and dolphins, we do not know anything about the innervation of joints and tendons. The skin of the body is hairless. Nevertheless, the assumption of poor sensory innervation of the skin in cetaceans has been contradicted by Slijper (1962), who observed reactions of stranded and captive dolphins to the gentlest touch.

In correlation with the large amount of axial musculature, the motor ventral roots of the cetacean spinal nerves appear to be larger than the dorsal ones, particularly in the posterior part of the system (cauda equina). There are up to 97 pairs of spinal nerves (e.g., 44 in the harbor porpoise: 8 cervical, 11 thoracic, and 25 lumbocaudal). On each side of the body, along the vertebral column, there are two plexus (cervical plexus: C_1–C_3; brachial plexus: C_4–Th_1). The peripheral nerves supplying the tail can be very long (up to 15 m in large baleen whales).

Other remarkable features of the cetacean spinal cord are its relative length and shape. Whereas in the harbor porpoise the relation of body length to spinal cord length is 3.75:1, baleen whales have values from 4:1 (fin whale) to 6.7:1 (right whale; *Eubalaena* sp.). A cervical enlargement (intumescence) for the innervation of the pectoral girdle and flipper has been described in different odontocetes and in the fin whale. The presence of a caudal intumescence, however, is controversial.

The internal structure of the spinal cord reflects peculiarities of the cetacean motor and sensory systems: long and slender anterior horns, occupying half of the gray matter, the posterior horns modest to stunted in appearance (Fig. 8a). A short and pointed lateral horn is discernible at thoracolumbar levels. The gelatinous substance, in general, is remarkably poorly developed in cetaceans, with only traces found in some spinal segments of the harbor porpoise and the fin whale. In mammals, this crescentic mass of small interneurons is involved intimately in the connectivity of cutaneous afferents of the dorsal spinal root with delicate fibers of the spinothalamic tract (pain and temperature). In cetaceans, the lack of gelatinous substance may correlate with the loss and modification of the posterior and anterior limb, respectively.

Whereas cell density and numbers of neurons in the cetacean spinal cord are not known, the dimensions of the cells in the anterior horn have been investigated in baleen whales. Despite the large difference in body mass, the sizes of the perikarya in the cervical and thoracic spinal cord are similar in the whale and human, but in the lumbocaudal area the whale has much larger perikarya with a volume presumably several times larger than in comparable human perikarya.

III. Functional Systems

A. Chemoreceptor Systems

Adult baleen whales still have a small, but functional, nose probably equipped with olfactory mucosa and an olfactory nerve, and they possess an olfactory bulb, slender olfactory peduncle, and an olfactory tubercle (Figs. 3 and 7), a situation resembling that of the human. Presumably as a consequence of the adaptation to sonar orientation, prey detection, and communication (high-energy sonar clicks in the upper respiratory tract), toothed whales have reorganized their nasal system to such a degree that (at most) a short olfactory peduncle is found in the adult animal very rarely [sperm whale; northern bottlenosed whale (*Hyperoodon ampullatus*)]. In general, toothed whale embryos display the anlage of an olfactory bulb, but the latter is reduced in early fetal stages. Interestingly, however, a "residue" of the bulb persists in the large ganglion of the terminal nerve (Buhl and Oelschläger, 1986) that is responsible for the establishment of the hypothalamo–hypophyseal–gonadal axis in prenatal mammals, and thus for sexual behavior and reproduction in adults. In dolphins, the terminal ganglia contain the highest number of neurons found within the mammalia (Ridgway *et al.*, 1987). These facts argue both for the nonolfactory nature of the terminal nerve and its possible implications in the control of blood flow in the nose and basal forebrain, in maintenance of the epithelial lining of the upper respiratory tract, and in the sensory control of sonar signal emission as well. A vomeronasal organ (Jacobson's organ) and nerve are absent in cetaceans and sirenians.

Despite the strong general reduction of the olfactory system in toothed whales, the olfactory tubercle seems to be well developed even in comparison with that in baleen whales, which possess a small but presumably functional olfactory system. In many cases, the tubercle may not be separated clearly from the neighboring diagonal band and prepiriform cortex, a configuration often called the "olfactory lobe" (Fig. 2a). In reality, it is the large corpus striatum (basal ganglia) that protrudes here at the basal surface of the brain as an "olfactory" tubercle and is covered by an incomplete layer of thin paleocortex analogous to the situation in humans. The remaining paleocortex (diagonal band, piriform cortex) is moderately developed. The amygdala as a whole, however, is rather large in cetaceans for other reasons.

Dolphins are clearly sensitive to chemical stimuli (both natural and artificial compounds), and some cetaceans were reported to have functional taste buds. With the olfactory part of the nose disappearing during prenatal development, dolphins still may resort to their taste buds and the trigeminal innervation of the oral cavity for chemoreception.

B. Visual System

In most cetaceans, the visual system is reported to be fairly well developed (Figs. 2–4, 6–8, 10, and 12). In the adult harbor porpoise, the optic nerve contains 81,700 axons, 147,000–390,000 axons in the bottlenose dolphin, 193,000–250,000 axons in the domestic cat, and 1,200,000 in the human. The Amazon river dolphin (*Inia geoffrensis*) shows a rather low axon count (15,500), and the optic nerve of the

Ganges river dolphin, whose eye lacks a lens and may be capable of serving as a light receptor only, contains a few hundred axons. Large whales have moderate numbers of axons. In baleen whales, the optic nerve contains approximately the same number of axons (252,000–347,000) as in the bottlenose dolphin, whereas the sperm whale, with roughly the same body weight and relatively smaller eyes, has only 172,000 axons.

Bottlenose dolphins have a thick retina composed of rods and cones. The fovea centralis is band shaped, and neurons in the ganglionic layer are very large (up to 150 μm in diameter) with thick dendrites and myelinated axons of up to 9 μm thick. Cetaceans have laterally placed eyes and, if at all, one small binocular visual field rostrally and ventrally as well as another one dorsally and slightly caudally. The optic fibers show a complete or almost complete decussation, and the lateral geniculate body is not laminated. The superior colliculus is large in most cetaceans, as is the case in many land mammals, including carnivores, ungulates, and primates. Dolphins show a definite stratification of the superior colliculi, where layers typical of terrestrial mammals are recognizable. In some baleen whale species, the superior and inferior colliculi are approximately the same size (length and width), whereas in others [Southern right whale (*Eubalaena australis*); blue whale (*Balaenoptera musculus*)] the inferior colliculi have double the surface of the superior colliculi. In toothed whales, this relation may range from 2:1 up to 7:1 (maximum: susu).

Electrophysiological mapping studies in dolphins have located the visual cortex not in the dorsocaudal or occipital part of the hemisphere but in a more central position near the midline (Fig. 12). Although well developed, the physiological importance of the cetacean visual system theoretically should be inferior to that of the auditory system because of functional restrictions in murky water and in darkness.

C. Auditory System

The auditory system in whales and dolphins basically corresponds to that in terrestrial mammals; however, the various components have been adapted morphologically and physiologically to the specific conditions of hearing under water (Figs. 2, 3, 4a, and 5–12).

In general, auditory structures are smaller in baleen whales than in toothed whales (compare Figs. 3 and 7–10). According to the impressive diameter of the vestibulocochlear nerve and the number of axons in the cochlear nerve, the cetacean ventral cochlear nucleus (VCN) and other auditory centers are very large (Figs. 5, 11, and 12). The secondary auditory fiber tracts (trapezoid body, acoustic striae) are well developed. In the La Plata dolphin as well as in the harbor porpoise and the common dolphin (*Delphinus delphis*), the absolute volume of the cochlear nuclei is 6–10 times larger than in the cat and the human; in the beluga (*Delphinapterus leucas*) it is 32 times larger, and in the fin whale it is 20 times larger. Numbers of cochlear neurons range between 583,000 and 1,650,000, i.e., 6–17 times that of the human. The ratio of primary cochlear nerve fibers to secondary cochlear neurons is between 1:5 and 1:8 (human: 1:4). The volume of other auditory nuclei is either very large in comparison or very low, even if we take into account the different body mass of the animals. In the La Plata dolphin, multiples 17× the volume of the cat's nuclei are found in the nucleus of the trapezoid body and 39× in the intermediate nucleus of the lateral lemniscus. A comparison between volumes of auditory nuclei in the common dolphin and the human yields similar results. There are multiples for the dolphin VCN (16×), lateral superior olive (150×), single nuclei of the lateral lemniscus (up to 200×), and for superior auditory centers such as the inferior colliculus (12×) and laminated medial geniculate nucleus (7×). The cetacean VCN is composed of five subunits consisting of specific neuron populations that are also found in terrestrial mammals. This has been proved by cytological investigations in the franciscana (Schulmeyer, 1992) involving the morphology of the axon terminations. The nucleus of the trapezoid body is well developed: A great mass of fibers passes from the VCN into the trapezoid body, to the ipsilateral and contralateral nuclei of the lateral lemniscus, and the inferior colliculus. Interestingly, the dorsal cochlear nucleus (DCN) could not be found in many toothed and baleen whales, perhaps because of its reduction to the point of insignificance. Obviously, this nucleus is engaged in the assessment and/or elimination of "auditory artifacts" caused by positional changes of the head and pinnae toward a sound source. In terrestrial mammals (including bats) with "normal" external ears and good movability of the head and pinnae, the DCN is well developed and even laminated.

The existence of the medial superior olive (MSO) is discussed in the literature on toothed whales. In some species, the two subnuclei of the superior olive cannot be distinguished, and whether the medial nucleus is very small or even lacking in other species, as has been reported for bats, is not clear at present. In mammals, the MSO is believed to be engaged in the processing of low frequencies and the lateral superior olive (LSO) in the processing of high frequencies and ultrasound. Therefore, it has to be expected that the LSO is larger in toothed whales and the MSO in baleen whales, reflecting the actual neurophysiological adaptation (audiogram) of these animals. The components of the midbrain tectum differ in size in baleen whales and toothed whales. Whereas in mysticetes the superior colliculi (vision) may be larger or smaller than the inferior colliculi (audition), odontocetes always have very large inferior colliculi (Figs. 2b, 4a, 5, 6, 8, and 10). The striking dominance of the sense of hearing in adult toothed whales has been emphasized by a number of investigators, among them Jansen and Jansen (1969), Morgane and Jacobs (1972), Schulmeyer (1992), and Oelschläger and Kemp (1998). Indeed, the auditory system has stamped the morphology, size, and connectivity of the whole odontocete brain due to the necessity of processing vast amounts of acoustic information and on account of the high propagation velocity of sound in water (Ridgway, 1986, 1990) and the need of background noise discrimination. In the adult sperm whale and other toothed whales, the auditory system seems to be the major source of information. Even when the animals dive to considerable depths and the visual system progressively loses its importance for orientation and the detection of prey, the auditory system may still be functional (navigation by auditory input). Toothed whales scan their surroundings with a sonar system (clicks) and are probably able to integrate the acoustic input together with visual in-

formation into two- or even three-dimensional ephemeral images within their extended neocortical auditory projection fields (Supin *et al.*, 1978). In addition, communication between individuals by means of acoustic signals clearly is very important for whales and dolphins, especially during hunting activity and/or when vision is reduced. Pelagic dolphins, in particular, tend to live in larger groups. In the open sea, their natural environment is largely represented by the distributional pattern of their kin, which changes more or less continually.

D. Vestibular System

The four major vestibular nuclei usually found in mammals are also present in cetaceans. The lateral vestibular nucleus of Deiters in cetaceans is most conspicuous and its dimensions fairly large, but the number of neurons does not seem to be exceptional. The other nuclei are rather small. The lateral vestibular nucleus does not receive projections via the vestibular nerve, and its connections to the lateral B-zone of vermis, dentate nucleus, fastigial nucleus, and the oculomotor complex are very similar to those of cerebellar nuclei. In mammals generally, the other vestibular nuclei receive input from the semicircular canals, but these are minute in cetaceans. All of the vestibular nuclei project via the medial vestibulospinal tract and medial longitudinal fasciculus to motor neurons of the neck musculature and to the nuclei of the ocular muscles, and they are involved in reflex arcs harmonizing the position and precision movements of the head with those of the eyes in the pursuit of prey.

E. Limbic System

In odontocetes, the various cortical and subcortical components of the limbic system show different degrees of development (Figs. 2b and 3–7). In adult toothed whales, including the sperm whale, the hippocampus and mammillary body are unusually small and interconnected by a relatively thin fornix, whereas the anterior thalamic nuclei and the habenulae are better developed as in other mammals. The amygdaloid complex is large in toothed whales (Schwerdtfeger *et al.*, 1984). In contrast to the nucleus of the olfactory tract, which is totally dependent on olfactory input, the amygdala (taken as a whole) is well developed in microsmatic species (baleen whales, human) and even in anosmatic species (toothed whales). This indicates that, apart from olfactory stimuli, input to the amygdala arises from other sources, among them the auditory system. Furthermore, the remarkable development of the cortical limbic lobe (periarchicortex) in the dolphin again points to the largely nonolfactory character of this system.

F. Characteristics of Major Peripheral Cranial Nerves

The eye muscle nerves are thin in small cetaceans, particularly in river dolphins with their reduced eyes where they may even be completely lacking (Pilleri and Gihr, 1970). In marine dolphins, the oculomotor nerve comprises the highest number of axons (about one-third that in the human), followed by either the trochlear or abducent nerves. In large whales (especially baleen whales), the numbers of axons in the eye muscle nerves are distinctly higher and correspond to the situation in humans.

The trigeminal nerve is the thickest cranial nerve in baleen whales and sometimes in the sperm whale as well, whereas in all of the other toothed whales the vestibulocochlear nerve has the maximal diameter (Figs. 2a, 3, and 7–9). The diameters of the axons tend to be thin in the trigeminal nerve, whereas cochlear axons rank among the thickest axons known. In the smaller toothed whales investigated, the trigeminal nerve contains 82,000–156,000 axons (human: 140,000). The fact that trigeminal nerves in sperm and baleen whales have about the same large number of axons (490,000 vs 370,000–500,000) may be explained by the extreme size of the forehead region innervated in these animals.

The vestibulocochlear complex is the largest cranial nerve in toothed whales, and occasionally in the sperm whale as well, and it is the second largest in baleen whales (Figs. 2a, 3, 5a, and 7–10). In the sperm whale, it contains 215,000 axons, whereas in baleen whales, axon numbers vary from 154,000 to 179,000. Smaller toothed whales have 84,000 (harbor porpoise) to 171,000 axons (beluga), with the latter thus ranking near the much larger baleen whales (human: 50,000). The ratio of auditory and vestibular axons within the eighth nerve is disputed in the literature. Whereas some authors found that cochlear fibers in the bottlenose dolphin (total: 116,500 fibers) comprise about 60% of all the vestibulocochlear fibers (a percentage known from the human), other authors reported a similar total axon number (113,000) but a much higher fraction of cochlear axons (97%) as opposed to a very low number of vestibular axons. In comparison with humans (19,000 vestibular axons), dolphins possess only one-fifth in vestibular axons, a fact that correlates well with their small semicircular canals, with their low number of vestibular ganglion cells, and with the observation that the diameter of the vestibular nerve is barely one-tenth that of the cochlear nerve.

The variation in thickness of the facial nerve and in the diameter of its fibers throughout the cetaceans again sheds some light on biological correlations. Thus, the facial nerve in the sperm whale is nearly as thick as the vestibulocochlear nerve, containing about three times as many axons as in large baleen whales and three to eight times more axons than in smaller toothed whales. Baleen whales rival sperm whales in body size, and in all of these giants the head may attain one-third of the total length and mass of the body. In contrast, the absolute and relative size of the head in other toothed whales is comparatively small. Accordingly, it may be speculated that the prominent thickness of the facial nerve and the large number of its motor axons in the sperm whale are attributable to the extreme size of the forehead, which has to be regarded as an oversized "sound machine" (Cranford). Here, the forehead is characterized by the unique amount of acoustic fat tissues and massive blowhole musculature (innervated by the facial nerve) that may help stabilize the giant fat bodies and adjust their shape (acoustic lenses) during the emission of sonar signals.

IV. Neocortex

A. Layering and Cell Morphology

For a biological interpretation of the cetacean brain, we must review some existing data about the neocortex, e.g.,

brain/body mass relationship, absolute and relative cortex mass, and the structure of the neocortex, i.e., the layering, neuron density, synapse number and density, as well as density of gliocytes. The latter cells nourish, isolate, protect, and possibly help stimulate and regenerate the neurons and therefore are as essential for neocortical activity as the neurons themselves.

No other brain surpasses the cetacean brain in richness and complexity of neocortex gyrification. Moreover, toothed whales exhibit encephalization indices similar to those of higher primates. The cetacean neocortex shows an extremely tight folding and has a maximal surface within mammalia. At the same time, dolphins have cortical widths known from ungulates (Hummel, 1975), and even large whales do not seem to attain the average cortical thickness of higher primates (human).

In principle, the cetacean neocortex is six layered and similar to that in other mammals (Fig. 5b). Regional differentiation, however, is less obvious, and cortex lamination is not well expressed, particularly due to the widespread absence of a distinct layer IV in adult toothed whales and the moderate granularization of the cortex in general. In whales, layer one (molecular layer) can comprise up to about one-third of the total cortical width, whereas layer II is thin but rich in small pyramidal neurons that stain intensively with cresyl violet (Nissl stain). This second layer corresponds to the outer granular layer in the human. Its pyramidal cells that border on the molecular layer are mostly "extraverted" in whales, i.e., they show a clear predominance of apical (subpial) dendrites over basal dendrites. Layer III is thick and characterized by a variety of pyramidal cells with comparatively smaller neurons populating the outer half of the layer, whereas larger cells occupy the inner half. In view of the special role played by layer IV (corresponding to the inner granular layer in the human) as a major input layer for thalamocortical specific afferents in advanced land mammals, the precise cytoarchitectonic definition of this layer in cetaceans and its neuronal composition are crucial. It was postulated that in eutherian mammals layer IV appears and develops in proportion to the progressive displacement of specific thalamic afferents from the first (molecular) layer to midlevels of the cortex. In evolutionary advanced primates and ungulates, layer IV of the sensory neocortex is relatively wide and consists mainly of small granular, i.e., nonpyramidal cells mostly of the spiny stellate type. The fact that a lower degree of granularization also exists in insectivores and insectivorous bats and that layer IV is often not discernible here led to the assumption that the structure of the cetacean neocortex is "primitive" and allegedly shows a considerable number of other plesiomorphic features. These are the lack of definite boundaries, gradual morphological transitions between functionally separate neocortical areas, a poor lamination pattern, a thick layer I, extraverted pyramidal neurons in layer II, a dense band of large pyramidal neurons referred to as layer III$_c$/V, overall weak granularization with a predominance among nonpyramidal neurons on the part of large isodendritic stellate cells, a well-developed layer VI, and a lack of giant pyramidal cells. In some cortical areas of the fin whale brain, however, a narrow zone where nerve cells are sparse or lacking seems to mark the site of layer IV, and the corresponding external stria of Baillarger was found in a dolphin. Very young postnatal bottlenose dolphins also show a "remnant" of this layer. The innermost part of the cetacean cortex, presumably corresponding to layers V and VI in terrestrial mammals, usually displays no clear stratification and fades out into the white matter.

According to Deacon (1990), the common ancestor of all cetaceans very likely possessed layer IV granule cells as do the hyraxes or conies, plesiomorphic members of the paenungulate order (animals with precursors of genuine hooves), which includes the sirenians and elephants. In the highly encephalized elephants, layer IV was found to be lacking in all cortical areas, and their neocortex architecture is strikingly similar to that of the fin whale. The loss of granule cells in layer IV in cetaceans was therefore regarded a rare derived trait that may be correlated with the shift of the orphaned terminations of the specific thalamic afferents (originally terminating in layer IV) back to layers I and II, thus allowing more neurons in layer II to persist.

However, based on Golgi studies, there is little reason for thinking that the neocortex in the dolphin exhibits less variety than in other mammals, and a fair proportion of true stellate and other nonpyramidal cells exists in the dolphin cortex scattered throughout layers III and V, which may combine functions of afferent, efferent, and associative layers. Moreover, the distribution of neuronal size classes is rather similar to that occurring in other mammals.

Comparative immunocytochemistry (GABA, calcium-binding proteins) in the primary visual and auditory cortex of dolphins has revealed that the overall quantitative characteristics of the neurons are similar to those in other mammalian orders, being closer to insectivores and rodents in some features and to bats and primates in other characteristics.

B. Neuron Density

The density of cells is subject to considerable variation throughout the cetacean neocortex not only from area to area but also within the individual layers, although the relatively small and densely packed neurons in layer II account for at least 50% of all the neurons in a given cortical block. Tower (1954) measured the neuronal density in unspecified cortical areas of two fin whales, arriving at a mean figure of 6800 cells/mm^3. He also reported a similar neuronal density (6900/mm^3) in an elephant brain of about the same size. In comparison with approximately 18,000/mm^3 in the human and more than 100,000/mm^3 in rat and mouse, Tower concluded that there was a direct relationship between cortical neuronal density and brain mass. Other cell counts, however, reported an average of 57,000 neurons/mm^3 for the adult human. Cell counts in a series of toothed whales again revealed some decrease in density with increasing body size and absolute brain mass (harbor porpoise, 13,200; bottlenose dolphin, 13,000–44,200; beluga, 12,300; humpback whale, 8300/mm^3). Total counts of neurons beneath 1 mm^2 of cortical surface do not take into consideration the different width of the neocortical plate in various mammals and result in 28,500 cells for the adult bottlenose dolphin and 46,400 in an animal of 18 days. By comparison, the figure of 147,000 was given for all neocortical areas studied in a series of mammals ranging from mouse to human, except for the primate visual cortex, which harbors about twice as many neurons. Cell counts in single cortical

sampling columns from pial surface to white matter with a cross-sectional area of 25 × 30 μm resulted in 19 cells for the elephant, 21 for the bottlenose dolphin (Güntürkün, personal communication), and 110 in the nonstriate cortex of other mammals. Although Rockel's assumption may be restricted to primates, carnivores, and some rodents, dolphins obviously have a much smaller number of neurons in a given volume sample of cortex than would be expected from the size of their brains.

The mean size of neuronal perikarya has no definitive relation to brain size. Whereas primates tend to have a similar mean neuronal size and size distribution, other mammals, including cetaceans, show a tendency to increase neuronal size with increasing brain weight. Dolphins have moderate neuron sizes more or less similar to those found in ungulates (sheep, cow, horse) and elephants. Volume measurements reported a maximal neuronal volume of over 20,000 μm^3 in the harbor porpoise, which is about double the maximal volume found in ungulates and small to medium sized for the human.

C. Synapses

The synaptic parameters of the visual neocortex show many of the qualitative and quantitative features of the general mammalian bauplan. For example, the quantitative relationship between the number of synapses with contacts to different components of cortical neurons such as perikaryon, dendritic shafts, and dendritic spines in the dolphin cortex does not differ significantly from these parameters in most other mammals. The same holds true for the distribution of other synaptic parameters throughout the cortical layers such as the area and form factor of individual synaptic boutons, the length of active zones (densities) of synaptic membranes, and several parameters relating to synaptic vesicles.

In their neocortex, dolphins show a mixture of conservative and advanced features at the cortical architectonic level as well as at neuronal and synaptic levels. When looking at the cortex as a whole, the aforementioned so-called conservative features occur mostly in superficial layers I and II, whereas deeper layers III–VI are characterized as more or less equivalent to those in advanced terrestrial mammals with the exception of layer IV. To date, adequate comparative data on ungulate groups or other aquatic mammals are not available. Moreover, cetaceans have a much lower neuronal density but, at the same time, a much higher synaptic density per volume unit and per neuron than terrestrial mammals. The majority of all synapses (70%) is found in cortical layers I and II: The latter seem to receive the brunt of cortical input as opposed to layer IV in many terrestrial mammals. Thus, in cetaceans, layer II seems to be the main relay element conveying information from the subcortical and intracortical afferents via layer I to the other cortical layers. All of these data, however, are difficult to interpret as to their significance both for function and/or physiology and for the evolution of the cetacean neocortex.

With respect to the total number of synapses in their cortices (0.87 vs 1.3 × 10^{14}), the dolphin and human resemble each other much more closely than other mammalian species. This appears to reflect primarily the generally large volume of neocortices in both dolphin and human brains as well as the maximal number of synapses per neuron compensating for minimal neuronal density in the dolphin.

D. Glia

Only a few data are available on gliocytes in the cetacean neocortex. In the bottlenose dolphin, glial density was found to vary in different cortical areas from 28,000 to 93,200 cells/mm^3, values rather similar to those in the human (average: 40,000–100,000 cells/mm^3). The number of gliocytes per number of neurons (glia/neuron ratio) is species-specific, i.e., varies among the mammalian groups and during ontogenesis due to changes in neuron density. This basically implies that larger brains have higher glia/neuron ratios. Thus, the ratio rises from small rodents (mouse, rabbit: 0.35) via ungulate species (pig, cow, and horse: 1.1), the human (1.68–1.78) and bottlenose dolphin (2–3.1), to large whales (fin whale: 4.54–5.85). Consequently, the glia/neuron ratio within each species increases from birth to maturity, thereby signaling the importance of glia for growing neurons and, thus, for neocortical function. Another implication is the necessity of comparing only mature specimens. Accordingly, in species with similar neocortex volumes, the glia/neuron ratio may be interpreted both ways, i.e., in favor of neurons or glia as factors of equal importance.

In summary, the morphology of the dolphin neocortex seems to be equivalent to that of advanced terrestrial mammals, but its specific features are not yet understood. With respect to ontogenesis and evolution, the allometric process of thinning out the number of neuroblasts and/or neurons via apoptosis and via the generation of increasing amounts of glia and neuropil for their connectivity seems to proceed faster in cetaceans than in other mammals. At the same time, the cortical plate seems to spread out more than in other mammals, leading to an extremely extended and convoluted neocortex with a minimal neuron density but maximal synaptic density.

V. Characteristics of Semiaquatic and Aquatic Mammals

A. General Remarks

The brain can be regarded as the true center of the body responsible for the maintenance of physiological conditions (homeostasis) and survival. By means of the cranial and spinal nerves, the brain collects all of the sensory information available, thereby evaluating, synthesizing, and using it for optimal behavior in manifold aspects: orientation, FEEDING, defense, COMMUNICATION, and reproduction. Thus, the brain not only represents all parts of the body but, at the same time, mirrors the situation of the animal within its ecological niche. On account of these tight correlations, evolutionary changes in the environment and in the biology of the species must show in the morphology of the nerves and brain. Rapid transgressions of mammalian groups into totally different habitats are related to strong "selection pressure," i.e., adaptational processes unfold rather quickly and may lead to profound changes in brain morphology and function, reflecting changes in the body's periphery. One obvious principle is seen in the increase or decrease in size of individual brain structures, which may result in qualitative changes. Comparative analysis of the brain, therefore,

can help unveil evolutionary strategies of the species by looking for qualitative and quantitative correlations between various brain structures and body mass and between those structures belonging to the same functional system.

B. Insectivores

The most obvious changes in the quantitation of the brain in all semiaquatic insectivores are as follows: a marked reduction of the primary and secondary olfactory centers, a slight to moderate size increase of the neocortex and myelencephalon, and a moderate to marked growth of the diencephalon (dorsal and ventral thalamic nuclei, geniculate nuclei), as well as other structures related to the trigeminal, auditory, or motor systems. There is a general but weak size increase of the limbic system, with the hippocampus showing the least change among the components of this system in comparison to terrestrial relatives. The trigeminal complex is thought to replace the olfactory system as the main sensory system in the search for food (vibrissae), whereas the accessory olfactory (vomeronasal) system seems to be unaffected by the animal's adaptation to water.

C. Carnivores

Other examples of CONVERGENT EVOLUTION are single mustelids (otters) and the pinnipeds. In comparison with their terrestrial relatives and with respect to basal insectivores, otters are distinctly more encephalized, and the same seems to be valid for pinnipeds (seals) and their potential terrestrial relatives. In contrast, sirenians have been reported to have low encephalization indices in comparison with herbivorous terrestrial "relatives," such as the hyraxes, a fact that may be related to the comparatively high body mass of sea cows and the arboricolous mode of life in hyraxes.

1. Eurasian River Otter (Lutra lutra) Here, the adaptations to the aquatic medium are only moderate: The olfactory system is markedly smaller than in terrestrial carnivores but better developed than in the seal. The hippocampus and amygdala are large. The visual system is well developed (thick optic nerve, lateral geniculate nucleus layered). The same holds true for the auditory system, but the acoustic tubercle (dorsal cochlear nucleus) is small. The trigeminal system is well developed (vibrissae), but the facial nerve and nucleus are of moderate size. As in the seal, the basal ganglia are moderately developed, but the globus pallidus is large. In the cerebellum of the otter, the vermis is considerably smaller with respect to the hemispheres than in terrestrial mammals but larger than in pinnipeds. The inferior olive in the otter is organized similarly to that in terrestrial mammals, but it is larger than in these animals and smaller than in the seal and porpoise. The pyramids are prominent thick bundles. The gracile and cuneate nuclei (proprioceptive body sensitivity) are also well developed in the otter.

2. Harbor Seal (Phoca vitulina) Pinnipeds spend much of their time on land. They have very good vision and their hearing is acute. The pineal organ is present. Both pairs of limbs are present although more or less modified, thereby indicating high somatic sensitivity in general. Apart from important differences, seals share many features with terrestrial carnivores, e.g., large telencephalic hemispheres with a well-developed corpus callosum. The hemispheres are covered with highly convoluted neocortex and nearly conceal the large cerebellum in dorsal aspect. The pons is flat but extended (Fig. 13). The olfactory bulb and tract are small and thin, and the anterior commissure is small. Hippocampus and amygdala are large, and the habenula is well developed. The visual system is well developed (thick optic nerve, large and layered lateral geniculate body, very large superior colliculus). The myelencephalon is wide, with the auditory system generally being well developed (thick eighth nerve, large ventral cochlear nucleus, trapezoid body, lateral lemniscus, medial geniculate nucleus and inferior colliculus), but the tuberculum acusticum (dorsal cochlear nucleus) is very small as in whales (no pinna). The trigeminal system is very pronounced (vibrissae), with the trigeminal being much thicker than the vestibulocochlear nerve, whereas the facial nerve and nucleus are of normal size (Fig. 13). The inferior olive is larger than in land carnivores but very similar to theirs in structure.

Among the fiber systems, the cerebral peduncles are very large and the pyramids thick, whereas the gracile and cuneate fascicles are smaller than in terrestrial carnivores but thicker than in cetaceans.

D. Sirenians: Dugongs and Manatees

In comparison with plesiomorphic dolphins such as the susu and franciscana, sea cows have small brains (Fig. 14). At about the same brain mass (220 g), the body of the young dugong (*Dugong dugon*) is about 4.5 times as heavy as that of the franciscana. The relative size of the telencephalic hemisphere (with respect to the total brain) is similar to that in the dolphin. With respect to basal insectivores, however, the size index of the cortex in the young susu is 3.5 times higher than in the dugong. In sirenians, gyrification of the cortex is only rudimentary. Also, there is little underlying white matter surrounding the very large ventricles, and the size of the corpus callosum is moderate. In the frontal region, cortical thickness (gray matter) is averaged at an exceptional 4.0 mm, and histological analysis suggests a potential motor cortical field at the rostroventral tip of the hemisphere as well as extended potential somatosensory fields on the adjacent lateral (convex) surface. Presumably, the primary auditory field and visual fields are located on the posterior lateral surface of the hemisphere and in the dorsal occipital region as in many other mammals. The cell number in the neocortex is reported to be sparse, but the subdivision into cortical fields and the lamination are more distinct than in cetaceans. The molecular layer (I) is of normal width. Layer II, which is most conspicuous, contains densely packed small pyramidal neurons with long apical dendrites. In the potential visual cortex, layer IV is composed of small almost granular pyramidal cells. Layer V is most pronounced in the potential motor field, and layer VI contains unique neuron clusters (Rindenkerne) in the potential somatosensory, visual, and auditory cortices. Sea cows have small olfactory bulbs and thin, ribbon-shaped olfactory tracts with small olfactory tubercles (Figs. 14a and 14b). Nevertheless, the olfactory system as a whole is distinctly larger in the sea cow than in the dolphin, but the vomeronasal organ

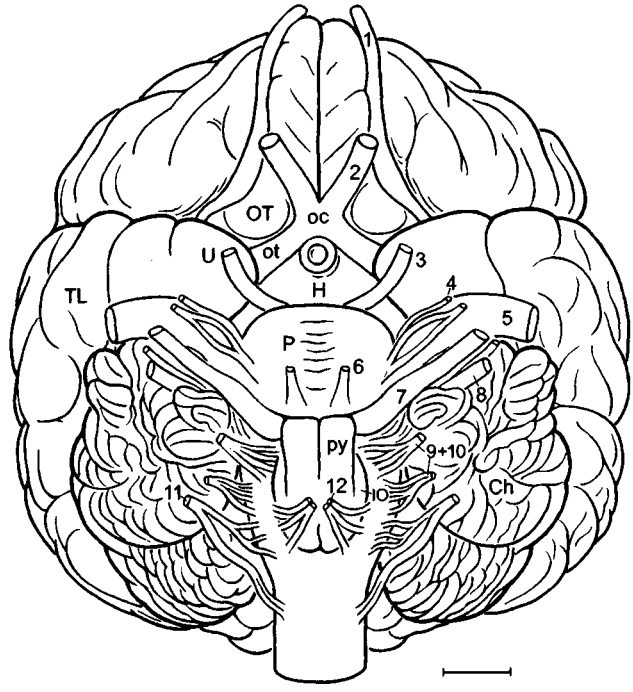

Figure 13 *Harbor seal brain in basal aspect. py, pyramidal tract. Scale: 1 cm.*

is also lacking. The anterior commissure is well developed. The hippocampus and fornix are reported to be even smaller than in plesiomorphic dolphins, and the mammillary bodies are small and not visible superficially. The visual system seems to be moderately developed (relatively thin optic nerve, nuclei of ocular muscle nerves highly reduced in size, small superior colliculus). A pineal gland is lacking. The brain stem of the dugong is small in comparison with that of the dolphin: The diencephalon is moderately developed (small visual thalamic nuclei) and the size increase of the mesencephalon with respect to body mass is very low. The myelencephalon is also rather small, probably due to the moderate size of the auditory and motor systems, and despite the large trigeminal nuclei and very thick nerve supplying the rostral part of the head (particularly the extremely important vibrissae). The long ascending and descending fiber systems are moderately developed. Whereas most components of the auditory system, such as the cochlear nerve, ventral cochlear nucleus, medial geniculate nucleus, and inferior colliculus, are more or less well developed (inferior colliculus distinctly larger than superior colliculus), the dorsal cochlear nucleus is very small. The facial nerve and nucleus are much better developed (motor activity and control of the muzzle in seaweed grazing). With reference to basal insectivores and in comparison with dolphins, the cerebellum is rather small in the sea cow. This may be partly attributable to the sluggish swimming behavior of this animal, which can hardly evade attacks by humans. The vermis, however, is relatively large as in aquatic carnivores (otter, seal). In the sea cow, the paraflocculus is also relatively large but much smaller than in cetaceans. Whereas the pyramids are thin, the decussation in the cervical spinal cord is distinct, but the pyramidal tract cannot be followed further caudalward. The gracile and cuneate nuclei (proprioceptive body sensitivity) are fairly well developed. The inferior olivary complex in sirenians is characterized as being small, but it bulges at the basal surface of the myelencephalon, with its medial (accessory) and lateral (principal) nuclei being of similar size. As a whole, the inferior olive very much resembles that of ungulates, but is distinct from that of the elephant.

E. Cetaceans

Cetaceans presumably originated from an extinct basal ungulate group (Condylarthra, Mesonychidae) that also gave rise to the living artiodactyls (Thewissen, 1998), and close relationships with single extant ungulate groups have been discussed as well. Although generally very sparse in the fossil record, skeletal parts can give a reasonable impression of the evolutionary changes from terrestrial ancestors to living cetaceans. Unfortunately, this does not hold true for the brain, which only is known from endocasts. The latter formed in the cranial vaults of fossilizing precetacean or cetacean mammals and can provide only limited information about the external morphology of the actual brain of those animals. Furthermore, the understanding of cetacean brains has been hampered in yet another respect: Comparative considerations led to the idea that, similar to primates, cetaceans could be derived phylogenetically directly from insectivores, which represent some kind of "ancestral group" for many extant mammals. Nevertheless, although the cetacean neocortex exhibits some features that seem to re-

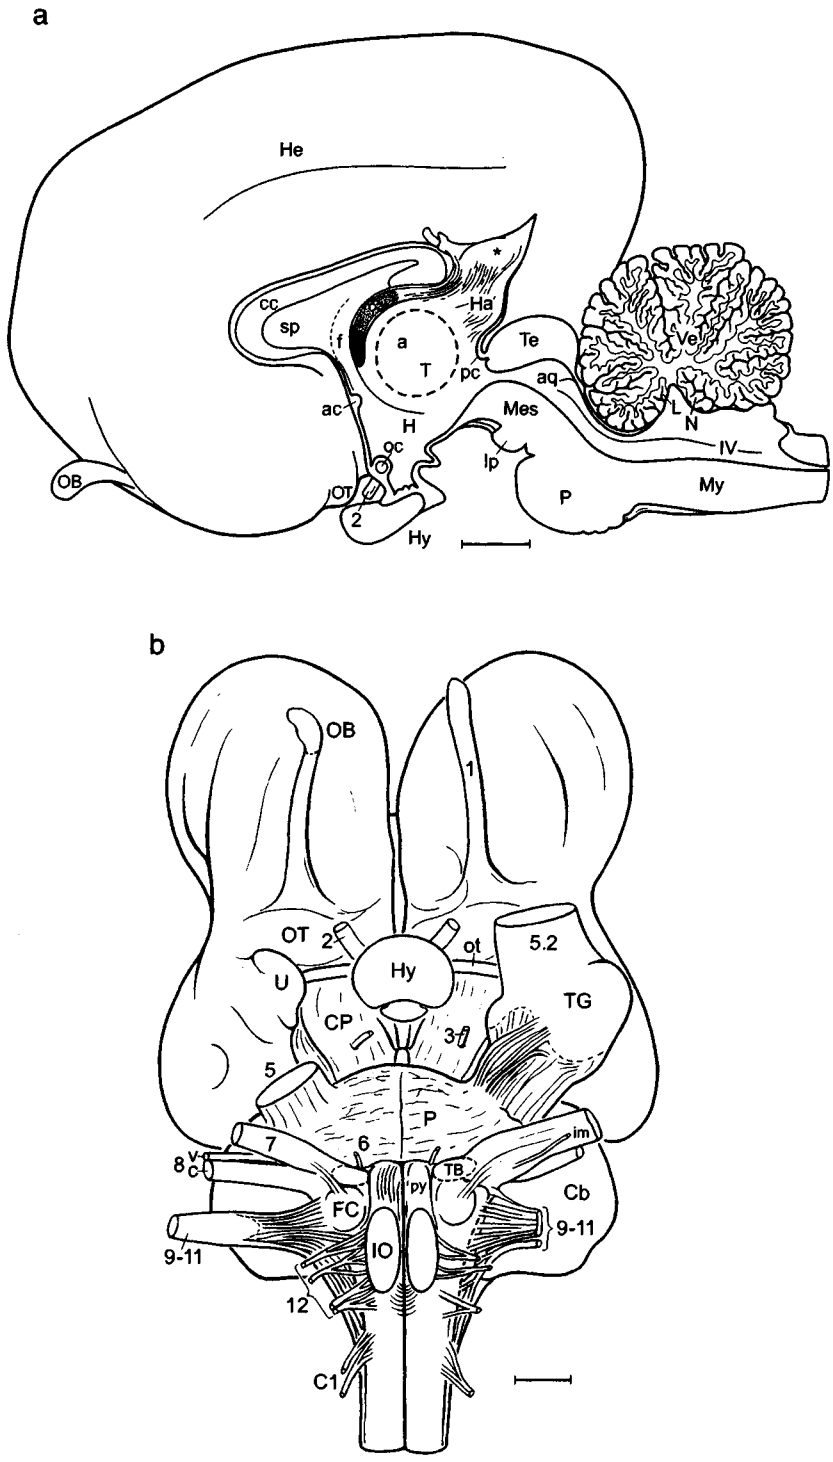

Figure 14 *Sea cow (dugong) brain: (a) mediosagittal aspect and (b) basal aspect. After Dexler (1913), modified. Asterisk, dorsal evagination of diencephalic roof; circle, choroid plexus and interventricular foramen; FC, facial tubercle; lp, interpeduncular nucleus; L, lingula; OB, olfactory bulb; TG, trigeminal ganglion; 5.2, maxillary branch of trigeminal nerve. Scale: 1 cm.*

call the situation in insectivorous brains, a more promising approach would be to compare cetaceans with plesiomorphic paenungulates such as the hyracoids (hyraxes or conies), proboscids (elephants), generalized artiodactyls such as the tragulids (Fig. 1), and also so-called "advanced" (derived) hoofed animals. Such a reconstruction of the hypothetical ancestors' brains on the basis of "closely" related extant mammalian groups would be of considerable value for understanding cetacean evolution in general.

In the franciscana (*Pontoporia blainvillei*), one of the least specialized living TOOTHED WHALES (brain mass of the adult: 220 g; body mass: 35 kg), the encephalization index (EI: 5.7) ranges above the level of prosimians (lemurs, *Tarsius*) and in the lower echelon of simians (monkeys, apes, human), whereas the EI level of marine dolphins (13.5) is above that of simian primates but clearly below that of humans. From what we know today, the franciscana brain shows all the features typical of toothed whales and mostly of whales, in general: (1) a large telencephalon and, at the same time, total loss of the rostral olfactory and the whole accessory olfactory system, and the reduction of the remaining paleocortex. The archicortex and some other components of the limbic system are very small, but the limbic cortex seems to be well developed. The neocortex is very much maximally extended and convoluted. As in primates, the neocortex is by far the largest brain structure in river dolphins and other cetaceans. Its size index is higher in river dolphins than the average of prosimians but clearly lower than that of simians. Even higher values for the neocortex can be expected for marine dolphins. Giant cetaceans are difficult to interpret because their brains, although approaching 10 kg in total mass, are dwarfed by their huge bodies. In addition to the neocortex, the striatum is one of the most progressive telencephalic structures and indicates a high functional capacity of the motor systems. The amygdala, another component of the basal ganglia and belonging to the limbic system, is considerable in size, although its corticomedial component largely consists of paleocortex. (2) The thalamus is large due to the exceptional volume of different nuclei (medial, dorsal, ventral, medial geniculate, and pulvinar). (3) The large volume of the midbrain is significant and is due to the extreme size of some components of the auditory system. Thus, for example, the inferior colliculus is much larger than the superior colliculus. (4) Another major character is the large size of the cerebellum and particularly of the paraflocculus and posterior interposed nucleus as well as associated structures (elliptic nucleus, pons, inferior olive and accessory fiber tracts). (5) Finally, the medulla oblongata is, comparatively speaking, also very large due to the outstanding development of most of the auditory nuclei as well as those of the trigeminal and facial nerves.

These five adaptational trends seen in the dolphin brain are more or less paralleled in semiaquatic insectivores (Bauchot and Stephan, 1966) and other aquatic mammals (otter, pinnipeds) where growth of single brain regions surpasses the reduction in other regions such that total brain size increases. Sirenians, however, seem to be rather different in many respects. Nevertheless, in some ways and to some degree, these different groups of mammals have been regarded as "stages" of convergent adaptation to the aquatic habitat.

F. Comparative Aspects

According to the present state of our knowledge, aquatic mammals differ in the quantity and thickness of the *neocortex* and in the degree of gyrification of the telencephalic hemispheres. Whereas in pinnipeds and terrestrial carnivores the primary neocortical fields coincide in location, their position is rather different in dolphins in comparison with other mammals. The changes and differences in neocortical structure and composition found in aquatic mammals are not very well understood and cannot be explained to date functionally.

The general appearance of the neocortex in otters and pinnipeds corresponds fairly well to that of their terrestrial relatives. Sirenians show a small neocortex volume but a reasonable layering and cell density. In contrast, the neocortex in cetaceans is voluminous and extended but rather uniform, layer IV is weakly developed, and neuron density seems to be lowest within the Mammalia. Whether in sirenians the neuron clusters (Rindenkerne) in layer VI correlate with their vibrissae (bristles) and are equivalent to the "barrel fields" in rodents remains unsubstantiated to date.

The *olfactory system* of aquatic mammals seems to exhibit a clear relationship to their lifestyle. Whereas in aquatic carnivores the olfactory bulbs and tracts are clearly reduced in size, sea cows come even close to the baleen whales. Toothed whales only very rarely have vestigial olfactory tracts and are characterized by residues of a secondary olfactory cortex. Obviously, the olfactory part of the nose inherited from their terrestrial ancestors could not be adapted successfully to the requirements of aquatic life and therefore was reduced in extant aquatic mammals or even lost in cetaceans. As another example of such an adjustment, Jacobson's organ (vomeronasal organ) is lacking in sirenians and cetaceans.

As in the cetaceans, parts of the *limbic system* (particularly the hippocampus) are reduced in some other aquatic mammals. Whereas in aquatic carnivores the hippocampus seems to be as large as in terrestrial mammals, sea cows and cetaceans have a minimal amount of archicortex. Other parts of the limbic system (e.g., fornix, mammillary body, mammillothalamic tract) are much reduced in toothed whales, but the anterior thalamic nuclei and the limbic lobe of Morgane are well developed. Here, we have a rather mysterious situation which, so far, defies explanation.

In the cetacean species investigated, the *anterior commissure* is generally very thin, obviously correlating with the reduction of its olfactory component. In sirenians and pinnipeds, the anterior commissure is neither as strongly reduced as in cetaceans (with respect to the whole brain) nor as thick as in the otter, and it is thin in comparison with that in land mammals. The *corpus callosum* is short and thin in dolphins but seems to be thicker in baleen whales. Its size (cross-sectional mediosagittal area) was shown to be inversely related to the mass of the brain (Tarpley and Ridgway, 1994). This potentially moderate interhemispheric connectivity may be related to the fact that neuronal density is exceptionally low in cetaceans and may indicate some interhemispheric independence as seen in the example of unihemispheral sleep in bottlenose dolphins. In sirenians, the corpus callosum is small in comparison to that in

terrestrial mammals (ungulates) but it is well developed in aquatic carnivores (pinnipeds).

The *basal ganglia* of dolphins are well developed, particularly the nucleus basalis of Meynert, whose size seems to correlate positively with the neocortex (temporal lobe) and is maximally developed in cetaceans and primates. The caudate nucleus and putamen unite in a thick fundus striati, which encroaches on the surface of the basal forebrain in the area of the olfactory lobe (olfactory tubercle, diagonal band). In comparison with the porpoise, the putamen of the seal and otter is much smaller, but the pallidum is well developed. In the sea cow, the basal ganglia are small compared with those of other aquatic mammals.

The *visual system* shows a very different degree of development: Otters and seals have large eyes and central visual structures, whereas in cetaceans the eyes and optic nerves are of medium size and in sea cows small. It is not clear whether there is an inverse relationship in mammals between eyesight and the degree of adaptation to aquatic life.

The *auditory system* reaches its maximal development in the Cetacea. Whereas all aquatic and semiaquatic mammals exhibit the same bauplan, pinnipeds possess well developed but much smaller auditory structures, and in Sirenia most auditory components are developed only moderately. The dorsal cochlear nucleus, which is believed to be engaged in the integration of positional effects of the head and pinnae in the hearing process, is reported to be of very small size in aquatic mammals generally. This might correlate with the fact that in these animals the external ear is reduced in size or even lacking.

Most aquatic mammals are characterized by a well-developed *cerebellum.* The highest relative cerebellar mass is found in cetaceans (dolphins) and it is lower in pinnipeds and in the otter, whereas the good-natured and restful herbivorous sirenians have a comparatively small cerebellum. Within the cerebellum, there was obviously an allometric shift in the size relationship between the vermis and hemispheres during the adaptation to aquatic life, thus resulting in a small vermis but large cerebellar hemispheres in the fully adapted cetaceans. In aquatic mammals, the paraflocculus is very large or even the dominant part of the cerebellum. In the porpoise, the paraflocculus is connected to a specific cerebellar nucleus (posterior interposed nucleus), which may have evolved as an extension of the dentate nucleus and is very large. The paraflocculus is less developed in sirenians than in cetaceans, and even less so in the seal and otter. The latter approach the situation found in terrestrial carnivores, paenungulates, and ungulates, where the paraflocculus is already well developed, especially in the amphibious hippopotamus.

In cetaceans, the size of the *pons* and its nuclei seems to correlate with the size of the cerebellum and neocortex and with the massive projections to and from the huge elliptic nucleus as well as with the size of the rostral part of the medial accessory inferior olive.

The *inferior olives* of semiaquatic and aquatic mammals have been characterized by morphological criteria. As is the case for most components of the cetacean brain, experimental data are not available here. Cetaceans show an extreme thickening of their medial (accessory) olive, more accurately the rostral part of this subnucleus, which bulges at the base of the myelencephalon and seems to be a secondary acquisition. The caudal part of the cetacean medial accessory olive resembles in shape more that in sirenians (dugong) and in ungulates than that in terrestrial carnivores. In the harbor seal, where the medial accessory olive is the largest of the subnuclei, it is larger than its counterpart in terrestrial carnivores but by far smaller than that in cetaceans. A similar situation is found in the otter, in which the olivary complex, however, is somewhat smaller than in the seal.

The *pyramids* appear to be somewhat better developed in sirenians than in the harbor porpoise; their crossing is very distinct. In comparison, pinnipeds and the otter have thick pyramidal cords, possibly as a heritage of their terrestrial carnivore ancestors. In contrast, ungulates (artiodactyls and perissodactyls) tend to have moderately developed pyramids. With their very weak spinal pyramidal tract, cetaceans seem to show an "overlapping" of phylogenetic heritage *and* morphological as well as physiological adaptations to aquatic life, i.e., a reduction of the peripheral locomotor apparatus (hindlimbs and pelvic girdle) and a strong modification of the anterior limb and girdle (flipper, shoulder girdle).

VI. Strategies in Aquatic Adaptation

In the semiaquatic and most aquatic mammals investigated (insectivores, otters, pinnipeds, river dolphins, marine dolphins), the brain taken as a whole and a number of its components show a convergent moderate to strong increase in size with respect to potential terrestrial relatives within their groups. There is considerable variability, however, in the different brain structures of the species concerned. Whereas in semiaquatic insectivores and the sirenians the total brain and telencephalon are moderately enlarged for the body in comparison with basal insectivores, the otters, pinnipeds, and particularly dolphins are increasingly more encephalized. Otters and pinnipeds have larger brains than their potential terrestrial relatives, but nothing is known about their quantitative composition.

In some groups of semiaquatic and aquatic mammals (single species of insectivores, otter, pinnipeds), the limbic system is well developed. In cetaceans and sirenians, however, the situation is more complicated. In cetaceans, the archicortex (hippocampus) is very small, as are the fornix and mammillary body, but not the amygdala. Moreover, the limbic lobe as a transitional area between archicortex and adjacent neocortical areas is large. It might be concluded, therefore, that the limbic system in cetaceans differs markedly from that in terrestrial mammals. In sirenians, the hippocampus was reported to be even smaller than in cetaceans and its size is obviously minimal within the Mammalia. It is unclear whether the strong reduction of the hippocampus, which in mammals is primarily concerned with attentiveness and vigilance, and serves as an intermediate store for all kinds of information and their "labeling" (short-term memory), correlates with the strong reduction (baleen whales) and even loss of the rostral part of the olfactory system (toothed whales). If we subscribe to the principle of a central position for the hippocampus in informational processing of mammals, we are unable to explain the coincidence in size between two groups otherwise so disparate in brain volume, physiology, and behav-

ior, and so different from other mammals. The small size of the hippocampus, however, could explain why dolphins have difficulties learning new activities that are not already part of their normal lives. In this respect, the extremely large surface area and the considerable volume of the dolphin cortex, which deviates much in architecture from the pattern seen in "progressive" terrestrial mammals, indicates that dolphins may possess an "intelligence" very different from our own as the sum of their adaptations to the aquatic environment during approximately 50 million years of separate evolution.

In conclusion, it seems that, in most cases, the adaptation of mammals to aquatic life, including the necessity of three-dimensional locomotion and diving in a turbid or dark environment, causes (1) an increase in the size of the brain due to the growth of special functional systems such as the auditory and motor systems, (2) an increase in neocortex volume, and (3) the strong reduction or even loss of the rostral olfactory system and its possible compensation or replacement by the trigeminal system. Interestingly, toothed whales and sirenians as the most advanced groups in terms of aquatic adaptation differ in a number of major characteristics. With respect to the basal insectivores (Stephan), even plesiomorphic odontocetes are much more encephalized than sirenians, and most of their brain components and functional systems show a distinctly stronger growth (earlier discussion). The profound differences in the morphology and quantitative composition of the brain in dolphins and sirenians may be related to the contrasting behavior in these animals. Whereas dolphins are extremely agile, swift animals with an intense social life, hunting different types of highly mobile prey with a powerful sonar detection system, sirenians have no sonar and are sluggish plant eaters with a thick integument and limited diving capabilities.

Concerning neocortex morphology, cetaceans and sirenians differ with respect to its thickness, extension, arealization, degree of layering, and presumably neuronal density. Taken as a whole, it seems that in contrast to the situation in the sirenians the extended neocortex of dolphins is responsible for the processing of large amounts of acoustic data needed for orientation, feeding, and social communication. Because of the extreme propagation velocity of sound in water, the time intervals left over for meaningful decisions are very short for swift swimmers and active hunters. A large number of modules in the extended cetacean neocortex may facilitate the quick scanning and subsequent reconstruction of ephemeral two- or three-dimensional images of their "complicated" environment.

Acknowledgments

The authors cordially thank Professor Dr. Jürgen Winckler (Dr. Senckenbergische Anatomie, University of Frankfurt am Main) for the enduring and generous support of our work. We are indebted to Dr. Thomas Holzmann (Frankfurt am Main) for permission to publish a figure from his dissertation. Special thanks are due to Mrs. Inge Szász-Jacobi for her excellent work in the preparation of the originals of the figures. We are grateful to Dipl.Biol. Michaela Haas-Rioth, Professor Dr. Onur Güntürkün (Ruhr-University Bochum), Professor Dr. Gerhard Hummel (University of Gießen), PD Dr. Walter K. Schwerdtfeger (German Ministry of Health, Bonn), and PD Dr. Helmut Wicht (Frankfurt am Main) who kindly read the manuscript and helped with discussions of the content and many valuable suggestions. Thanks are also due to Jenny Narraway (Hubrecht Laboratory, Utrecht, The Netherlands) for the loan of the microslide series of the fetal narwhal and to Kelly Del Tredici, Ph.D. (Frankfurt am Main) for carefully editing the English manuscript.

Brain Size Evolution

Lori Marino
Emory University, Atlanta, Georgia

The study of brain size among three major living groups of marine mammals, cetaceans, pinnipeds, and sirenians, is a study in contrasts. Phylogenetic and ecological factors have shaped the course of brain evolution in each group in distinct ways. The resulting diversity of brains provides an illustration of the different successful paths that were taken in the evolution of marine mammals.

I. The Meaning of Encephalization

Brain size evolution is embodied in the concept of encephalization, which was originally put forth as an encephalization quotient (EQ) by psychologist Harry Jerison. Jerison widely applied this measure to comparisons across different species. EQ is a measure of observed brain size relative to expected brain size derived from a regression of brain weight on body weight for a sample of species. EQ values of one, less than one, and greater than one indicate a relative brain size that is average, below average, and above average, respectively. For example, a species with an EQ of 2.0 possesses a brain twice as large as expected for an animal of its body size. The EQ values reported here are based on a large sample of living mammalian species from Jerison (1973).

In addition to the whole brain, changes in the size of various brain components have also occurred throughout marine mammal evolution and contribute to changes in the overall brain size. Some of these changes are measurable, but undoubtedly many changes in the relative size of structures occurred in all marine mammals that are not apparent from the fossil record.

II. Accessing the Fossil Record

Studies of brain size evolution in fossil marine mammals have depended on measuring the volume of the endocranial cavity in fossil specimens. Because the specific gravity of brain tissue is nearly the value of water, volumetric data have been typically converted to units of weight. In addition to the general problem of finding intact fossil crania, early studies were hampered by difficulties accessing the sediment-filled endocranium. Researchers have taken advantage of the fortuitous occurrence of intact natural endocasts but these are rare. Also, earlier studies often resulted in overestimates of brain mass from endocranial volume because they did not take into account that total endocranial volume is partly composed of non-neural, e.g., vascular, components. Cetaceans, for instance, possess a massive endocranial system of blood vessels, called the rete mirabile, that surrounds the brain and can sometimes account for nearly 20% of total endocranial volume. Most recent studies take these vascular structures into account when estimating brain size from endocranial volume. Computed tomography (CT) has proven to be an important tool in the study of fossil endocranial features because it

is nondestructive and enables more accurate, precise, and reliable measurement of endocranial features than traditional methods.

III. Brain Sizes in Fossils and Modern Species

A. Brain Size Evolution in Archaeocetes

The fossil record of early cetacean brain evolution includes the transition from the immediate land ancestor of cetaceans to the extinct aquatic forms known as archaeocetes. The best candidates for the cetacean land ancestor are the Paleocene and early Eocene Mesonychia. With EQs from 0.18 to 0.51, the mesonychians were not particularly encephalized compared with modern mammals. The range of EQs estimated for early, middle, and late archaeocetes is from 0.25 to 0.49 (Table I and Fig. 1). Therefore, archaeocetes appear to have experienced little increase in encephalization above their land precursors.

B. Brain Size Evolution in Odontocetes

The suborder Odontoceti appeared during the early Oligocene and radiated rather dramatically in that epoch and into the Miocene. Despite the existence of a fair number of specimens, there is surprisingly little systematic data on brain size in fossil odontocetes. Those data that do exist suggest that by the early-mid Miocene at least several odontocete species possessed encephalization levels substantially above that of archaeocetes and within the midrange of living species (Table I and Fig. 1). These data imply that some important changes in brain size occurred during the Oligocene after the turnover from archaeocetes to early odontocetes. Unfortunately, there are no brain size data on odontocetes during the Oligocene. Data on brain size in odontocetes during the Pliocene and Pleistocene are likewise lacking.

The EQs of living odontocetes are generally on a par with nonhuman primates, but some species have achieved a level of encephalization second only to modern humans (EQ ~ 7.0) and equal to or above that of the recent hominid ancestor *Homo habilis* (EQ ~ 4.4). Therefore, a number of odontocetes species are significantly more encephalized than other mammals, including nonhuman primates. There is, however, a range of encephalization levels within the odontocetes. The sperm whale (*Physeter macrocephalus*), with an EQ of 0.58, is an example of an odontocete species subject to disproportionate body enlargement for which the measure of EQ is not particularly meaningful. The Delphinidae, however, are the family that contains several species with exceptionally high EQs above 4.0. These include the bottlenose dolphin (*Tursiops truncatus*), the tucuxi (*Sotalia fluviatilis*), the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), and the shortbeaked common dolphin (*Delphinus delphis*).

Odontocete brain evolution was also characterized by increased foreshortening and widening of the brain, which coincided with telescoping of the skull. There was a trend toward increased relative size of auditory processing regions, such as the acoustic cranial nerve and inferior colliculus. In living odontocetes this is evident in the larger relative size of the inferior colliculus to the analogous midbrain visual processing area, the superior colliculus. In addition, structures associated with the processing of olfactory information regressed. Furthermore, the cerebral cortex of odontocetes (and cetaceans in general) has achieved an extremely high level of gyrification. Although surface morphology is not always discernible from fossil endocasts, it is generally thought that this was not a feature of archaeocete brains.

C. Brain Size Evolution in Mysticetes

The suborder Mysticeti appeared and diversified in the Oligocene and consisted of primitive toothed taxa in addition to the earliest baleen-bearing whales. Extant groups appeared in the mid-late Miocene. There are two problems associated with examining brain size evolution in mysticetes. First, data on fossil and living mysticete brain size are scarce. This is partly due to the difficulties associated with extracting and measuring such large brains. Second, mysticete brains tend to be smaller than expected relative to body size despite their large absolute size. This is partly due to the enormous body masses achieved by mysticetes. As in the sperm whale, mysticete bodies are greatly enlarged in ways that do not necessarily require a concomitant increase in neural tissue. EQs of living mysticetes are therefore unrepresentative of actual brain enlargement, with all values falling substantially below 1.0 (Table I and Fig. 1). For this reason, although encephalization has probably occurred throughout mysticete evolution, EQ is not an appropriate measure of it in this group, particularly in comparison with terrestrial mammals. In fact, to the extent that disproportionate increases in body size have played a role in body enlargement in any fully aquatic species, EQ will be underestimated relative to terrestrial mammals.

Many of the changes in morphology and size of brain components that occurred in odontocetes also characterize mysticete brain evolution, but to a lesser extent. For instance, unlike in odontocetes, olfactory tracts have remained in some mysticete species and the hypertrophy of the auditory processing regions is not as extreme as in odontocetes.

D. Brain Size Evolution in Sirenia

Sirenian brain evolution has been markedly conservative regarding relative brain size. Fossil endocasts of early Eocene sirenians (among the earliest) were small in relation to the skull and already very similar to modern forms. Sirenian encephalization levels are among the lowest of modern mammals. According to the same formula used to derive cetacean encephalization quotients in cetaceans, the Florida manatee (*Trichechus manatus*) possesses an EQ of about 0.35 and the dugong (*Dugong dugon*) about 0.5. The EQ of the extinct Steller's sea cow (*Hydrodamalis gigas*) was approximately 0.25 (Table I). Body size enlargement explains some of the reason for these low EQs, but, given that cetaceans of the same body size possess higher EQs, not all.

Unlike odontocetes, sirenians do possess olfactory bulbs. Perhaps the most striking contrast, however, is the fact that cetacean and sirenian brains anchor the two ends of the spectrum of cortical gyrification. Whereas the cetacean cerebral cortex is thin and highly convoluted, the sirenian cortex is unusually thick and almost lissencephalic (smooth). Interestingly, despite these differences, the relative volume of the cerebral

[b]For living species, estimated brain and body weights are averaged across several specimens in most cases.
[c]Body weight estimates for fossil specimens are often general estimates of adult species-specific values and are not necessarily from the same specimen(s) for which brain weight estimates are obtained.

cortex in both sirenians and cetaceans is on a par with nonhuman primates.

E. Brain Size Evolution in Pinnipedia

Pinnipeds diverged from terrestrial carnivores during the early Miocene. This is a relatively more recent date than cetaceans and sirenians diverged from their land ancestors. The pinniped brain, therefore, still resembles that of terrestrial carnivores. Living pinnipeds possess EQs that hover around the average for terrestrial mammals. For instance, the ringed seal (*Pusa hispida*) possesses an EQ of 1.75, the harbor seal (*Phoca vitulina*) 2.08, and the Weddell seal (*Leptonychotes weddellii*) 0.76 (Table I). These values are fairly representative of pinniped EQ in general. Pinniped olfactory structures are reduced but not to the same degree as in cetaceans. The cerebral cortex is highly convoluted (and more so than most terrestrial carnivores) but lies somewhere in between the extreme degrees of gyrification and thickness found in cetaceans and sirenians. The pinniped brain is somewhat more spherical in shape than in terrestrial carnivores but did not undergo the dramatic change in overall morphology exhibited in cetaceans.

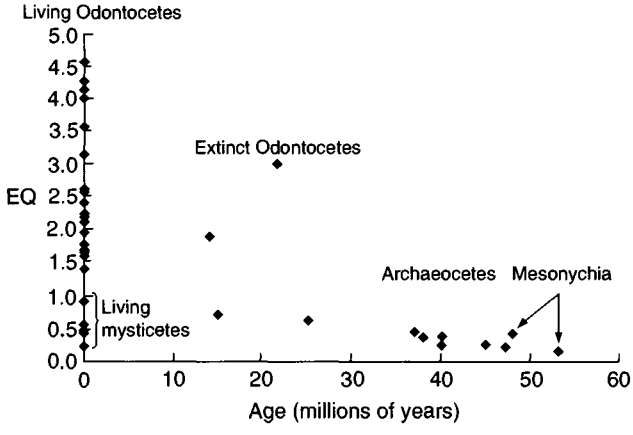

Figure 1 *Pattern of change in encephalization over geological time in Mesonychia, archaeocetes, and extinct odontocetes compared with living odontocetes and mysticetes. Encephalization is plotted as EQ where the reference group is a large sample of living mammals.*

IV. Conclusions

Much more information is needed before we can obtain a complete picture of patterns of brain size evolution in marine mammals. However, what does seem clear is that the different marine mammal groups evolved along distinct paths that led to a great variety of levels of encephalization in modern species. For instance, among odontocetes there was a substantial increase in encephalization in the Oligocene lineages, which has led to the existence of a number of dolphin and porpoise species with relative brain sizes challenging only the hominid mammalian line. The relationship between mass and organization must be explored further, as well as the phylogenetic and ecological factors that led to the differential development of brain size among the various marine mammal groups.

Breaching

HAL WHITEHEAD
Dalhousie University, Halifax, Nova Scotia, Canada

Breaches are leaps from the water. The breach of a large whale is almost certainly the most powerful action performed by any animal; that of a dolphin rising many body lengths above the surface is one of the most breathtaking, but breaching is not an immediately functional activity for an aquatic animal. Observers of cetaceans have long pondered the breach, and science has made some inroads into our ignorance of breaching, but important questions remain open, including, "Why breach?"

I. What Is a Breach?

A breach may be defined as an intentional jump from the water in which at least 40% of the animal's body emerges. It is distinct from "lunging" (often the result of feeding at the surface) when less than 40% emerges and from "porpoising" when small cetaceans (and other marine mammals) reduce drag while swimming fast close to the surface by making horizontal leaps. In breaching, emergence from the water seems an intent rather than a result of another activity. While breaching is used for all cetaceans, the term leaping is more common for dolphins and porpoises.

When breaching, sperm whales (*Physeter macrocephalus*) and dolphins approach the surface vertically from depth. Other animals swimming in water less than a few body lengths deep, e.g., humpback and right whales (*Megaptera novaeangliae* and *Eubalaena* spp.), make a horizontal approach to the breach, gaining speed until, at the last moment, they raise their heads and flukes, pivoting on their flippers so converting horizontal momentum into vertical motion, and thus rising through the surface. To make a full breach, a humpback whale must break the surface at about 15 knots (~8 m/sec), close to its maximum speed. It is likely that some of the most spectacular breaches of other species also represent the full power of the animal.

After breaking the surface, whales and dolphins have many styles of breaches. In the classic breach of a large whale (such as a humpback or right) the animal emerges from the water at about 20–30° from the vertical, twisting so as to land on its back or side, having shown about 90% of its body above the surface at peak emergence (Fig. 1). However, about 20% of the breaches of sperm and humpback whales are "belly flops," with the animal landing ventrally (Fig. 2), and smaller cetaceans make what are sometimes called "clean-entry leaps" when, after leaping, the animal returns to the water smoothly, beak first (Fig. 3). Young whales and dolphins will frequently completely clear the water with their breaches (Fig. 3), sometimes by several body lengths. Some dolphin breaches, such as the spinning breaches, which give the spinner dolphin (*Stenella longirostris*) its name, are remarkably elaborate. Breaching animals produce large splashes upon reentry into the water, which can be visible at many kilometers.

Breaches are often performed in bouts. Extreme is 130 breaches in 75 min, probably all performed by the same humpback whale on Silver Bank, West Indies. As such sequences progress, animals tend to show less and less of their bodies, visibly appearing fatigued.

II. Which Whales and Dolphins Breach?

Quantitative breaching rates are only available for a few species and are usually not comparable. However, it is clear that there are substantial differences between species in the rates of this and other forms of aerial activity. Frequent breachers include the humpback, right, and sperm whales, as well as virtually all offshore dolphins. In contrast, balaenopterids (blue, *Balaenoptera musculus;* fin, *B. physalus;* sei, *B. borealis;* Bryde's, *B. edeni;* minke, *B. acutorostrata, B. bonaerensis*), most beaked whales (except the northern bottlenose, *Hyperoodon ampullatus*), porpoises, and river dolphins breach much more rarely.

Breaching rates, then, are not related to size and, at least in the large whales, are inversely related to speed—stouter, slower animals tend to breach more. Instead, interspecifically the best correlate of breaching rate is sociality. Animals found in larger groups, and for whom social structure seems more important, breach more frequently.

Figure 1 *Sperm whale breaching off the Galápagos Islands. Photograph courtesy of H. Whitehead laboratory.*

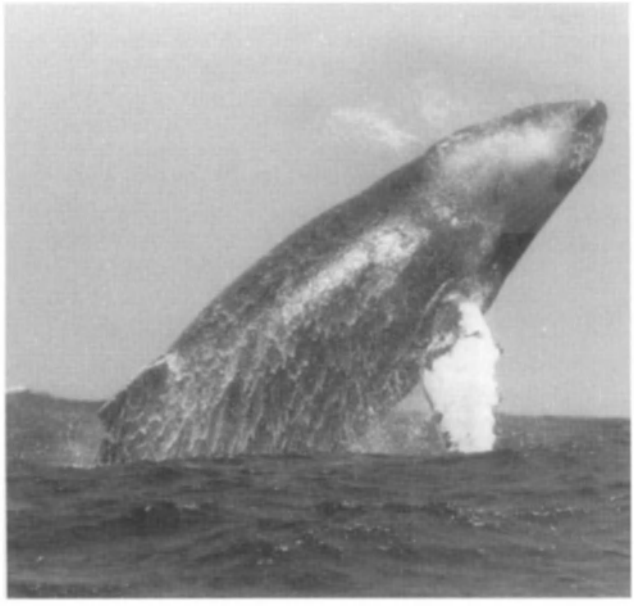

Figure 2 *Humpback whale belly flopping on Silver Bank, West Indies. Photograph courtesy of H. Whitehead laboratory.*

III. When Do Whales Breach?

The circumstances in which breaches occur can provide important clues as to their purpose or function. In some species, different segments of the population breach more frequently than others. For instance, calves of many species breach more frequently than adults. In sperm whales, the gregarious females breach more often than the much larger, and more solitary, males.

Figure 3 *Hector's dolphins* (Cephalorhynchus hectori) *breaching off South Island, New Zealand. Photograph courtesy of Lars Bejder.*

Most baleen whales have pronounced seasonal cycles, feeding in winter at high latitudes and breeding in winter nearer the equator. Humpbacks in the western North Atlantic breach about seven times more frequently on their winter breeding grounds in the West Indies than when feeding off Newfoundland.

In a number of species (including humpback, right, and sperm whales) breaching is observed more frequently when groups are merging or splitting. Male humpback whales may breach when they stop singing on the Hawaiian breeding grounds. Breaching is often observed together with lobtailing and/or flippering, with different animals performing different activities at the same time, or one animal switching between the different activities. Studies of humpback and right whales have also shown that breaches by one animal seem to trigger breaches by neighbors. On Silver Bank, breaching humpbacks form clusters about 10 km across. One of the most interesting, and in some ways unexpected, findings that has emerged from several studies of different species is that breaching rates of large whales increase with wind speed. There is currently no generally accepted explanation for this widespread pattern.

IV. When Do Dolphins Breach?

Variations in the breaching rates of dolphins seem less consistent across species. For instance, spinner dolphins off Hawaii have maximum breaching rates before a foraging hunt; in dusky dolphins (*Lagenorhynchus obscurus*) off Argentina and Peale's dolphins (*Lagenorhynchus australis*) off Chile, rates increase during hunts, peaking afterward; bottlenose dolphins (*Tursiops* spp.) off South Africa also show peak breaching rates after the hunt, but bottlenose dolphins around Coco Island, Costa Rica, breach at roughly the same frequency in all behavioral contexts.

One of the most detailed studies of breaching in dolphins is that of K. S. Norris and coworkers on the very aerobatic spinner dolphins off Hawaii. In this species, breaching was closely related to diurnal activity patterns, being mostly seen from fast-moving active schools in the afternoon.

V. Why Breach?

Few animal activities can have been ascribed so many, and so varied, functions as the breaches of whales and dolphins. Some suggested functions can now be discarded, including breaches resulting from animals being chased by swordfish (*Xiphius gladius*) or being accidental when animals travel too fast near the surface. However, the available scientific results are consistent with quite a range of other potential reasons for breaching.

A number of authors have suggested that the breach may help cetaceans feed by scaring, stunning, herding, or trapping fish or other prey. Although many, probably the majority, of breaches of most species occur in nonfeeding circumstances, the closely related activity of lobtailing is known to sometimes assist feeding, so a direct benefit to food capture cannot be ruled out as a function for some breaches, perhaps especially the "clean-entry leaps" of dolphins.

Similarly, we cannot completely rule out some rather prosaic potential benefits of breaching such as stretching, looking

above the water, or inhaling water-free air in rough weather. However, these too are unlikely to be important functions of most breaches.

One proposed benefit that is more consistent with at least some of the evidence is ectoparasite removal. Among the baleen whales, the more heavily infested species tend to be the most frequent breachers, and in Hawaiian spinner dolphins, 44% of breachers had remoras attached. However, spinners without remoras also breached, and much of the circumstantial evidence points to a very different function—communication.

As noted earlier, the more social species of cetacean breach more and, in most studies, breaching occurs most often when socially important activities are occurring, such as during changes in group composition or group activity. As sociality is based on communication between members of the same species, the strong inference from these results, then, is that breaching is a form of communication.

However, there is a paradox in that while breaches are excellent at conveying information to visually based human observers above the surface, they are far less prominent for the potential or actual social companions of the breacher. Other whales and dolphins cannot generally see the breacher's body arcing above the surface, and while the reentry makes a noticeable underwater sound, it seems to be less loud than the natural vocalizations of the animals. The paradox may be resolved by considering the theory of "honest signaling": signals are especially useful in animal communication if they convey some important attribute of the signaler that cannot be faked. The distinctive underwater sound or bubble pattern produced by a full breach, while not especially prominent in its own right, is an honest signal of the physical abilities of the breacher (which often seems to leave the surface at close to its maximum speed) and its desire to communicate this by using a significant amount of energy (about 1% of a humpback whale's estimated daily resting metabolic expenditure per breach).

Thus the breach may be a useful signal to nearby potential or actual social companions. What might it be signaling? Suggestions for large whales include aggression, "extreme annoyance" (perhaps with a nearby vessel), an "act of defiance," COURTSHIP, or a display of strength by males. Some scientists have suggested that a breach may be used to add emphasis to some other signal, perhaps a vocalization or visual display. By showing the extent of its physical prowess, and expending a significant amount of energy, the whale accentuates the importance of a companion signal. For dolphins, breaches have mainly been considered signals concerning schooling. For instance, it has been suggested that breaches may be used to define the deployment of a school, to recruit dolphins to a cooperative feeding event, or as social facilitators that reaffirm social bonds.

Finally, there is play. This is probably the most commonly attributed function of breaching by the general public, but it is also seriously considered by scientists who recognize play as a valid, but hard to define, type of BEHAVIOR. Biological definitions of play usually focus on its lack of immediate biological function, resulting in play becoming a "garbage can" into which activities without an obvious function, such as breaching, get placed in a haphazard fashion. It is likely that many breaches described by human observers as "playful" actually function as important signals. However, it is also likely that some breaches, especially those by young animals, provide no immediate benefit, instead, like other forms of play, helping equip the breacher with abilities that may be beneficial in later life.

Breathing

DOUGLAS WARTZOK

Florida International University, Miami

Oxygen is the final electron receptor in the metabolism of marine mammals as it is in all other mammals. Marine mammals obtain oxygen from the air they breathe at the surface. In contrast, most feeding, mating, and other activities essential to survival occur beneath the surface. Thus most marine mammals minimize the time they are at the surface and have evolved to load oxygen quickly and use it efficiently. For marine mammals, the breath-holding portion of the breathing cycle is significantly extended compared to the oxygen intake portion.

Because a distinguishing feature of marine mammals is their breath-holding ability, this characteristic has received much more attention than their breathing. However, a number of aspects of marine mammal breathing have necessarily been modified from terrestrial mammals in order to accommodate their submerged lifestyles. As with many modifications from terrestrial mammals, those related to breathing show the greatest difference in those species that dive the deepest and the longest.

Cetaceans, sea lions, and manatees usually take only one breath per surfacing. Manatees return to a normal, shallow dive after a single breath. The deeper-diving cetaceans take a series of breaths, each in a subsequent surfacing, before an-

other dive. Seals remain at the surface for a series of breaths after a dive.

I. Lung Oxygen Stores

Every inspiration that fills the lungs with air brings in four times as much nitrogen as oxygen. Because nitrogen is neither bound to a carrier in the blood nor metabolized in the tissues, the partial pressure of nitrogen in the blood will equilibrate with that in the lungs. If gas exchange is allowed to take place during a dive, the resulting higher partial pressure of nitrogen in the blood and tissues will result in the formation of nitrogen gas bubbles when the external pressure is reduced as the animal comes to the surface. Thus deep-diving marine mammals limit the exchange of gas from lungs to blood during dives.

Most phocids have been observed to exhale before diving. Weddell seal (*Leptonychotes weddellii*) pups, which are observed to dive after an inspiration, are an occasional exception. At this developmental stage they are shallow divers. California sea lions (*Zalophus californianus*) may dive after a partial inspiration, but then vent air during descent. Dolphins and porpoises making shallow dives routinely dive on inspiration. These breathing behaviors correlate well both with the proportion of total oxygen stores in the lung at the start of a dive and with lung size in proportion to the body size of various marine mammals. Phocids dive with 7% of total oxygen stores in the lung, fur seals with 13%, and delphinids with 22% (Fig. 1). The proportionate size of the lung in phocids and manatees is about the same as in terrestrial mammals such as the horse and human (Fig. 2), whereas the lung size is greater than expected in delphinids and smaller than expected in whales. An outlier in these considerations is the sea otter (*Enhydra lutris*) whose lung is close to three times the expected size for its body mass and accounts for 75% of oxygen stores. The sea otter is not a deep-diving marine mammal, and the relatively large lung in the sea otter may be primarily used for buoyancy when the animal is resting at the surface.

II. Tidal Volume

The tidal volume of marine mammals is a larger proportion of the total lung capacity (TLC) than it is of terrestrial mammals. In a typical terrestrial mammal the volume of air inhaled and exhaled in one breath is in the range of 10 to 15% of TLC. In marine mammals, tidal volume is typically greater than 75% of TLC. The maximum tidal volume or vital capacity (VC) in terrestrial mammals is no more than 75% of TLC, whereas in marine mammals the VC can exceed 90% of TLC. Several factors contribute to the large tidal volume in marine mammals. Marine mammal lungs contain more elastic tissue than those of terrestrial mammals. The ribs contain more cartilage and are thus more compliant than those of terrestrial mammals. The lung is also more compliant. Marine mammal lungs can collapse and reinflate repeatedly, whereas in terrestrial mammals, lung collapse is a serious situation that requires intervention to reinflate. Although both terrestrial mammals and marine mammals inspire actively and expire passively, the features noted earlier allow a much greater elastic recoil of the lungs, chest cavity, and diaphragm, and thus a greater tidal volume in proportion to TLC.

The terminal portions of the airways in all marine mammals are supported and reinforced by cartilage or muscle. One purpose of this reinforcement is to provide a less collapsible region into which alveolar gases can be forced during a dive to prevent gas exchange with blood at high pressures. This prevents increased nitrogen tensions in the blood and tissues as noted previously. A second purpose of the reinforcement is to keep the terminal airways open even at high flow rates of gases in and out of the lung during a breath and to allow high expiratory flow rates even as the lung volume decreases. Figure 3 shows the flow volume profile comparison during exhalation between a

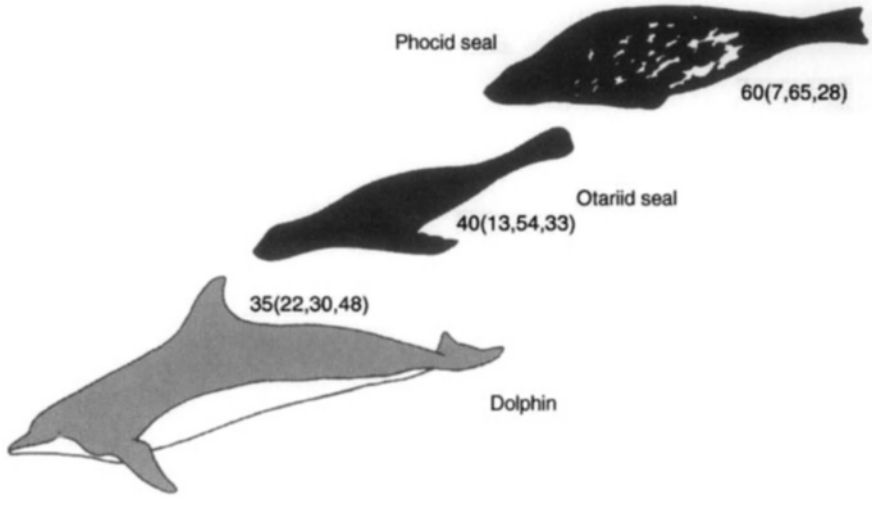

Figure 1 *Generalized total oxygen store of major taxa of marine mammals expressed in ml O_2 kg^{-1}. L., "Diverse Divers: Physiology and Behavior." © 1989 Springer-Verlag.*

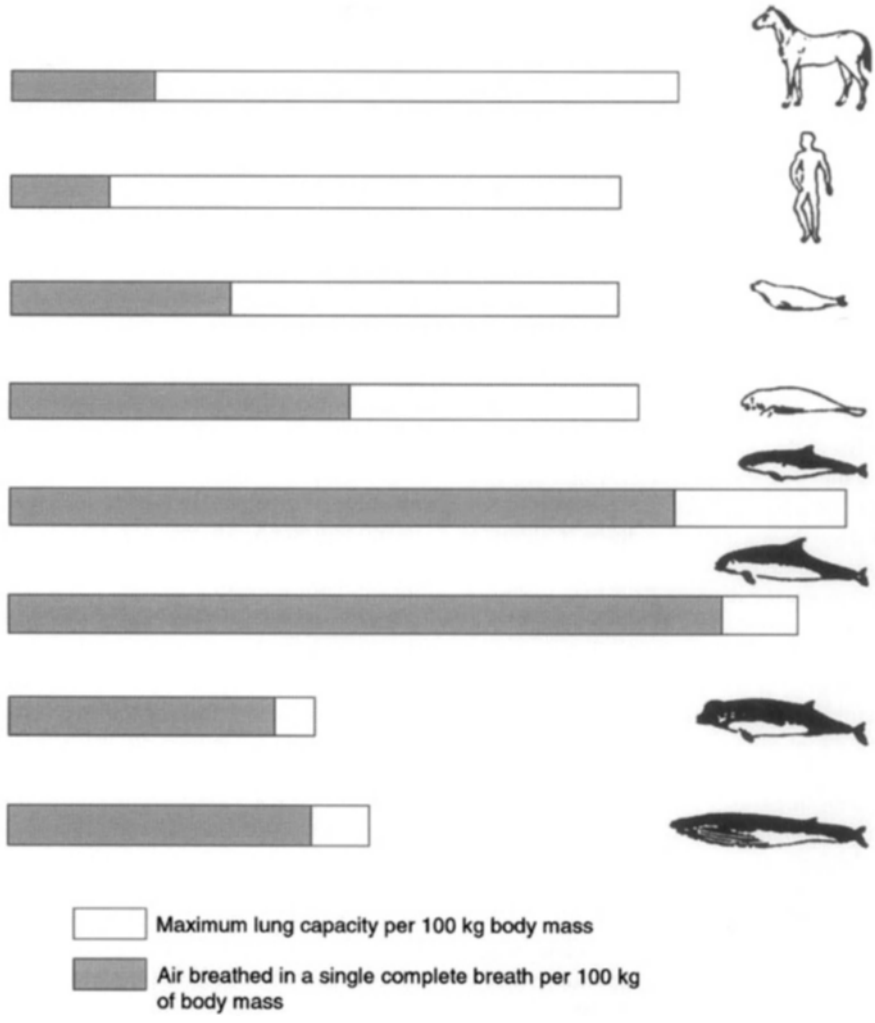

Figure 2 *The maximum amount of air the lungs can hold, and the amount of air breathed in and out with each breath, calculated per 100 kg of body mass for a horse, a human, a seal, a manatee* (Trichechus *sp.*), *a harbor porpoise* (Phocoena phocoena), *a bottlenose dolphin, a bottlenose whale* (Hyperoodon *sp.*), *and a fin whale* (Balaenoptera physalus). *Modified, with permission, from Slijper, E. J. "Whales and Dolphins." © 1976, University of Michigan.*

harbor porpoise and a human. There are two striking differences. First, the flow rates are much higher in terms of VC/sec. Second, the flow rates remain very high; even down to a small fraction of the VC. These two factors together allow very rapid exhalation of the full VC. Inspiration takes somewhat longer.

The bottlenose dolphin (*Tursiops truncatus*) completes an exhalation and inhalation cycle in approximately a third of a second. With a tidal volume of 10 liters, flow rates through the air passages can be as high as 70 liters/sec. In gray whale (*Eschrichtius robustus*) calves the duration of expiration and inhalation is closer to half a second, but the tidal volume can be as great of 62 liters, and the maximum flow rate as great as 202 liters/sec. Gas flows through the external nares at speeds up to 44 m/sec during inspiration and 200 m/sec during expiration. Cetaceans usually initiate expiration prior to the blowholes breaking the surface. The explosive nature of the expiration creates the small droplets that make the blow visible and clears the upper respiratory passages and the area around the blowholes of any residual water. Most of the time the blowholes are above the surface is used for inspiration.

The large tidal volume allows for more oxygen loading and greater carbon dioxide unloading during a single breath at the surface. Even in a resting state, the carbon dioxide content of expired air in seals is twice as great as it is in humans. After extended breath holds, alveolar oxygen levels can be as low as 1.5%. The oxygen and carbon dioxide content of expired air after surfacing can provide indirect evidence of physiological adjustments to diving. In bottlenose dolphins, the oxygen content in the first

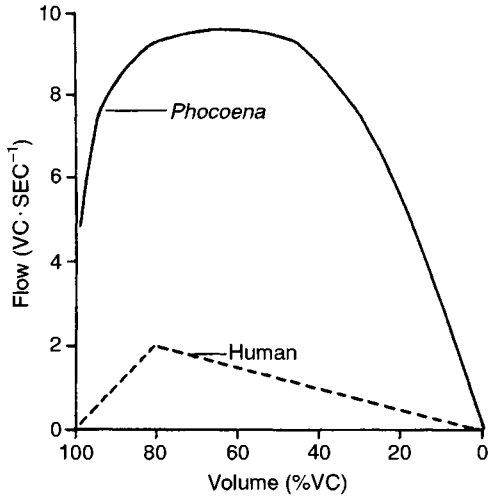

Figure 3 *Comparison of the flow–volume curves of a human (dashed line) and a harbor porpoise (solid line). Note that in the human, after the volume falls below about 80% of vital capacity, the flow rate declines steadily, but this is not the case in the porpoise. Modified, with permission, from Kooyman, G. L., and Sinnett, E. E., Mechanical properties of the harbor porpoise lung,* Phocoena phocoena, Respiration Physiology *36, 287–300, © 1979, Elsevier Science.*

breath after a dive to 200 m is greater than it is in the first breath after an equivalent amount of swimming at 20 m. The interpretation is that the collapse of lungs in the deeper dive prevented the exchange of oxygen with the blood during the dive. For the same reason, the content of carbon dioxide in the first breath is always less after a dive to depth than after a dive near the surface. In gray seals (*Halichoerus grypus*), the end tidal partial pressure of oxygen in the first exhalation after surfacing is similar to that in the last breath before submergence, again indicating that the lungs were collapsed at depth and there was no gas exchange.

III. Hyperventilation

Marine mammals often hyperventilate both before and after a dive. Hyperventilation before a dive leads to increased oxygen tensions and reduced carbon dioxide tensions. Hyperventilation arises through an increase in the frequency of breathing and the tidal volume. Although both can initially increase during hyperventilation, lung dynamics requires an eventual reciprocal relationship between tidal volume and frequency of breathing. In Weddell seals, hyperventilation of five to six times resting is accomplished by increasing the tidal volume 1.5 to 2 times and the respiratory frequency 3 times. If the respiratory frequency rises above 25 breaths/min, the tidal volume, as a proportion of the TLC, is close to that of terrestrial mammals. Harp seals with respiratory rates of 27 breaths/min and harbor seals (*Phoca vitulina*) with rates of 35 breaths/min have tidal volumes between 20 and 30% of TLC. Because marine mammals normally have such large tidal volumes, they have much less ability to increase total ventilation in response to exercise than terrestrial animals. A human can increase respiration by 4 times and can increase tidal volume by greater than 4 times for an overall increase in ventilation of more than 16 times resting compared to the 5 to 6 times resting maximum for a Weddell seal.

Marine mammals often exhibit an increase in heart rate on approach to the surface. It has been suggested that this anticipatory tachycardia coincides with the restored perfusion of peripheral tissues so the oxygen levels in the blood drop even lower as the carbon dioxide levels rise. These changes in blood gases increase the gradient between partial pressures in the blood and the lungs and lead to more rapid oxygen uptake and carbon dioxide exhausting during the first breaths at the surface. When gray seals show no anticipatory tachycardia, they do not achieve the maximum rate of oxygen uptake during the first few breaths.

The increased heart rate and breathing on surfacing lead to a rapid restoration of oxygen tensions. In fact, in Weddell seals the blood oxygen partial pressures in the postdive recovery period routinely end up exceeding the resting values. It appears that the purging of carbon dioxide is more critical for determining readiness to dive again than is the replenishing of oxygen. In Weddell seals the partial pressure of carbon dioxide falls to resting levels within a couple minutes after aerobic dives, but may take up to 10 min to reach resting levels after long dives, which rely on anaerobic metabolism. The fact that hyperventilation can continue for an hour after the partial pressures of oxygen and carbon dioxide return to resting levels indicates that prolonged hyperventilation is driven more by lactate-induced changes in the acid–base balance in the blood.

IV. Ventilation Control

Seals show a more fully developed mammalian reflexive response of increased ventilation to decreases in inspired oxygen concentration or increases in inspired carbon dioxide concentration at an earlier age than terrestrial mammals. However, adult seals show little ventilatory response to decreased oxygen concentration. Instead the adult seals respond by increasing the proportion of time they are at the surface relative to the total time between dives. Apparently the adult seals are able to substitute behavioral control of diving patterns for reflexive control of ventilation.

Breathing hyperoxic gas increases the dive time of Weddell seals, has no effect on the dive time of manatees, and shortens the dive time of hooded seals. A suggested explanation for the latter surprising finding is that the seal breathing a hyperoxic gas mixture dove before it had exchanged all the carbon dioxide and the increased carbon dioxide tensions resulted in the shortened dive time.

Both the nostrils of pinnipeds and the blowhole of cetaceans are normally closed when the controlling muscles are relaxed. The closure in pinnipeds is maintained by muscle tone and pressure of the moustacial pad. Contraction of the nasal and moustacial pad muscles results in a movement of the pad and opening of the nostrils. In cetaceans, muscles must contract to open the blowhole and to move the nasal plug so that it is not blocking the airway.

Pinnipeds on land often show a breathing pattern similar to that during diving with breathing periods (eupnea) being shorter than breath hold periods (apnea). The ratio between apnea and eupnea while on land is greatest in those species that normally dive for the longest periods. The periods of apnea also tend to be longer when the animals are asleep than when they are awake. Even the longest bouts of sleep apnea appear to be aerobic: plasma lactate and glucose remain stable even though oxygen tensions drop to very low levels, carbon dioxide tensions increase, and respiratory acidosis occurs. In elephant seal (*Mirounga* spp.) pups, awake apnea does not exceed about 5 min whereas sleep apnea can be as long as 14 min. The pups show a parallel increase in mean sleep apnea and mean dive duration during their first year of life.

Pups of several species have been observed to have a higher breathing rate than adults. Weddell seal pups take 16 breaths/min compared to the 8 breaths/min rate of adults. Pups of Australian (*Neophoca cinerea*) and New Zealand (*Phocarctos hookeri*) sea lions take 13 breaths/min whereas adults of these species typically breathe 3 to 5 times per minute.

On land and in the water different stages of sleep in pinnipeds are associated with different breathing patterns in different species. During rapid eye movement sleep, breathing is regular and at rates up to 16/min in gray seals, irregular in harp seal pups, and absent in elephant seal pups. Elephant seal pups sleeping in shallow water rise to the surface to breathe without showing brain wave patterns associated with wakefulness. In contrast, Caspian seals (*Pusa caspica*) sleeping below the surface awake prior to surfacing and breathing.

Some species of delphinids show unihemispheric brain waves associated with sleep. Thus there is one cerebral hemisphere that is always awake to control surfacing and breathing patterns. Northern fur seals (*Callorhinus ursinus*) sleeping in water also sometimes show unihemispheric sleep patterns with one cerebral hemisphere awake to control surfacing and breathing. In contrast to delphinids, no pinniped has shown exclusively unihemispheric sleep brain waves.

V. Oxygen Loading and Dive Time

Several authors have modeled the diving behavior of marine mammals based on oxygen loading curves at the surface compared with energy expenditure while below the surface. There have been various models based on what the animal may be attempting to maximize, be it time in a deep prey patch, gross energy intake during a dive, net energy intake, energetic efficiency, etc. All the models conclude that there should be some relationship between the duration of a dive and the time breathing at the surface, either predive or postdive. Although some species do show such relationships over certain dive time intervals, not all species show the expected patterns. The time Weddell seals spend at the surface is independent of preceding dive duration up to the aerobic dive limit. Beyond that time, the surface time increases exponentially with the preceding dive time. However, gray seals show a direct proportionality between dive time and surface time up to dive times of 7 min. Surface time is independent of dive time for dive times greater than 7 min. Surface time of sperm whales (*Physeter macrocephalus*) shows a slight trend to decrease with increasing dive time, but is basically independent of dive time. Elephant seals can maintain, over periods greater than 24 hr, a pattern of long, deep dives followed by surface intervals of 3 min or less. Some of these differences are attributable to species variation among groups with different diving strategies and oxygen loading needs. Additional explanations of the breakdown of models relating surface oxygen uptake to underwater duration and activity include lowered metabolic rates underwater, passive gliding descents, and animals not maximizing any of the foraging-related parameters. For example, ringed seals (*Pusa hispida*) appear to be constrained by a risk aversive strategy. Diving under shore fast ice, ringed seals gain access to air only at a few breathing holes. If a seal finds a breathing hole occupied by another seal or detects a polar bear above the hole, it will need oxygen reserves to locate an alternate breathing site.

VI. Water Conservation during Breathing

Because marine mammals obtain most of their water requirements from their prey and through metabolic production of water, conservation of water is an important adaptation in marine mammals. Renal adaptations for water conservation are discussed elsewhere, but water can also be lost through ventilation. Both pinnipeds and cetaceans exhale air that is not saturated with water vapor. In bottlenose dolphins the respiratory water loss is reduced by 70% over what it would be compared to a terrestrial mammal breathing dry air. Countercurrent heat exchange and induced turbulence in the nares and nasal sac system allow for the extraction of a majority of the water vapor in the air coming from the lungs. In seals, the bones in the anterior part of the nasal cavity (turbinates) create a very dense mesh through which the expired air must pass. Moist air flowing over this large surface area gives up much of this water before being exhaled.

VII. Breathing Patterns in Response to Disturbance

Changes in breathing patterns have been used extensively as indicators of disturbance of marine mammals in response to human activity. In many cases, a statistically significant change has been observed in the interbreath interval, total number of breaths during a surfacing, or proportion of time spent at the surface. Although these changes may be statistically significant, it is questionable whether they are biologically significant for an individual animal or indicative of any long-term consequences for the population.

Breeding Behavior

SEE *Mating Systems: Reproductive Behaviors*

Breeding Sites

MARK A. HINDELL
University of Tasmania, Hobart, Australia

Giving birth to young and the subsequent nursing of those young present unique problems to marine mammals. The strategies that marine mammals employ to deal with these problems can be divided into two groups: (a) those animals that need to leave the water to breed (seals and polar bears, *Ursus maritimus*) and those that remain at sea to breed (cetaceans, sirenians, and sea otters, *Enhydra lutris*). Whichever strategy is used, a crucial component of the reproductive process is the site used for breeding (here, the term breeding is restricted to parturition and suckling and does not include mating). Breeding sites used by marine mammals are quite diverse, both in terms of geography and physical characteristics, ranging from polar to equatorial regions and from sandy beaches to deep ocean basins. Which sites are used for breeding by a particular species is determined by a complicated mixture of factors, including evolutionary history, requirements of the young, requirements of the adults, biological characteristics (such as the proximity of prey), and physical characteristics (such as water temperature or beach substrate).

I. Species That Leave the Sea to Breed

All species of seals and polar bears leave the sea in order to give birth, and most also need to be ashore to suckle their young. Some species (predominantly the phocids) remain ashore for the entire lactation period, whereas in others (the otariids), the females regularly return to sea to forage during lactation. Of the phocids, only harbor seals (*Phoca vitulina*) and walruses (*Odobenus rosmarus*) have been reported to suckle young at sea. The sites used by these animals for breeding activities can be divided into two groups: those that breed on land and those that breed on ice.

A. Marine Mammals That Breed on Land

Pregnant polar bears leave the arctic pack ice with the onset of spring to breed on land. The deteriorating summer pack ice is too unstable a substrate for the bears, which have a relatively long period of cub dependence. Females excavate caves in the side of riverbanks or hillsides, thereby getting close to the permafrost and providing an environment with a stable temperature. As summer progresses and snowfall increases, these caves get snowed in and the females need to maintain a cavity with sufficient wall thickness to provide insulation, but also thin enough to allow the passage of air.

About twenty species of seals breed on land. This includes all of the species of otariids (fur seals and sea lions) and six of the phocids (true seals) (Table I). None of these species use any kind of shelter and all give birth and suckle on the beach exposed to wind, rain (or snow), and waves. Land-breeding seals often occur in very large aggregations during the breeding season, which may offer some protection for young seals from the weather, but this also puts them at risk of being damaged in fights between adult seals. Land-based breeding sites occur at all but the most extreme polar latitudes.

Some species utilize both land- and ice-breeding sites. Gray seals (*Halichoerus grypus*) breed on beaches in northern Europe and America, but on pack ice in Northern Canada. Although primarily a land-breeding species, harbor seals also breed in pack ice in northern Canada.

Most land-breeding seals use islands as their principal breeding sites, with only a few species utilizing mainland beaches. This is likely to be an attempt to avoid large, mainland preda-

Gray seal, *Halichoerus grypus*	Island/mainland/ice

[a]From Reidman (1990).

tors, including humans. Generally, species have quite specific requirements of their island-breeding sites, and so suitable island-breeding sites are often limited. Consequently, those sites that are suitable tend to hold very large numbers of seals, which provides an ideal condition for the evolution of polygeny.

Different species have different substrate requirements. Most species use gradually sloping sandy beaches, such as those used by northern elephant seals. Fur seals, which are generally more agile than phocids, can also breed on rocky substrates, but again this is quite species specific. For example, at Madquarie Island, where both Antarctic (*Arctocephalus gazella*) and sub-Antarctic (*A. tropicalis*) fur seals breed, *A. gazella* use open beaches, whereas *A. tropicalis* breed on nearby rocky headlands. The reasons for these different preferences are unknown, but may arise from resource partitioning.

Proximity to a food source may be another factor that determines the location of breeding sites for some land-breeding seals. For example, female otariids need to return to sea to replenish their energy reserves regularly during the lactation period. As their pups are fasting during these trips to sea, faster growth and heavier weaning masses can be achieved if the foraging trips are kept as short as possible. Breeding sites are often located close to the continental shelf break or other oceanographic features that tend to have enhanced primary productivity. In cases where this is not possible, such as the sub-Antarctic fur seal breeding site on Amsterdam Island, female foraging trips are much longer than in other species (or populations) and the pups have correspondingly lower growth rates.

Land-breeding phocid seals generally have no requirement for feeding during lactation, and therefore the breeding sites can be located considerable distances from the foraging sites. Southern elephant seals (*Mirounga leonina*), for example, tend to feed in high-latitude waters, but breed thousands of kilometers away on sub-Antarctic islands. In this case the primary requirement of a breeding site is suitable beach structure and perhaps a moderate climate to help the pup in its early life.

B. Marine Mammals That Breed on Ice

Thirteen species of pinnipeds breed on ice, either floating pack ice or fast ice attached to land (Table II). Ice-breeding seals tend to be monogamous, and this is likely to be a consequence of the breeding habitat. Unlike suitable beaches for land-breeding seals, ice is not a limited resource, and females can haul out anywhere to breed, so aggregations of females tend not to occur. This limits the opportunities that males have to monopolize access to several females, and the best strategy for them is to find a female and remain with her until estrus. Weddell seals (*Leptonychotes weddellii*) are an exception to this rule, as they breed on fast ice, with limited access to open water. Female Weddell seals therefore tend to aggregate around tide cracks and other sources of permanent open water.

Most ice-breeding seals give birth and suckle their young on the ice. Exceptions to this rule are ringed seals (*Pusa hispida*) and Baikal seals (*P. sibirica*), which can use ice lairs under ice ridges. These lairs afford some protection from the elements and perhaps from predators, although polar bears are adept at locating and breaking into these lairs.

TABLE II
Ice-Breeding Marine Mammals, Including the Primary Ice Type

Species	*Ice type*[a]
Obodenids	
Walrus, *Odobenus rosmarus*	Pack ice
Phocids	
Weddell seal, *Leptonychotes weddellii*	Fast ice
Ross seal, *Ommatophora rossii*	Pack ice
Crabeater seal, *Lobodon carcinophaga*	Pack ice

Ringed seal, *P. hispida*	Fast ice
Harbor seal, *Phoca vitulina*	Pack ice/land
Larga seal, *Phoca largha*	Pack ice
Gray seal, *Halichoerus grypus*	Pack ice/land
Bearded seal, *Erignathus barbatus*	Pack ice

[a]From Reidman (1990).

Although pack ice is the breeding substrate, many species have preferred geographic regions to which they move for the breeding season. Harp seals (*Pagophilus groenlandicus*), for example, migrate to the southerly edge of the pack ice and occupy only a small part of their overall range during the breeding season. The biggest areas are around Newfoundland and off western Greenland. Hooded seals (*Cystophora cristata*) show a similar pattern of migration, moving from widespread northerly feeding areas to more proscribed breeding areas, which appear to be associated with the continental shelf at the southern extent of the summer pack ice. This may provide the adults with access to the shelf for feeding immediately after weaning their pups.

II. Species That Stay at Sea to Breed

Three groups of marine mammals are sufficiently adapted to a marine existence that do not need to leave the water to give birth or suckle their young. These are the cetaceans, the sirenians, and the sea otters. By giving birth at sea, these animals are no longer constrained to use what is essentially a limiting resource: land. Nonetheless, many species still have quite specific requirements of their breeding sites and migrate thousands of kilometers to reach their breeding grounds. Because such profound separation of feeding and breeding sites incurs large energetic costs, the specific characteristics of these areas must be of considerable importance.

Dugongs (*Dugong dugon*) and manatees (*Trichechus* spp.) have no specialized breeding site requirements, although newborns may be kept close to shore or in protected bays or inlets. Young are born and remain with their mother while she forages on sea grass beds. Likewise, sea otters tend to give birth at sea

(often among kelp beds) and the cubs remain with their mothers. Neither group appears to migrate to specific regions for breeding and remain within their foraging areas.

Cetaceans are the only group of ocean-breeding marine mammals in which some species have clear separation of feeding areas and breeding areas. Within the cetaceans, breeding sites can be loosely categorized as (i) coastal, (ii) open ocean, or (iii) nonspecific. Species with nonspecific-breeding sites are those that show no evidence of requiring different environments for breeding. This group contains most of the odontocetes and several of the mysticetes. Many of the smaller odontocete species do make seasonal migrations, but these are not clearly linked to breeding and seem more related to changes in prey distribution.

Several species of beaked whales appear to have year-round high-latitude distributions and do not migrate for breeding, giving birth and suckling their young in polar waters. This behavior is also seen in two mysticete species: the common minke (*Balaenoptera acutorostrata*) and the bowhead (*Balaena mysticetus*) whales. Bowhead whales are never far from pack ice, including during the breeding season.

A. Cetaceans with Coastal Breeding Sites

Humpback whales (*Megaptera novaeangliae*) have several recognized breeding grounds and all are associated with coastal regions. The Southern Hemisphere populations use either the coast of the major southern continents (South Africa, Australia, or South America) or smaller oceanic islands such as Tonga and Fiji, with the preferred sites generally north of 30°. The Northern Hemisphere humpbacks move to the Caribbean, Hawaii, or Cape Verde Islands.

Gray whales (*Eschrichtus robustus*) move south from arctic feeding grounds to breed in Baja California and, as with humpbacks, the breeding sites are close inshore. In fact, they are so inshore that they are close enough to be seen from land and form the basis of a tourist industry.

Of the inshore breeding cetaceans, the right whales (*Eubalaena* spp.) are least migratory. Neither the southern (*E. australis*) or the northern right whale species (*E. glacialis* and *E. japonica*) make long migrations to their breeding sites, but all three species favor coastal sites and sheltered bays for giving birth. Individual southern right whales show strong breeding site fidelity and use the same bays on several consecutive breeding events.

Only one odontocete species, the beluga (*Delphinapterus leucas*), seems to have an inshore migration, and often breeds in shallow inshore waters. Why these species seek out inshore waters in not really known. Aside from the thermal advantages common to all migrating whales (see later), the specific advantages associated with inshore breeding are likely to be related to environmental conditions and predator avoidance.

B. Cetaceans with Oceanic Breeding Sites

Less is known about the characteristics of the breeding sites for these species due to their lack of coastal aggregations, so much of what is known comes from early tagging studies and whaling records.

Fin whale (*Balaenoptera physalus*) breeding sites are widely spread over oceanic waters in temperate and subtropical waters. Some fin whales move toward land and even form loose aggregations, but they do not cross the continental shelf, remaining in deep water. The little information available for blue whales suggests that they use similar breeding sites to fin whales. This may also be the case for sei whales (*B. borealis*), although they may not penetrate tropical waters. Brydes whales (*B. edeni*) do not appear to migrate to breed, presumably this is a reflection of this species' largely tropical habitat all year round.

There is ongoing debate regarding the reasons for the use of temperate or equatorial breeding sites by mysticete whales. Thermal and energetic advantages to newborn calves is one possibility, but if so, why do some species such as the minke and bowhead whales, as well as many smaller odontocetes, remain in high-latitude waters to breed? An alternative view is that the abundant and predictable food supply of food at high latitudes declines over the dark winter months, but only species with a large body size (and lower mass specific metabolic rates) are able to make the long migrations that allow them to take advantage of warmer waters.

Bryde's Whales

Balaenoptera edeni and *B. brydei*

HIDEHIRO KATO

National Research Institute of Far Seas Fisheries, Shimizu, Japan

Bryde's whales are the least known of the large baleen whales. We are not even sure how many species are represented in this complex of temperate and tropical whales.

I. Characters and Taxonomic Relationships

Bryde's whales were long confused with sei whales (*Balaenoptera borealis*) because of morphological similarities; this confusion lasted into the 1970s. Bryde's whales were first described by Anderson (1878) based on examination of a stranded balaenopterid on Thaybyoo Creek beach, Gulf of Marataban,

Burma. He gave it the scientific name *Balaenoptera edeni* in honor of the British high commissioner in Burma, Sir Ashley Eden. Olsen (1913) found another new species among "sei whales" caught in Durban, South Africa, and gave it the scientific name *B. brydei* in honor of his sponsor Johan Bryde, a pioneer in South African whaling from the traditional whaling port of Sandefjord. Junge (1950) concluded that the two names were synonymous based on examination of a skeleton collected in Pulu Sugi, Singapore. Further studies by Omura (1959) and Best (1960) supported Junge's view, and their conclusion had been generally accepted until recently, with *B. edeni* having priority as the scientific name. (The common name remained "Bryde's whale" probably due to its wide popularity.) However, today it is not clear how many species of Bryde's whale-like baleen whales there are or what their scientific names should be (Rice, 1998). Wada and Numachi (1991) found that a small form occurring off the Solomon Islands and Java did not accord with other Bryde's whales in allozymes. These results suggesting the existence of two species were supported by mtDNA analyses reported by Yoshida and Kato (1999). Rice (1998) proposed provisional recognition of the existence of two species, with the nomenclature unsettled. The problem is that it is not yet known to which of the two species the holotype specimen of *B. edeni* (in Calcutta) belongs. It is not distinctive morphologically (at the upper end of the size range for the small form, but still physically immature) and comes from an area of overlap of the two species. If GENETIC analysis determines that it belongs to the small species, then the small species will bear the name *B. edeni*. If it proves to be of the large species, then that species will bear the name, *B. brydei* will fall into synonymy, and a new name (and holotype specimen) will be needed for the small species.

Bryde's whales are medium-sized balaenopterids. Females are larger than males throughout life, by about 2 feet (0.5–0.6 m) at full maturity. It is believed they reach 15.5 m, but most are much smaller. As demonstrated by Best (1977) for South African Bryde's whales (Table I) animals from coastal stocks or stocks inhabiting rather areas are generally smaller than those from migratory pelagic stocks. Southern Hemisphere animals are also larger than Northern Hemisphere animals. In the South Africa and western North Pacific stocks, body length increases rapidly until 4–5 years, reaches about 90% of asymptotic length for both sexes at about 10 years, and ceases to increase at about 20–25 years (Best, 1977). The length–weight relationship is given by the equation (Ohsumi, 1980):

$$W = 0.0126\, L^{2.76},$$

where W is body weight in metric tons and L is body length in meters.

If mean lengths at physical maturity in the western North Pacific stock are substituted into the equation, weight estimates are 15.0 (at 13.0 m) and 16.6 (at 13.5 m) tons for males and females, respectively.

Bryde's whales closely resemble sei whales but have a number of distinctive characteristics (Fig. 1). Body color is principally dark smoky gray above and white below, but the dark area extends down to include the throat grooves and the flippers. The boundary between dark and light areas is diffuse. The rostrum is V shaped as in other balaenopterids (Fig. 1). The head occupies about 24–26% of the body. The dorsal fin is extremely falcate with a tapering tip and is located at 25.2–26.6% of body length anterior to the flukes. The flukes are broad (23.5–24.4% of body length), with rather straight posterior margins.

TABLE I
Distinguishing Characteristics of the Two Forms of Bryde's Whales off Donkergat[a]

Characteristic	*Inshore form*	*Offshore form*
Distribution	<20 miles off the coast	>50 miles off the coast
External appearance	Very few oval scars, several with scrapes under tail	Numerous oval scars, no scrapes under tail
Baleen shape (length: breadth quotient)	2.22–2.43	1.83–2.24
Food	Anchovies, pilchards, maasbankers	Euphausiids, myctophids, *Lestidium*
Size at sexual maturity	Males 39–40 ft. Females 41 ft.	Males 42–43 ft. Females 41–42 ft.
Breeding season	Unrestricted	Principally autumn
Mean number of ovulations per reproductive cycle	3.75	1.00
Calculated ovulation rate	2.35	0.42
Size at physcial maturity (= L∞)	Males 43 ft. Females 45 ft.	Males 45 ft. Females 47–47 ft.

[a]After Best (1977).

Figure 1 *(Top) Bryde's whale in western North Pacific in summer 1993 (photograph by Tomio Miyashita); (Bottom) head region has a lateral ridge on the rostrum of an animal off South Africa (photograph by Keiko Sekiguchi, 1997).*

Pelagic Bryde's whales, such as those in the western North Pacific stock or the offshore form off South Africa, bear large numbers of oval pit-like scars from bites by the tropical cookie cutter shark (*Isistius* sp.), evidence of migration to tropical waters. This scarring is usually most extensive on the lateral side of the peduncle, leading to an appearance like that of galvanized iron. Such scarring is rare on animals of the coastal form off South Africa; this may also be true for coastal animals in neritic waters off Kochi, southwest Japan, indicating the whales do not migrate to tropical waters. Best (1977) further noted that the coastal form has thin scratches on the undersurface of the tail and ventral keel and suggested that these scratches are due to accidental touching of the sea bottom in shallow waters.

The throat grooves extend to or beyond the navel, whereas those of the sei whale do not reach the navel. The number of grooves between the flippers is 54–56.

The most distinctive external character allowing the discrimination of Bryde's whales from other baleen whales is the presence of three prominent ridges on the rostrum (Fig. 1). The ridges run from just behind the tip of the snout to anterior to the blowholes and are composed of one central ridge and two lateral subridges.

Bryde's whales have 285–350 dark slate-gray baleen plates on each side of the mouth. They are much broader and have coarser bristles than those of sei whales. The longest plate may reach 40 cm in length above the gum. Best (1960, 1977) reported a clear difference in the proportion of length to breadth of the plates in South Africa, with those of the inshore form being more slender than those of the offshore form. Kawamura (1978) found animals in the South Pacific to have finer bristles than those in the western North Pacific stock, probably reflecting a difference in their feeding habits.

The SKULL occupies about 24.1–25.8% of total body length. It is relatively broad, short, and flat for a balaenopterid skull (Fig. 2). The rostrum is also relatively short and pointed. Its sides are nearly parallel posteriorly but slightly convexly curved anteriorly. The curved and robust mandible is also conspicuous among balaenopterids. The vertebrae formula is C 7 + D 13 + L 13 + Ca 21 – 22 = 54–55 (Omura *et al.*, 1981), for a total slightly lower total count than in sei whales (56–57). Cervical vertebrae are unfused, and thoracic (dorsal) vertebrae have short neural processes. The ribs are relatively thin and broad and usually number 13–14. The first rib has a double head, a characteristic shared with the sei whale. The phalangeal formula is I (6), II (5), IV (5), V (3).

II. Distribution, Stocks, and Ecology

Although there is a general pattern of MIGRATION toward the equator in winter and to higher latitudes in summer, Bryde's whales are seen throughout tropical and warm temperate waters of 16.3°C or warmer year round. Their occurrence has been reported from all tropical and temperate waters in the North and South Pacific, Indian Ocean, and South and North Atlantic between 40°N and 40°S (Fig. 3).

In the western North Pacific, Bryde's whales occur in temperate and tropical waters off the Pacific coasts of Japan, Taiwan, and the Philippines to 150°W, with the northern limit corresponding approximately to the southern margin of the sub-Arctic boundary at about 40°N and the southern limit at about 2°S. This is the western North Pacific stock, with ABUNDANCE ESTIMATED at about 24,000 (CV = 0.20; IWC, 1997). Bryde's whales inhabit the east China Sea; this stock extends to the coastal waters of the Pacific side of southwest Japan but is restricted to the west of the Kuroshio warm current (Kato *et al.*, 1996). In the Philippines, Bryde's whales are significantly smaller than those of the western North Pacific stock. They are distributed from there to the Gulf of Thailand, Burma, New Guinea, and the Solomon Islands, all likely "small or dwarf forms" considered to constitute a different species. Bryde's whales also occur in eastern tropical Pacific waters mainly west of 150°W between 20°N and 10°S;

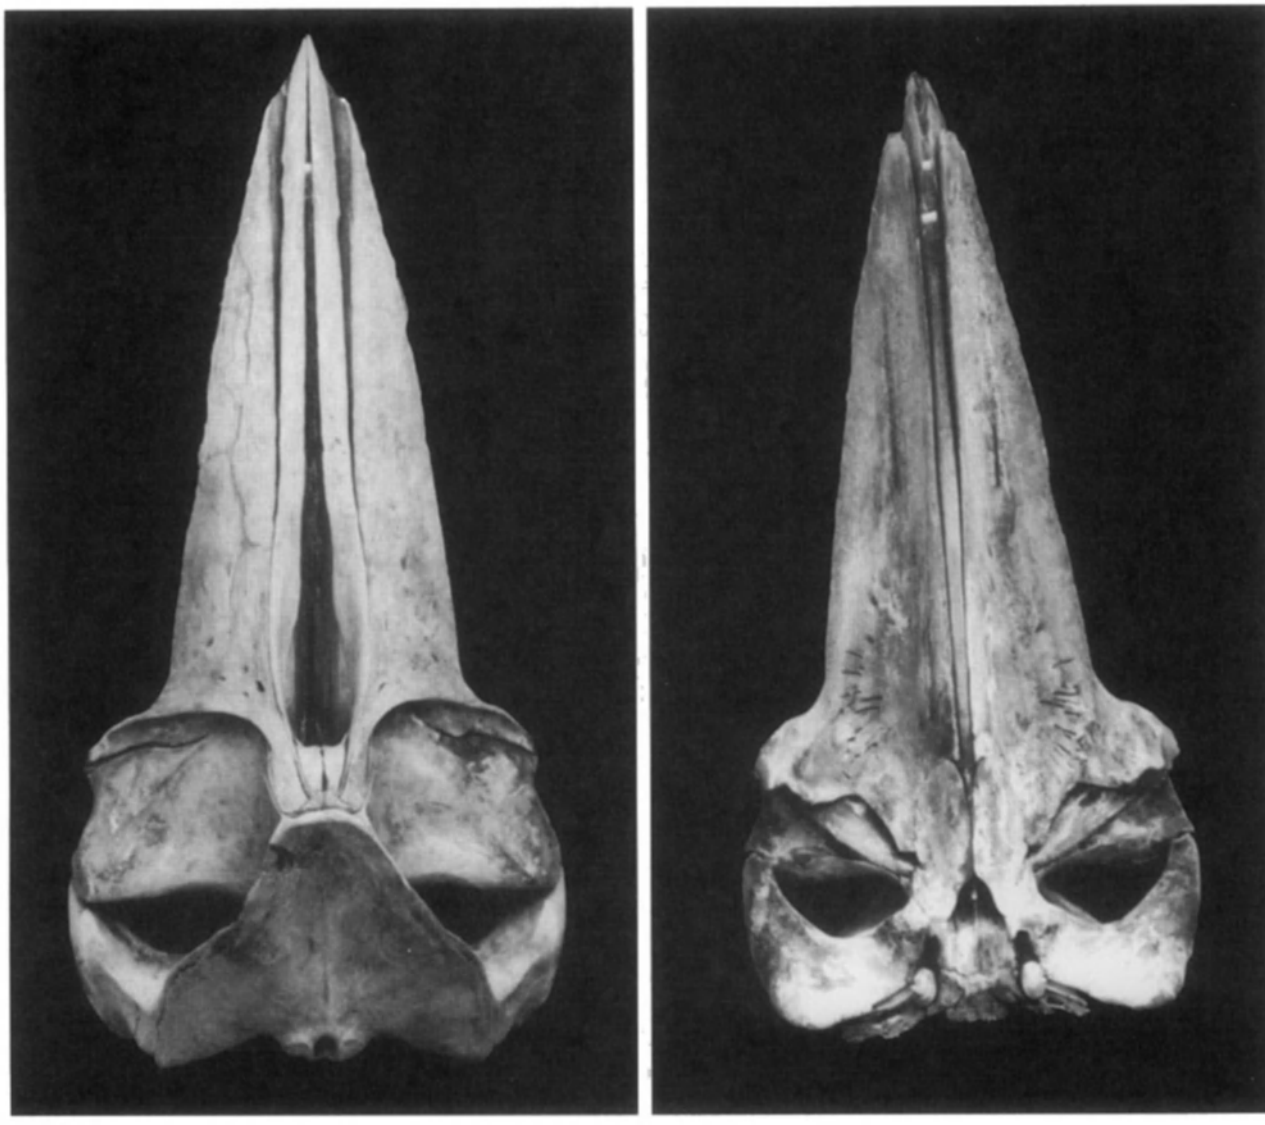

Figure 2 *Dorsal and ventral views of a skull of Bryde's whale caught in the western North Pacific and landed at Bonin Island in July 1983. Photograph by Hidehiro Kato.*

abundance is estimated at 13,000 (CV = 0.202; Wade and Gerrodette, 1993). Bryde's whales also inhabit the Gulf of California throughout the year; these are assumed to constitute an independent stock. They are also widely seen in the south, occurring continuously from the east coast of Australia to 120°W in a zone between the equator and about 30°S, including northern New Zealand. In the eastern South Pacific, the species is distributed in coastal waters off South America from the equator to 37°S. Occurrence seems to be related somewhat to seasonal upwelling events. Little is known about stock structure in these areas, but it is expected that the coastal stock(s) is genetically different from those of the western South Pacific.

Bryde's whales are common throughout the Indian Ocean, from waters north of 40°S such as the Bay of Bengal and the Arabian Sea. Geographical concentrations occur south of Java to the west coast of Australia (east of 90°E), in the central Indian Ocean (65–90°E), off Madagascar (35–65°E), and off South Africa (east of 35°E). Stock structure in these areas has not been fully examined other than to confirm the existence of inshore and offshore forms off South Africa (see later). However, it would not be realistic to assume that one homogeneous stock is distributed over the Indian Ocean.

Two allopatric forms of Bryde's whale known as the inshore and offshore forms are found off the west coast of South Africa (Best, 1977). The inshore form is restricted to within 20 miles from the coast and is seen there throughout the year. The offshore form occurs in waters over 50 miles from the coast and migrates north to the equator in winter. Accurate estimates of population abundance are not available for either stocks. Little is known about distribution and stock structure in the rest of the Atlantic, especially in the Northern Hemisphere. However, Bryde's whales have been sighted or stranded from Morocco

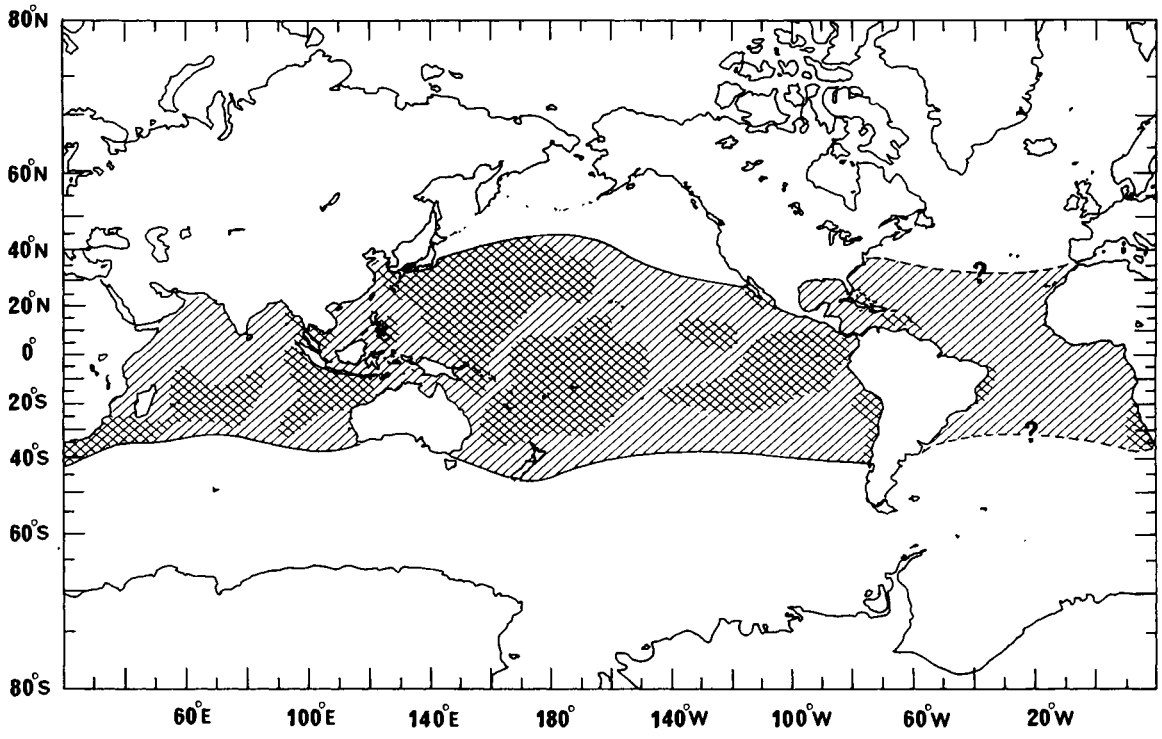

Figure 3 *Worldwide distribution of Bryde's whales based on published or available information. Dense hatch represents areas in which higher densities are expected.*

south to the Cape of Good Hope in the east and from Virginia south to Brazil in the west, including the Gulf of Mexico, the Caribbean, and off Venezuela.

Bryde's whales feed mainly on pelagic schooling fishes such as pilchard, anchovy, sardine, mackerel, herring, and others. However, they also feed on small crustaceans such as euphausids and copepods and on cephalopods and pelagic red crabs (Pleuroncodes) (Nemoto and Kawamura, 1977; Best, 1960, 1977; Kawamura, 1980; Ohsumi, 1977a). They are considered opportunistic feeders, unlike sei whales, which concentrated on copepods. Off South Africa, they tend to be dependent on euphausiids in pelagic waters and feed on schooling fishes in coastal waters; thus feeding habits may be characteristic of stocks (Best, 1977). Balaenopterids consume about 4% of body weight daily at the peak of the feeding season; this corresponds to approximately 600–660 kg per day for a Bryde's whale.

Bryde's whales are sometime seen within high-density patches of bonito (*Sarda*) in pelagic waters in the North Pacific. This may be a result of two predators chasing the same prey. Similarly, off the coasts of Kochi and Kasasa, southwest Japan, it is very common to see Bryde's whales feeding in patches of sardines or juvenile tuna, especially in summer. They have also been observed to utilize bubble net foraging with slow circle swimming under the surface.

III. Behavior and Life History

Bryde's whales do not gather into large groups. They are usually seen singly or in groups of 2–3 in the North Pacific, with a maximum group size of 12. They usually surface steeply like other balaenopterids. The blow is 3–4 m high. The dorsal fin is seen after the blow and then sometimes the dorsal keel. They seldom fluke up before DIVING. It is generally believed that they usually move at 2–7 km/hr, but can swim as fast as 20–25 km/hr and dive up to 300 m. Bryde's whales breach more often than other balaenopterids (Fig. 4). Bryde's whales produce powerful low-frequency moaning sounds averaging 0.4 sec in duration (range, 0.2–1.5 sec) with most of the energy concentrated at 124–250 Hz and a frequency modulation of as much as 15 Hz (Cummings, 1985).

While Bryde's whales have a life history similar to that of other balaenopterids, there are species-specific aspects due to their remaining in tropical and temperate waters throughout the year. As for many other migratory large cetaceans, little is known about the breeding grounds, even for inshore or coastal stocks, although it is generally believed that they must be somewhere in lower latitudes from the migratory stocks. In waters off Kochi (east China Sea stock), females accompanied by small calves sometimes appear in early spring, but there is no evidence that they give birth there. In pelagic stocks, peaks of both conception and calving are in winter, although these are much more diffuse than in other migratory balaenopterids. Best (1977) reported that breeding is not seasonally restricted for inshore animals off South Africa; this may be true for other local stocks.

Gestation lasts for about 11 months. Length at birth is about 4 m. The sex ratio at birth is not different from parity (Best, 1977). Lactation lasts about 6 months and calves wean at about 7 m in body length. Males attain sexual maturity at 11–11.4 m

Figure 4 *Breaching of a Bryde's whale off Kochi, Japan. Photograph by Akinobu Mochizuki.*

and females at 11.6–11.8 m in the western North Pacific stock. Taking into account bias due to operations and regulation of whaling, Best (1977) found length at sexual maturity for the inshore form to be less than for the offshore form off South Africa, by 1 foot in females and 3 feet in males. The mean age at sexual maturity is slightly less than 7 years. Based on the annual ovulation rate (0.42–0.46; Best, 1977; Ohsumi, 1977b) for pelagic Bryde's whale stocks, the calving interval is about 2 years. Inshore waters off South Africa are very frequent ovulators (1.88 per year), but this does indicate a higher pregnancy rate but rather probably results from the extended breeding season. In summary, Bryde's whales have a 2-year reproductive cycle composed of 11–12 months gestation, 6 months of lactation, and 6 months resting.

IV. Conservation Status

Bryde's whales were not harvested commercially or substantially until recent times; their value became relatively important in the late 1970s with the shift of whaling to the smaller species. However, commercial harvest of this species has been prohibited by a moratorium imposed by the INTERNATIONAL WHALING COMMISSION (IWC) in 1987.

Because Bryde's whales had been mainly exploited after substantial improvement of IWC stock management procedures adopted in 1975 (the MNP or new management procedure), stocks have kept relatively stable. A reliable estimate of the population trend for North Pacific Bryde's whales has been available for the western North Pacific stock from a comprehensive assessment conducted by the IWC in 1995 and 1996. According to the assessment (IWC, 1997), the population has been increasing since 1987, and the current population level (mature females in 1996 relative 1911) ranges from 56.7 to 81.4%.

Burmeister's Porpoise

Phocoena spinipinnis

JULIO C. REYES

Areas Costeras y Recursos Marinos, Pisco, Peru

Described by Hermann Burmeister in 1865, this is one of the five species of the family Phocoenidae, a group of cetaceans whose members share the presence of small, spade-shaped TEETH. The Spanish name for this porpoise, "marsopa espinosa" or "spiny porpoise," refers to the series of tubercles present in the dorsal fin. It was long considered a rare species, but research in the last decade has shed light on the natural history and conservation problems of this cetacean.

I. Distribution

Burmeister's porpoise is restricted to South American waters, from Santa Catarina, in southern Brazil, around the Cape Horn north to Bahía de Paita, in northern Peru. As more studies focus on this species, its range appears to be continuous. The existence of Pacific and Atlantic stocks has been proposed, but no studies have yet addressed this matter.

II. External Form

In the Atlantic part of its range, Burmeister's porpoises may grow up to 200 cm; off the Pacific coast, the maximum size recorded corresponds to a female 183 cm long from Peruvian waters. The males, however, are significantly larger than females. The body is robust, with a small, blunt head, and proportionately large flippers (Fig. 1). A conspicuous feature of the species is the dorsal fin, which is triangular in shape and canted backward in an unusual fashion for a cetacean. Moreover, the leading edge of the dorsal fin has a series of small tubercles that become sharper as the animal grows (Fig. 2).

COLORATION varies from dark gray to brownish gray on the back and sides, and a light gray ventral region. Surrounding the eye, a dark patch can often be noted. A dark gray stripe runs from the chin to the base of the flipper. This "flipper stripe" is asymmetrical, being markedly wider on the left side (Fig. 3). A

Figure 1 *Side view of a Burmeister's porpoise caught in Peruvian waters.*

Figure 2 *The dorsal fin of a Burmeister's porpoise.*

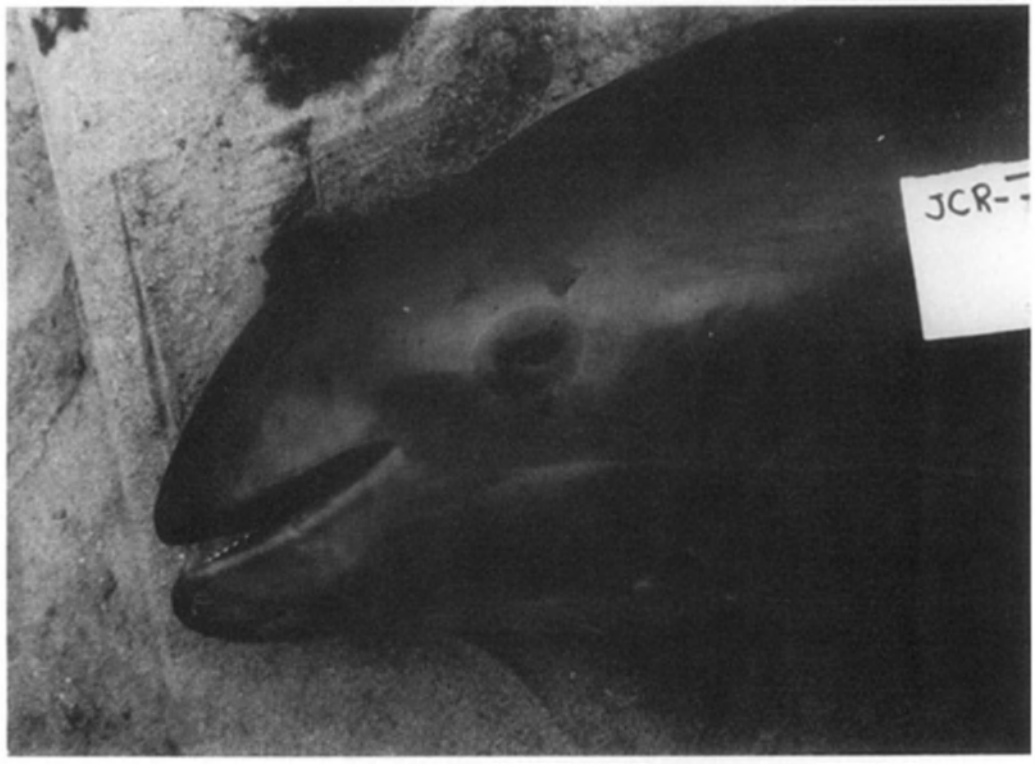

Figure 3 *Close-up of a Burmeister's porpoise head, showing the eye patch and flipper stripe.*

pair of stripes is also present on the abdominal region. The pattern of these ventral stripes is sexually dimorphic.

III. Habitat and Ecology

Although it is considered a coastal, inshore species, Burmeister's porpoise has been observed up to 50 km from shore, at a depth of 60 m. These movements to offshore waters appear to respond to migration of the prey species. Some animals have been recorded upstream in the Valdivia River, in southern Chile.

Burmeister's porpoise feeds on a variety of both pelagic and demersal fish, including anchovies, hake, jack mackerel, sardine, drums, and, less frequently, squids and shrimps.

At sea this porpoise is difficult to observe. It swims with a gentle roll on the surface, with little of its body exposed. This behavior may change to very fast swimming when approached by a boat, although not porpoising or performing bow riding. The group size usually ranges from 2 to 8 animals, but aggregations of 22 and up to 70 porpoises have been reported.

IV. Reproduction

Females reach sexual maturity when they are 154.8 cm long, shorter than the length of attainment of sexual maturity for males, estimated to be 159.9 cm. There does not appear to be seasonality in the reproductive cycle of the male. Pregnancy may last 11–12 months, and the length at birth is approximately 86 cm. Some pregnant females may be simultaneously lactating, indicating that annual reproduction may occur. Based on the counting of dentine layers in the teeth, one porpoise 174 cm long was estimated to be 8 years old.

V. Interaction with Fisheries

The coastal habitat of Burmeister's porpoise makes it vulnerable to fishing activity. Through its range, the species become incidentally entangled in fishing nets. In Uruguay, several porpoises became entangled in shark nets. In the southern part of Argentina, several fisheries account for the capture of a small number of porpoises. In southern Chile, entanglements and possible harpooning of animals have been reported. From central Chile to northern Peru the species becomes incidentally entangled in nets set for a variety of small pelagic and demersal fishes, sharks, and rays. Only in Peru do captures of Burmeister's porpoises reach an annual figure of 2000 animals.

California, Galapagos, and Japanese Sea Lions

Zalophus californianus, *Z. wollebaeki*, and *Z. japonicus*

CAROLYN B. HEATH
Fullerton College, California

The California, Galapagos, and Japanese sea lions are closely related species that together comprise the genus *Zalophus*. They occupy (or occupied, in the case of the presumably extinct Japanese sea lion) widely separated regions of the Pacific, including the temperate western and eastern North Pacific and the tropical Galapagos Archipelago (Fig. 1). The varying environmental conditions experienced throughout this range, along with the corresponding variations in behavior, provide fascinating insights into their behavioral ecology.

I. Taxonomy and Distribution

The California, Galapagos, and Japanese sea lions are now regarded as separate species: *Zalophus californianus* (Lesson, 1828), *Z. wollebaeki* (Sivertsen, 1953), and *Z. japonicus* (Peters, 1866), respectively. Previously they were typically considered to be geographically isolated subspecies (*Z. californianus californianus*, *Z. c. wollebaeki*, and *Z. c. japonicus*), but recent discoveries of substantial morphological and behavioral differences among them led to their reclassification. Further studies are needed to delineate the differences among species and to identify any subspecies or stocks. Differences in mitochondrial DNA indicate that the Pacific and Gulf of California populations of California sea lions have long been genetically isolated. However, no differences have been found in the cranial morphology of the two populations, and subadult males appear to migrate between colonies in the southern Gulf of California and those along the Pacific Coast of Mexico. The degree of interchange between Mexican and U.S. populations is not known.

The main breeding areas of California sea lions include the Channel Islands in southern California and Mexican islands off the Pacific coast of Baja and in the Gulf of California. Rarely, births may occur as far north as the Farallon Islands off central California. Outside the breeding season, animals (mostly males) are common as far north as Vancouver Island. Vagrants occur as far north as Prince William Sound, Alaska, and as far south as Chiapas, Mexico. Females and immatures may disperse from the breeding islands to forage, but apparently do not migrate as extensively as males.

Galapagos sea lions breed on all the islands of the archipelago. In 1986 a small rookery was established outside of the Galapogas on Isla de La Plata off the coast of Ecuador. Vagrants have been reported along the mainland coast of Ecuador and on Islas del Coco (Costa Rica) and Gorgona (Columbia).

Although historical and archaeological records are incomplete, Japanese sea lions appear to have lived in coastal areas from Kyushu to southern Kamchatka. Their range was likely centered along the west and east coasts of Honshu, off Shikoku and Kyushu, in the Seto Inland Sea, and on islands in the Sea of Japan and the Izu region. Known rookeries include Takeshima and Ullung-do in the southern Sea of Japan, the northwest and also central-eastern coasts of Honshu, and four islands in the Izu region. Vagrants have been noted to southwestern Sakhalin, the Kuril Islands, southern Kamchatka, and the east coast of South Korea.

II. Population Trends and Exploitation

The annual return of pinnipeds to predictable breeding areas makes them particularly vulnerable to exploitation. Subsistence HUNTING of California sea lions probably occurred for several thousand years without much of an effect on the population. However, commercial harvesting during the 1800s and early 1900s in southern California and Mexico reduced the population to only about 1500 animals by the 1920s. The harvest, which at various times was for hides, blubber, meat, predator control, or the whiskers and BACULA sold as aphrodisiacs, probably focused on adult males. A floundering market coupled with protective legislation allowed the population to start increasing by the 1940s, although some killing and live collecting continued until the 1970s. The 1972 U.S. Marine Mammal Protection Act and similar legislation in Canada and Mexico

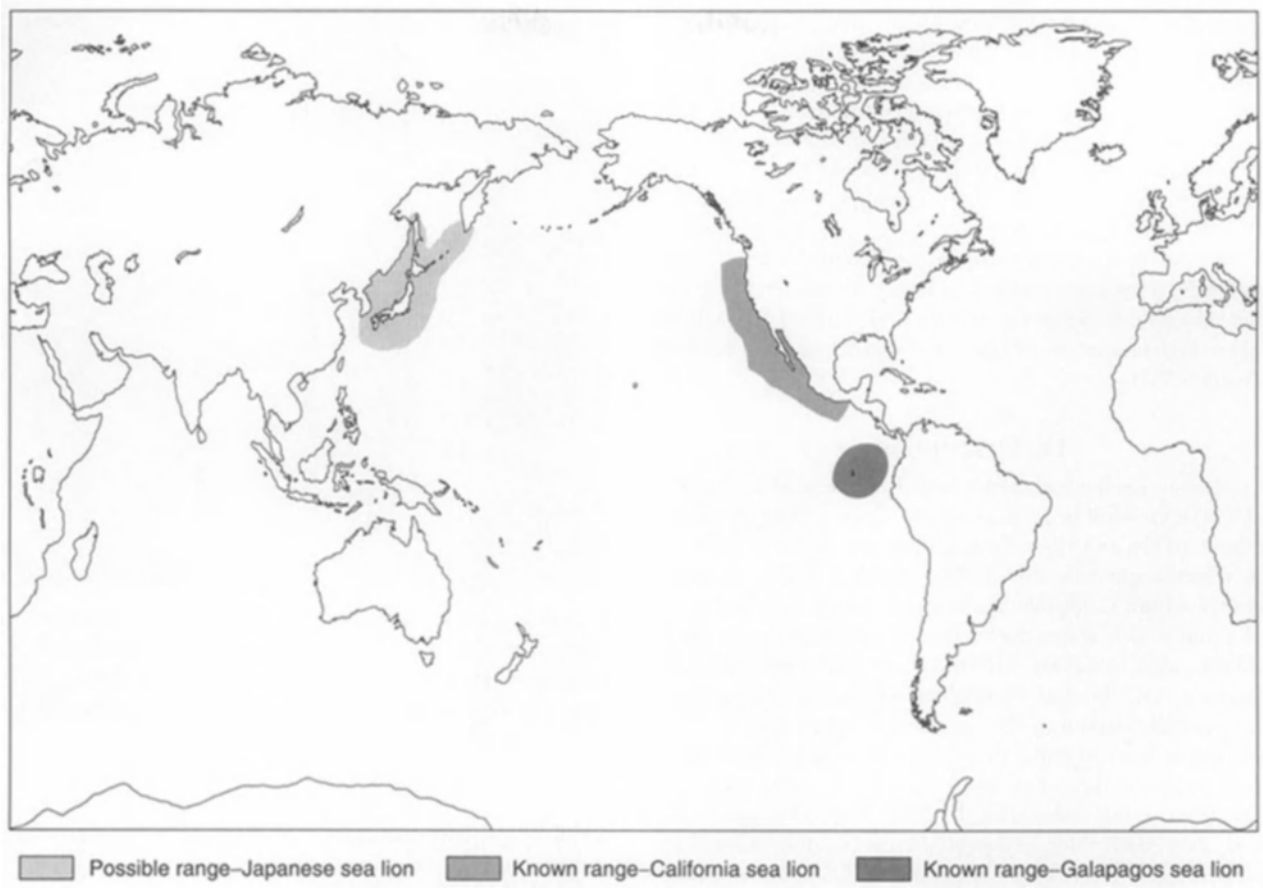

Figure 1 *Ranges of California, Galapagos, and Japanese sea lions.*

greatly facilitated the population's recovery. The U.S. population of California sea lions is currently estimated to be 167,000–188,000, with about 34,000 pups produced annually. Overall, the population is increasing at a rate of roughly 5% per year; however, periods of growth are frequently reversed during strong El Niño events. A 1992 census of the Mexican Pacific coast recorded about 10,000 California sea lions, compared to nearly 28,000 counted a decade earlier (Maravilla and Lowry, 1996). Allowing for uncensused animals at sea, the current Mexican Pacific population may be roughly 13,000 to 22,000. Clearly the population fluctuates in this region; its relationship to changes in the U.S. population is not known. A 1992 census of the Gulf of California population recorded about 23,000 animals; correction factors yielded a population estimate of about 31,000 (Aurioles and Zavala, 1994). Thus, the total California sea lion population is about 211,000–241,000.

The Galapagos sea lion has been largely spared the commercial exploitation that depleted the California sea lion population. However, the number of Galapagos sea lions apparently does fluctuate frequently due to El Niño events and epidemics of seal pox. The population was estimated at 20,000–50,000 in 1963. Following the 1997–1998 El Niño, which was accompanied by up to 90% pup mortality and 45% overall mortality, the population was estimated at only about 14,000 individuals (Salazar, 1999).

Between 30,000 and 50,000 Japanese sea lions may have existed in the mid-1800s. Heavy, unregulated hunting depleted the population such that by the 1950s 50 to 60 animals on Take-shima were the only ones reported. The IUCN lists the species as extinct; some scientists believe this status needs to be confirmed by surveys in remote regions.

III. Habitat and Environment

California and Galapagos sea lions breed on sandy beaches and rocky areas on remote islands. Because females must forage at sea during lactation, breeding areas are restricted to regions of high marine productivity. California sea lion rookeries along the Pacific coast are in a very productive upwelling zone, and productivity in the Gulf of California is also very high due to tide- and wind-generated upwelling. The waters of the continental margin adjacent to areas once used by breeding Japanese sea lions are quite productive. While low productivity generally excludes otariids from breeding in the tropics, the islands in the Galapagos Archipelago are bathed in nutrient-rich upwelling currents. This creates an isolated pocket of high productivity, which supports the Galapagos sea lions. The importance of high productivity can be seen in the devastation that occurs during El Niño events, when a plume of warm, nutrient-poor water emanating from the equatorial Pacific

decreases the availability of the sea lions' prey. These frequent, but unpredictable events are most severe in the eastern tropical Pacific where the Galapagos sea lion lives, with lesser impacts at the higher latitudes occupied by California and Japanese sea lions. Sea lions living in the Gulf of California, Mexico, may be largely protected from the effects of El Niños; strong tidal mixing there should be able to resupply nutrients to surface waters during an El Niño event.

The breeding habitat occupied by *Zalophus* ranges from temperate to tropical regions. As a result, breeding animals are often subjected to high temperatures while on land. The affects of these high temperatures and of El Niño events are described in Section VIII.

IV. Description

California sea lions are highly sexually dimorphic: the weight and length for adult males is about 350 kg and 2.4 m compared to about 100 kg and 1.8 m for adult females. Males in the Gulf of California appear to be smaller than their Pacific counterparts. Newborn California sea lion pups weigh 6–9 kg for females and males, respectively. They are dark brown to black until they molt to a tawny brown color at 4–6 months (Fig. 2). Females remain this color throughout adulthood, whereas male coats typically darken as they age. Adult males usually are a dark brown, but can range from light brown to black. All individuals appear darker when wet. It is difficult to distinguish females from young males until the latter begin developing the broad chest, dark color, and sagittal crest of adult males (Fig. 3). The sagittal crest, which is unique to *Zalophus*, is usually topped by white fur and is quite conspicuous. Galapagos sea lions are smaller than California sea lions and appear to be much less sexually dimorphic. Females weigh about 80 kg. No weights are available for males. Young California and Galapagos sea lions are especially playful, spending much time chasing and mock fighting with each other, playing with objects such as kelp and feathers, and bodysurfing. All age classes are fairly vocal; territorial males are exceedingly so. Little is known about the physical characteristics of the Japanese sea lion.

V. Life History and Annual Cycle

In southern California, where California sea lions have been studied extensively, animals can be found on the breeding islands year-round. The number ashore increases rapidly in May with the onset of the breeding season. At this time adult males begin fighting for territories along the shorelines of the rookeries. Most are unsuccessful and retreat to sea or to "bachelor" beaches nearby. Those that establish territories maintain their boundaries with ritualized displays and frequent barking. Territorial males fast throughout their tenure, surviving on fat accumulated during the off-season. Tenure lasts from 1 to 45 days and may end when residents are displaced by another male or when their fat reserves are depleted. Some males maintain territories for multiple breeding seasons. Throughout May and June females give birth to a single pup a few days after coming ashore. Vocal and olfactory imprinting follows birth and is used by mothers and pups to reunite after separations (Fig. 4). Mothers spend the first week postpartum with their pup and then begin alternating feeding trips at sea with suckling bouts on land. The feeding trip length is largely determined by the distance to the foraging grounds and the availability of prey. It averages 2–3 days, but varies with location and year. Stays on land average 1–2 days. This pattern continues until the pup is weaned. Most pups are weaned by 10–12 months of age. The number that continue to suckle as yearlings or even 2 year–olds varies among years (Francis and Heath, 1991). Females mate

Figure 4 *An adult female California sea lion vocalizes to her newborn pup. Mothers and pups imprint on each others' calls and smell at birth, which helps them recognize each other and reunite after separations. Note remnants of amniotic sack on pup. Photo by C. B. Heath.*

about 27 days after giving birth, an unusually long interval for otariids. Not all females breed every year. At many rookeries, females form "milling" groups as a prelude to mating (Fig. 5). In these groups of 2–20 females, the females often mount each other and the territorial male. Eventually 1–2 of the females mate and the milling activity ends (Heath, 1989). While ashore, both males and females make regular movements to the water to cool off (Peterson and Bartholomew, 1967).

After the breeding season ends in August, most adult and subadult males leave the southern California rookeries and migrate north, where they feed throughout the fall and winter. Females and juveniles appear to disperse to feed in the general vicinity of the breeding islands. Pup mortality is roughly 15–20% for the first 6 months of life. In the southern Gulf of California, at least, it then increases to about 40% for the next 6 months as pups venture into the water (Aurioles and Sinsel, 1988). Sexual maturity occurs at about 4–5 years of age, although males are not large enough to hold breeding territories for several more years. Longevity is estimated at 15–24 years. Sources of mortality include starvation, infection, sharks, killer whales, toxic phytoplankton blooms, entanglement, shooting, and disease.

California sea lions living in the Gulf of California, Mexico, experience a similar annual cycle with some notable differences. The pupping season lasts 1–2 weeks longer for at least some rookeries in the northern half of the Gulf (Morales, 1990), and the interval between birth and mating appears more variable than in the U.S. population (Heath, 1989). About 40% of the adult males in this region remain around the breeding islands year-round (Zavala, 1990), and the age of weaning appears to be both older and more variable than in southern California (Heath *et al.*, 1996).

The breeding season is very protracted in the Galapagos sea lion, and territorial males are observed most of the year. Births occur from June to March, but the peak pupping period varies among rookeries and years. The interval between birth and mating has been estimated at about 3 weeks. Territorial males sometimes go to sea to feed, thus often losing their territory to another male, but sometimes reclaiming it upon their return. Migration within the archipelago is minimal. Normal pup mortality to age 6 months is about 5%. Most pups are weaned within 1 year, but may continue to suckle as yearlings or 2 year olds if their mother does not have a new pup.

As with all other parameters, we have virtually no information regarding the life history of Japanese sea lions.

VI. Social Relationships

California sea lions are highly intelligent and adaptable animals, capable of learning a simple sign language in captivity (Schusterman and Krieger, 1986). Both California and Galapagos sea lions can recognize individuals in the wild through scent, sound, and probably sight. They are also gregarious animals, with much opportunity for social interaction during the breeding season, at least. These traits would seem to dispose them to sustained relationship with other individuals; however, the only obvious social unit is between mothers and their offspring. Perhaps longer term studies of permanently marked individuals will reveal other types of relationships.

VII. Diet

California sea lions eat a wide variety of prey, which is determined to some degree by its relative availability. The most common prey items in southern California are northern

Figure 5 *A "milling" group of California sea lions. These groups form in some areas as a prelude to mating. Females often mount each other or the territorial male while in these groups. Note the male's saggital crest, which is unique to* Zalophus. *Photo by C. B. Heath.*

anchovy, Pacific whiting, rockfish, cephalopods, jack and Pacific mackerel, and blacksmith (Lowry *et al.*, 1986). The first three species are also important in the Mexican Pacific and Gulf populations, as are midshipmen. Myctophids, sardines, cutlassfish, alopus, cusk eels, and bass are frequently prey in various areas of the Gulf (Sanchez, 1992). Diet varies greatly among years, seasons, locations, and probably individuals. El Niño events cause shifts in the DIET, and species otherwise rarely consumed, such as the pelagic red crab, may become more common in the diet. Feeding can occur at any hour of the day. Dives typically last for about 2 min, but can be as long as 10 min. Dive depth averages 26–98 m, but can be well over 200 m (Feldkamp *et al.*, 1991). The staple of the Galapagos sea lion diet is sardines. During El Niño events, however, partial shifts to green-eyes (1982–1983) and myctophids (1997–1998) have occurred (Trillmich and Dellinger, 1991; Salazar, 1999). Galapagos sea lions forage within a few kilometers of the coast, feeding during the daytime on a near-daily basis. Dive depth averages 37 m, but can reach 186 m. There is no information on what the Japanese sea lions ate.

VIII. Behavioral Ecology

Life is a compromise, and pinnipeds have evolved many adaptations in response to the sometimes conflicting pressures of breeding on land and feeding at sea. Certain environmental conditions can increase the costs or benefits of some of these adaptations and bring about compensatory changes in behavior. Two such conditions—high air temperatures on ROOKERIES and decreased prey availability during El Niño events—play particularly important roles in shaping the breeding and foraging behavior of California and Galapagos sea lions.

A. Temperature and Its Effects on Breeding Behavior

California sea lion females are very particular about male behavior. Boisterous, overly attentive, or aggressive males are typically abandoned and left to sit alone on their territories. Any interference with female movements is simply not tolerated. Should a male attempt to block a female's path, she needs only to extend her neck out and up, and sway it side to side as she walks. This long-neck display signals males that she requires free passage; the rare male that does not respond to this will likely be subjected to a display of jerky hopping and flipper slapping, which will dissuade him from interfering further. Males seem to have little option but to acquiesce if they are to be successful at breeding.

Why might this situation exist, especially in such apparent contrast to some otariid species where females may be herded, threatened, and even injured by territorial males? The explanation appears to partly lie in the animals' thermoregulatory needs. The particularly warm climate in which *Zalophus* breed increases the cost of moving between marine and terrestrial habitats. The blubber, fur, and large size, which insulate against cold ocean waters, can lead to overheating while ashore, thus making necessary regular access to wet substrate or water for cooling. The breeding fat of adult males intensifies their thermal stress, thereby limiting the distribution and number of territories. Successful males have territories containing access to water; others must abandon their territories (and any hopes of mating) during the heat of the day. Breeding females must also have access to cooler shoreline areas on a near-daily basis, and they regularly travel through several males' territories while moving from resting to cooling areas. Furthering this pattern of female movements is the unusually long interval (about 21–27 days) between birth and MATING. During that interval females must also make regular feeding trips to sea to replenish their milk supplies. A male that prevented these premating thermoregulatory and feeding excursions by herding the females would be left with, at best, only severely stressed females, which are not likely to mate. Thus the combination of warm breeding areas and delayed mating together foster a system in which males may control each other, but not the females. Rather, when it is time to mate, many females leave the male's territory in which they have given birth and mate with another male that they may have encountered in their movements about the rookery. Females show a surprising degree of unity in their selection of mates. As a result, many males holding territories during the breeding season never or rarely mate, while a few males mate with many females (Heath, 1989). This dramatically increases the degree of polygyny in California sea lions: males make the first cut by excluding many of their gender from the rookeries and females make another cut via their selection of mates.

The influence of temperature on behavior can also be seen in the high percentage of copulations that occur in contact with the water. This percentage increases in hotter regions, as does the amount of time females spend cooling off at the shoreline. In the Gulf of California, where air temperatures are very high, nearly all territorial defense and breeding activities are restricted to the water (Garcia, 1992; Heath, 1989).

Galapagos sea lions show a similar response to high air temperatures with their great reliance on shoreline areas for cooling. However, observations of their breeding behavior are inadequate to compare to California sea lions. Environmental conditions in at least part of the former range of the Japanese sea lion are similar to those of its congeners. However, barring the discovery of historical records, we will never know if their behavioral responses were the same as those of the California and Galapagos sea lions.

B. Responses to El Niño

The environmental changes that occur during El Niño events also elicit behavioral responses by *Zalophus*. However, unlike the fairly constant heat stress experienced on rookeries, the environmental stresses associated with El Niño are unpredictable and only occur every few years. In addition, because the degree of stress varies among events and locations, the sea lions' responses must be somewhat flexible. El Niños cause a reduction in prey availability for *Zalophus* throughout much of its range. The potential consequences of this reduction are mitigated somewhat by adaptations that have evolved over the sea lions' long history of coexistence with El Niños. However, the severe impacts of some El Niño events demonstrate the limits of these adaptations. The 1982–1983 El Niño was a particularly strong one, and much is known about its effects on the Cali-

fornia sea lions that breed in southern California. Some nonbreeding sea lions in this region responded to local prey depletion by migrating north to more productive areas. Many immatures and some adult females left their normal winter foraging areas and migrated to central California (Huber, 1991). Emigration was thus apparently an option for some individuals to reduce the effects of El Niño. Territorial males in southern California showed no measurable affects from this event, most likely due to their preseason foraging farther north. Adult females, however, appeared to be more tied to the general vicinity of the BREEDING SITES, where prey reduction was more pronounced. The increase in spontaneous abortions during the 1982–1983 winter indicates that some of these females were unable to find adequate prey (Francis and Heath, 1991). Females that did manage to produce full-term pups then faced the greater challenge of nourishing them. Feeding during lactation makes females quite vulnerable to localized decreases in food availability. In southern California they attempted to compensate for decreased prey by increasing their foraging effort while at sea, partially shifting their prey, and by slightly prolonging their feeding trips (Lowry *et al.*, 1986; Ono *et al.*, 1987). These efforts, however, were inadequate to compensate for the strength of the 1982–1983 El Niño. Females apparently made less milk: pups suckled less, grew more slowly, and weighed less at age 2 months (Ono *et al.*, 1987). Pup mortality increased, and pup production decreased by 30–71% at various islands. Fewer of the male pups were weaned by age 1 year, and more of them stayed on their birth island and suckled into their second year. Fewer females mated during the El Niño summer, presumably a sign that they were undernourished. As a result, pup production was still low in the following year. Because pup production took several years to return to pre-El Niño levels, it is possible that there may have been some mortality of breeding females and juveniles associated with this event. In Mexico, pup production on at least one Pacific island decreased by 50% during the 1982–1983 El Niño, while effects appeared to be very weak in the Gulf (Aurioles and Le Bouef, 1991). An even stronger El Niño occurred in 1997–1998. While not as widely monitored for its effects on California sea lions, they appear to have been even greater.

The reduction of prey during El Niño events is particularly strong in the eastern tropical Pacific. Because Galapagos sea lions are isolated from alternative feeding areas by vast expanses of unproductive tropical waters, emigration to better feeding areas is not an option for them. Mortality has thus been very high for this species during El Niño events. Between 80 and 95% of the pups born in 1982 did not survive their first year of life. Pup production at various rookeries in 1983 was between 3 and 65% of normal years. Adult female mortality was estimated at 20%, and territorial male mortality was particularly severe (Trillmich and Dellinger, 1991). During the 1997–1998 El Niño, pup mortality was close to 90%, and mortality for the overall population was about 45% (Salazar, 1999).

Oceanic conditions also change in Japan during El Niño events, but what effects this may have had on the Japanese sea lions is not known.

The oceanographic counterpart to El Niños are Las Niñas, periods of generally cooler ocean temperatures and greater productivity. Little is known of their effects on pinnipeds or any role they might play in the recovery from El Niño events.

IX. Interactions with Humans

Like all marine mammals, California and Galapagos sea lions spend a good portion of their lives in remote areas or underwater, hidden from our view. However, the California sea lion is one of the most familiar marine mammals. This is due in part to their being the most commonly used "seal" performer in animal park shows and also to their habituation to human presence in some areas, especially where there is a comfortable dock or buoy to be acquired by this tolerance. These activities are indicative of their intelligence and flexible nature, which itself can sometimes lead to less positive interactions with humans.

A. Fisheries Interactions

Enviable hunter or lowly thief? The answer to this question is largely a matter of perspective. Certainly, California sea lions are highly skilled at catching their prey of fish and squid, and their growing population consumes many tons of them yearly. As with many predators, they are also flexible and opportunistic in their search for food, as their diet and thus foraging patterns vary with age, location, and environmental changes caused by things such as El Niño and commercial fishing. While this flexibility is partly responsible for the recovery of this species, it at times also brings them into direct COMPETITION WITH HUMAN FISHERIES. Healthy populations of fish, sea lions, and humans have coexisted throughout much of our history; however, the demand for marine resources generated by a rapidly increasing human population, coupled with its increasingly efficient exploitation of those resources, has heightened concerns about competition between humans and other marine predators. This, combined with the highly visible actions of individual sea lions that have learned to exploit the easy take from fishing lines and nets, has led some to view California sea lions as marine pests rather than an integral part of a healthy ecosystem.

B. Habitat Overlap

Another form of competition occurs when sea lions make themselves at home on docks and other man-made resting areas. While this can be quite inconvenient, in areas such as Pier 39 in San Francisco, the situation has been converted into a popular tourist attraction.

C. Pollution

The growing arsenal of toxic chemicals and waste that makes its way into marine mammals' habitats and prey has generated much concern. This is particularly relevant for the Channel Islands population of California sea lions; their proximity to the major metropolitan areas of southern California exposes them to a great deal of urban and industrial runoff, waste, and debris. Because they are high-level predators, sea lions are vulnerable to compounds such as organochlorines (e.g., DDT and PCBs) that become increasingly concentrated as they move up the food chain. Laboratory studies of such compounds have revealed that they can suppress pinniped immune systems, rendering them more vulnerable to disease. However, establishing such clear cause-and-effect relationships in wild populations

exposed to organochlorines is more difficult due to confounding factors. California sea lions were found to have elevated levels of organochlorines associated with increased stillbirths and premature pupping, but the level of contribution of disease to this problem could not be determined. Although the specific links among chemicals, immune system responses, and disease or mortality are incompletely understood, enough indications of problems exist to warrant caution and further research.

D. Entanglement

Entanglement with marine debris is a problem found in all populations of California and Galapagos sea lions. Materials such as packing bands and discarded fishing line or nets can become caught on the animals' necks or flippers, leading to injury, infection, reduced feeding efficiency, or death. Sea lions are also killed incidentally in some fisheries.

The southern California population of California sea lions is currently thriving and is thus apparently quite able to recover from its interactions with humans. The extinction of the Japanese sea lion, however, reminds us that there can be limits to this recovery. This is especially true for smaller populations, such as those of the Galapagos sea lions or the Mexican population of California sea lions. If harmful human activities were to increase substantially or happened to coincide with natural stresses such as epidemics or El Niño events, recovery might not be so rapid or complete.

Callosities

Mason T. Weinrich
Whale Center of New England, Gloucester, Massachusetts

Perhaps no external feature on any baleen whale is as distinctive as the hardened patches of skin, called callosities (pronounced cal-OS-it-ies), found on the head of North Atlantic, North Pacific, and southern right whales (*Eubalaena glacialis, E. japonica,* and *E. australis,* respectively; Fig. 1). These features are characteristic of the genus and are immedi-

Figure 1 *The head of a northern right whale* (Balaena glacialis) *showing the most prominent callosity (usually called the bonnet).*

ately notable and visible upon sighting the whale. Old whalers called the most visible callosity, on the tip of the rostrum, the "bonnet"; that name has stuck through the present day.

The term callosity gained acceptance in the first part of the 20th century. The word extends from the term "callus," which refers to a variety of thickened tissues in many species. A variety of terms have been used in the past, primarily based on the function assumed by the author. Speculation included the possibility that the callosity was an "excrescence" (a commonly used term in the late 19th century) from BARNACLES found on the head, abrasions from rubbing the head, or that they were irritations from WHALE LICE. A number of whalers and scientists have noted the coincident occurrence between hair clusters on the whale and callosities, and Payne *et al.* (1983) noted that callosities also occur in the same locations as facial hair in humans, e.g., above the eyes, between the nostrils (blowholes) and upper lip, and on the skin covering the mandible. In fact, there are several locations where callosities are found and hairs are not present, and vice versa (e.g., small callosities are often also found immediately posterior to the nostrils). However, large callosities have at least a scattering of hairs over their surface, and smaller ones often have a single hair near the center of the callosity.

Callosities are a naturally occurring physical feature of the whale. They have been reported to be visible on both late-term (2.5 m) fetuses and newborn calves, although in some cases they may develop shortly after birth. In calves, the callosities are smooth and gray in color, but quickly acquire a pitted, jagged texture. It is thought that this may come from whale lice (*Cyamid* spp.), which, through eating a portion of the skin which comprises the callosity, create an area of lowered laminar flow in which they could adhere more easily to the whale. Certainly whale lice are widely present over the surface area of callosity tissue. To date, *Cyamus ovalus* and *C. gracilis* have been found on both northern and southern right whales. In addition, *C. erraticus* has also been reported from southern right whales. While the callosities maintain their gray color throughout life, they often appear white, yellow, or orange because of the coloration of the whale lice living there.

The function of callosities remains unknown. Male right whales have, on average, a greater portion of the surface area of their head covered by callosity tissue than females. These may be used by males in mating competition, and observations have been reported where males in mating groups deliberately ran the dorsal side of their heads along the backs of other males, with the recipient of the scrape reacting by "twisting and writhing" (Payne and Dorsey, 1983). Given the sensitivity of cetacean skin, it would be likely that contact from the callosity of another animal would be painful. While use in competition may account for the greater amount of callosity tissue in males, it does not explain why callosities are also present in females.

In the past 30 years callosities have received increased attention from cetologists photo-identifying individual right whales, as the shape and area of the callosities vary between individuals. In the southern right whale, individual identification is facilitated by a configuration where the bonnet covers only the front portion of the rostrum, and there are several additional "rostral islands" between the bonnet and the blowholes. This is referred to as a "broken" callosity. Researchers can then use the shape of the bonnet in addition to the number, location, and shape of the rostral islands to identify individuals. In the North Atlantic right whale, however, the bonnet can cover the entire area between the tip of the rostrum and the blowholes, referred to as a "continuous" callosity (found rarely, but occasionally, in southern right whales). Identification is further confounded because whale lice on and around the callosities are mobile, significantly masking the true edge of the callosity. Callosity edges in the same animal can then appear different in several sightings of the same individual. By using additional distinctive features, including the three-dimensional configuration of the callosities, additional scars or marks, and crenulations on the lower lip, North Atlantic researchers have still been able to reliably identify each individual. Photographic catalogs of identified right whales, primarily of their callosity patterns, have been published for the North Atlantic (by the New England Aquarium, Boston, MA) and Peninsula Valdez, Argentina (by the Whale Conservation Institute, Lincoln, MA).

Additional collections of photographs of individual right whales based on callosities and other natural markings exist in various institutions around the world.

SeaWorld Inc., San Antonio, Texas

I. Marine Mammals in Captivity

Animals have been held in CAPTIVITY in one form or another for hundreds, if not thousands, of years. Private collections turned into "public" collections. A private animal collection at Schloss Schönbrunn, Vienna, Austria, was opened to the public in 1765 and is considered to be one of the first modern zoos.

The first marine mammals to be held in captivity may have been polar bears (*Ursus maritimus*) and various pinnipeds. Reeves and Mead (1999) provide an excellent overview of marine mammals in captivity. Harbor porpoises (*Phocoena phocoena*) may have been held as early as the 1400s, polar bears since about 1060, and walruses (*Odobenus rosmarus*) since 1608. As with terrestrial animals, marine mammals were held in private collections.

However, most pinnipeds and some sirenians were not held in captivity until the late 1800s and early 1900s. Being considerably more difficult to capture, transport, and maintain, cetaceans, with few exceptions, have only been held in captivity since the mid-1900s. According to Reeves and Mead (1999), 4 species of sirenians, 33 pinnipeds, 51 cetaceans, the polar bear, and the sea otter (*Enhydra lutris*) have been held in captivity. Of these, 2 species of sirenians, 15 cetaceans, 22 pinnipeds, the polar bear, and the sea otter have reproduced in captivity. Among these, however, only a few species, such as the polar bear, California sea lion (*Zalophus californianus*), harbor seal (*Phoca vitulina*), bottlenose dolphin (*Tursiops truncatus*), and killer whale (*Orcinus orca*), have enough numbers and have been reproductively managed with enough production to be considered part of a successful captive breeding program.

Successful captive breeding of any marine mammal requires more than just holding the animals in a pool. Not only does it, as a bare minimum, require sexually mature males and females, but also adequate housing, nutrition, and consideration of the animals' social needs. It becomes obvious when analyzing the history of successful births and survivorship of these species in captivity that early animal managers had little thought or, in some cases, knowledge of the requirements necessary for the development of successful breeding programs. Contrast past records of breeding and survivorship with recent trends beginning in the mid-1980s where captive breeding successes have equaled or, in some cases, surpassed the best scientific estimates of wild population breeding and survivorship and one can see just how far the captive marine mammal community has evolved. Detailed censuses of captive marine mammals in North America (Andrews *et al.*, 1997; Asper *et al.*, 1990) have shown the increasing numbers of captive-bred marine mammals, particularly California sea lions, harbor seals, and bottlenose dolphins. In 1995, 70% of the California sea lions, 56% of the harbor seals, and 43% of the bottlenose dolphins on display in North American facilities were captive-born. This compares with 3, 4, and 6%, respectively, in 1975.

II. Why Breed Marine Mammals in Captivity?

A. Legal Necessity

In the "early days," when animals were just being displayed as "curiosities," it was easier to collect replacements when animals died. In most countries today this is simply not possible. Despite only a few species of marine mammals being threatened or endangered, they and their habitats are protected by a myriad of national and international laws and regulations. While a number of countries are considering regulation of the minimum conditions (e.g., pool size and volume, water quality, food quality and handling, medical care) under which marine mammals may be held in zoos, marine parks, or research facilities, apparently only the United States has such regulations in place. Even though the natural habitat of most marine mammals cannot be duplicated in captivity, the trend is toward larger, more complex, habitat-oriented displays and exhibits. Together, the various laws and regulations have reduced the collection of wild marine mammals and have eliminated smaller facilities that did not have the financial resources to adequately provide for their animals as required by law.

For obvious reasons, the just-mentioned laws and regulations favor captive breeding programs. A successful captive breeding program eliminates costly field expeditions and ani-

mal transports. Wild-caught animals are often of uncertain health status and may require routine treatments such as deworming.

B. Maintaining/Enlarging a Captive Population

A successful captive breeding program can provide animals for other institutions with adequate holding facilities but without the financial resources to maintain a breeding colony or (if even possible) to collect wild animals. Captive-born animals have a known medical history and, to some extent, are imprinted on their keepers. Captive breeding programs have, out of necessity, reduced the impact on wild populations of marine mammals. Professional organizations such as the American Zoo and Aquarium Association (AZA) have established studbooks and other programs to assist with the management of captive animal breeding colonies. For example, studbooks track individual animals from birth to death and their reproductive histories. Computer programs are used to pair animals to optimize genetic diversity. In the United States, formal studbooks exist for the beluga whale (*Delphinapterus leucas*), common bottlenose dolphin, West Indian manatee (*Trichechus manatus latirostris*), gray seal (*Halichoerus grypus*), harbor seal, northern fur seal (*Callorhinus ursinus*), and polar bear and several others are under development. Similar studbooks are in place on other continents. The AZA also hosts a Marine Mammal Taxon Advisory Group whose function is to promote managed captive breeding of marine mammals.

C. A Breeding Program as a Scientific Resource

A successful captive breeding program is a unique scientific resource in that it allows one to document, in great detail, various aspects of reproductive behavior, reproductive physiology, and the subsequent birth, growth, and development of the offspring. This is particularly valuable for cetaceans, which are typically difficult to study in great detail in their natural habitat due to various environmental factors and the fact that they spend most of their lives underwater. It is, however, most important to recognize that studies on captive marine mammals, even in the best breeding colonies, do not and cannot replace field studies. Both types of studies (i.e., laboratory and field) are necessary to fully describe the biology of a species.

Routine components of a proper animal husbandry program include regular physical exams, collection of blood, urine, and fecal samples, body measurements, and body weights. These samples and data are virtually impossible to collect from wild marine mammals. Consider, for example, what it would take to get a daily urine sample from a wild bottlenose dolphin or killer whale! Captive animals are easily conditioned to provide urine samples and to station for blood sampling, body measurements, and so on. Figures 1, 2, and 3 illustrate the kinds of observations that can be made and the kinds of data that can be gathered.

D. A Breeding Program as a Conservation Resource

A successful captive breeding program may provide the physical and human resources necessary to save some species of marine mammals in imminent danger of extinction (see Ralls and Meadows, 2000). These resources may allow us to maintain a viable gene pool until the habitat can be restored or other reasons for endangerment are eliminated. While such an undertaking is certainly honorable and the right thing to do, the magnitude of the job should not be underestimated and there are, at the present time, obvious limits based in good measure on the sheer size of the animals. For example, the population of right whales (*Eubalaena glacialis*) in the western North Atlantic Ocean is about 350 animals and may be decreasing due to human activities. These animals may reach lengths of 18 m and weights on the order of 20 tons. No facility in existence today (or likely to be in the foreseeable future) could hold a breeding group of right whales. However, threatened or endangered marine mammals such as the Hawaiian and Mediterranean monk seals (*Monachus schauinslandi* and *M. monachus*, respectively) and the river dolphins (families Platanistidae, Iniidae, Pontoporiidae, and Lipotidae) could be maintained in viable captive breeding colonies.

Figure 1 *Birth of a killer whale at SeaWorld Florida.*

III. Assisted Reproductive Technologies

The domestic animal industry (cattle, hogs, horses) long ago realized that it is much more efficient to move genetic material (e.g., semen) to different facilities than it is to move the whole animal. Methodologies for semen collection, preservation, and transportation, along with methods for artificial insemination (AI), induction of ovulation, and even embryo transplantation, were developed and are in widespread use worldwide today. Some of the techniques have been applied successfully to endangered animals. It seems a logical next step in the captive breeding of marine mammals to apply some of these techniques.

The development of AI, the most common assisted reproductive technology (ART), for commercial use began in the 1950s. The successful application of AI and other ART to domestic species and humans was in part because of their accessibility for research into their reproductive mechanism or reproductive physiology. Of critical importance for the successful application of ART in any species is the determination of how reproductive hormones and behavior relate to ovulation (Sorensen, 1979).

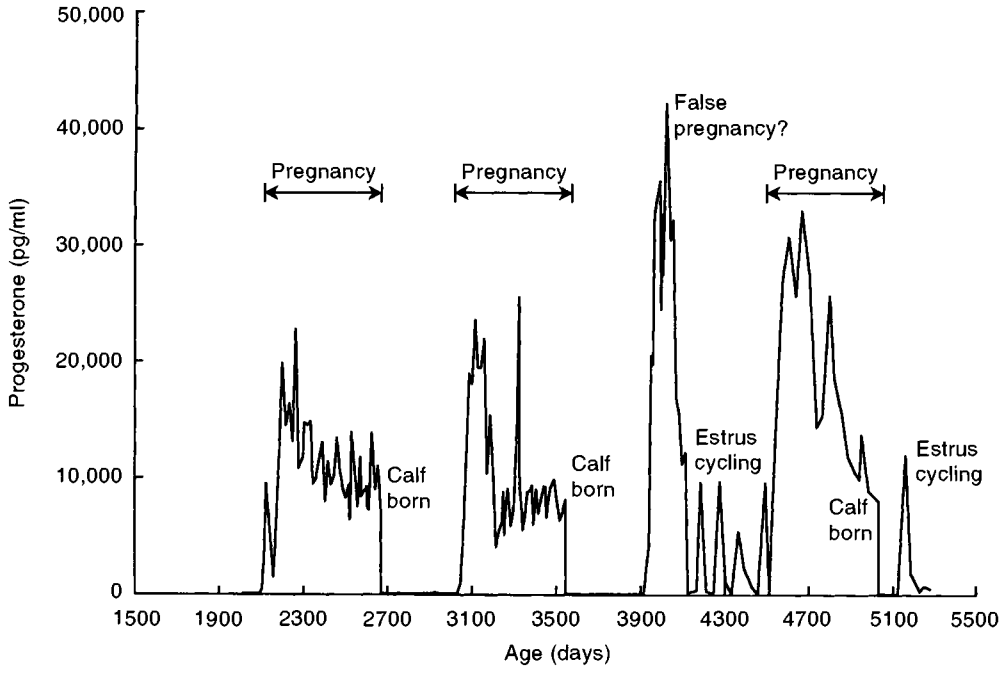

Figure 2 *Serum progesterone of killer whale from birth through sexual maturity and calving and showing estrous cycling and pregnancies. Progesterone levels were "zero" until after 1900 days of age.*

Once ART were developed in domestic species, it was naively believed that they could easily be transferred to exotic species. However, relatively little success was realized with exotic animals until the late 1970s when an endocrinological breakthrough occurred. This breakthrough was the ability to analyze reproductive hormones in urine. This technology was successfully used to characterize the endocrinological events in a wide range of exotic species, including for the first time marine mammals, or the killer whale (Walker *et al.*, 1988). The killer whale has proven to be easily trained to provide urine samples for endocrinologic evaluation and, as such, has provided detailed insight into its reproductive function. Despite this early success, no further attempts at applying ART to this species have occurred until recently.

The most common marine animal in captivity, the bottlenose dolphin, has been the subject of a few intensive investigations into its reproductive function. These investigations include the development of semen cryopreservation techniques and attempts at inducing or regulating ovulation (Robeck *et al.*, 1994). Despite the information obtained, detailed information concerning endocrinological events as they relate to ovulation has not been obtained and, as a result, AI was never successfully developed.

What then are the needs for the development and application of ART to marine mammals? The most obvious ART that should be developed and the one that is most likely to have an immediate impact on the genetic management of captive marine mammals is artificial insemination. Once developed, AI would provide an immediate mechanism for marine mammal managers to increase the genetic fitness of their respective populations without having to rely on the transportation of animals between facilities. Wild animal population studies have shown that dolphins develop strong social ties to other animals and that these bonds can be maintained for the life of the animals. To what extent these bonds are important for the health of these animals can only be speculated, but it seems prudent for managers who have groups of compatible animals to hesitate changing the social structure by either removing or introducing more conspecifics. Further, bringing animals from other locations may expose the new population of animals to bacterial or viral organisms, which they have no natural resistance against.

What steps are required to develop AI? As stated earlier, one must first be able to monitor, by visualization (surgically or through sonography) or endocrine methods, ovarian activity. Endocrine markers can predict ovulation only after they have been related to actual visualization of the ovarian activity. The ability to consistently find and observe ovarian activity transabdominally with ultrasonography was first demonstrated in the bottlenose dolphin by Brook (1997). This simple technique has since been successfully utilized to consistently locate ovaries in many other captive marine mammals, including the killer whale, the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), and the false killer whale (*Pseudorca crassidens*) (Fig. 4). This ability then opens the door, with frequent body fluid sampling (most likely urine) for the identification of an effective endocrine marker of ovulation. Once ovulation can be predicted, then the ability to collect semen is an obvious requirement. Currently, only a few marine mammal species have been successfully collected on a regular basis. Early on during the process of trying to collect semen from these animals, electroejaculation was utilized with limited success. However, stress caused to the animals during collection and inconsistent results

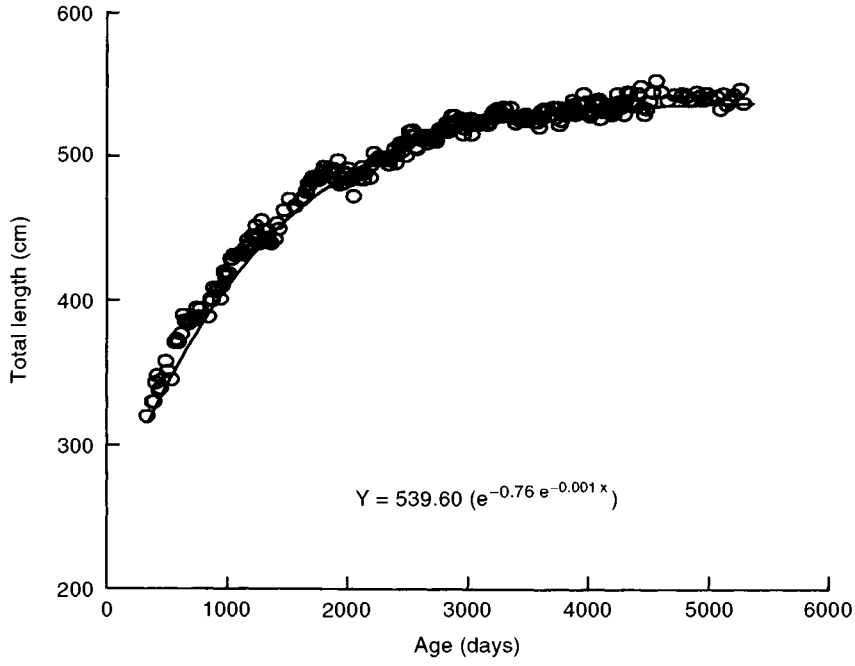

Figure 3 *Killer whale growth (length) curve as an example of data that can be gathered from captive-bred animals.*

made this method unsuitable. Also, it was determined that bottlenose dolphins, animals that seem to have consistently elevated libidos, were relatively easily trained to provide semen via manual stimulation. Since the success with bottlenose dolphins, a killer whale and two Pacific white-sided dolphins have been trained to provide semen on a regular basis. Obviously, for AI to be widespread, all genetically valuable males should be trained to provide semen.

Once the semen has been collected, it must be stored temporarily for immediate use or permanently by cryopreservation.

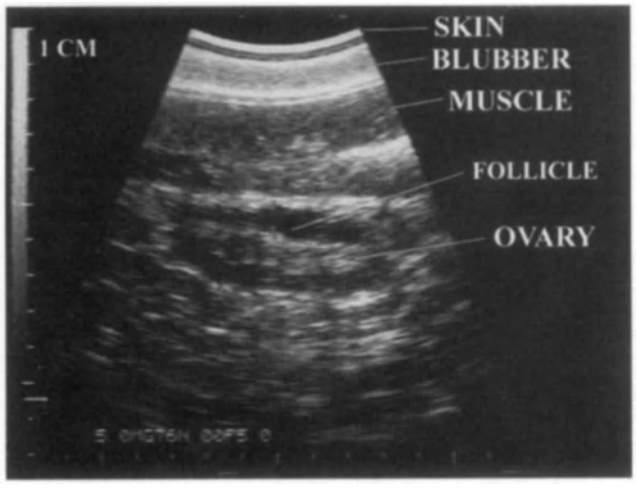

Figure 4 *Sonographic image of an ovary of a Pacific white-sided dolphin showing a follicle.*

Semen cryopreservation has been successfully accomplished by different methods (straws, pellets, or cryovials) in all of the species for which semen has been obtained. Although cryopreserved semen provides a long-term supply of genetic material from a particular animal and is the only method currently available to store semen for long (greater than a few days) periods of time, when used with AI it results in reduced conception rates. The reduced conception is believed to be the result of damage that occurs to the semen during the freezing process. As a general rule, cryopreserved semen must be deposited in the uterus and at close proximity to ovulation. Fresh cooled semen, having better motility and viability, can be placed with less accuracy, generally in the cervix, and with a greater time interval prior to ovulation. Thus, when attempting to develop AI, first attempts are generally made using fresh cooled semen.

As must be obvious from this discussion, a thorough understanding of female reproductive tract anatomy is essential to developing effective catheterization techniques for semen deposition. Despite the close phylogenetic relationship between captive delphinids, significant variation exists in their reproductive tract morphology. For example, bottlenose dolphins, being the best documented of captive species, have a pseudocervical vaginal fold or flap that must be traversed before encountering the true cervix. The space formed by the fornix surrounding the true cervix and the distance from the pseudocervical flap to the distal opening or external os of the cervix has been identified as the spermathecal recess. Deposition of fresh semen into this space (as opposed to vaginal placement) appears mandatory for a successful procedure. However, successful use of frozen semen for AI will probably require navigation through the pseudo and true cervix for uterine deposition. Knowledge of the

anatomy of the bottlenose dolphin would do little to help placement of semen into the closely related member of the delphinid family, the Pacific white-sided dolphin. This species has a series of three annular folds that present anatomical barriers to the placement of semen. Finally, another member of the delphinid family, the killer whale, has a completely different arrangement consisting of two longitudinal ridged cervices in series.

Once the semen has been deposited and ovulation has occurred, how do you determine if you have had success? With the application of ultrasound for pregnancy detection, more and more marine mammal practitioners have become aware of the fact that all species of captive delphinids can exhibit variable periods of false pregnancies. These periods of elevated progesterone are currently endocrinologically indistinguishable from pregnancy. Thus, pregnancy can only be confirmed with the use of ultrasound.

Once AI has been developed successfully, other ART may begin to have effects in captive and potentially wild animal populations. One of the most intriguing developments in ART is the continued improvement of semen sexing techniques. Currently, semen sexing has been used to influence the sex ratio by close to 90% in either direction. However, the semen is damaged in the process, resulting in a significant reduction in viability. This translates into a requirement for interuterine or oviduct semen deposition. Unless or until the technique can be improved, semen deposition might be possible with laparoscopic techniques currently and tenuously being applied to cetaceans.

IV. Challenges for the Future

If self-sustaining populations are to be developed, then all reproductively capable animals must contribute to the gene pool. Producing viable offspring is the primary goal of any captive breeding program, but it must be managed to avoid overpopulation of the facility and to prevent or minimize inbreeding. This may require separate facilities for adult males, preparturient females, and females with new offspring. Breeding may be regulated simply by separating the sexes or by neutering (physically or chemically) both males and females.

Currently, many populations of marine mammal are kept in small groups or same-sex groups. Therefore, a large portion of reproductively mature animals within these groups are not reproducing. These animals are functionally excluded from contributing to the collective captive gene pool. Therefore, valuable financial resources and pool space are being used for a minority of the available genetic lines. This inefficient use of animal resources must be corrected before long-term population stability can be achieved. Judicious use of contraception and development of AI would help managers reach maximum utilization levels. However, if the maximum utilization of genetic resources does not result in a predictable stable population, then genetic infusions from wild stocks will be necessary. ART may provide another answer to this future dilemma if semen and possible oocytes can be collected from wild animals that are incidentally or purposely killed in fisheries or other commercial activities. These gametes can be placed into suitable captive animal recipients for reproductive purposes. As an example, researchers in Japan have created embryos by IVF (*in vitro* fertilization) from gametes collected postmortem from fin whales. Unfortunately, suitable captive recipients for this species do not exist. As an alternative to the ART solution or until ART were perfected, mangers could "borrow" adult males from wild populations for 1–2 years for breeding purposes and then return them. This, of course, involves considerable expense and there is no guarantee that any given animal would breed successfully.

Captivity

PETER CORKERON
James Cook University, Townsville, Queensland, Australia

I. The Debate

The debate over the ethics of marine mammals in captivity is essentially about cetaceans (whales, dolphins, and porpoises) because other marine mammals such as seals and sea lions do not inspire the same passion as whales and dol-

phins. The allure of cetaceans is so powerful that they are now a symbol of the animal liberation movement. This ongoing debate over whether cetaceans should be kept in captivity is relatively recent in contrast to the history of human/marine mammal interactions. For centuries, human interest in marine mammals was based on the commercial value of killing seals and whales for oil, meat, and hides. The larger animals represented greater profit, so small marine mammals such as dolphins were mostly considered to be pests to fishermen. Occasional reports of marine mammals being kept in captivity as curiosities are scattered throughout history: polar bears were kept by Scandinavian rulers prior to the Middle Ages; a killer whale (*Orcinus orca*) that had been live stranded was kept and used for sport by Roman guards during the first century A.D.; and seals were kept in menageries by the 18th century. In the mid-1800s, P.T. Barnum displayed belugas (*Delphinapterus leucas*) and bottlenose dolphins (*Tursiops truncatus*) in his New York museum for a short time, and in the late 1800s, the Brighton Aquarium in England displayed harbor porpoises (*Phocoena phocoena*) for several months. A new era of modern marine mammal exhibits began in the late 1930s, when Marine Studios at Marineland opened in Florida.

At first, marine mammal facilities were quite popular. During the 1950s, 1960s, and 1970s, the number of aquaria and zoological parks displaying marine mammals increased rapidly to meet public demand, especially in Europe, North America, and Australasia. Simultaneously, technology and methods for the capture, transport, and maintenance of marine mammals improved with increasing knowledge and experience. Scientists took advantage of the availability of the animals at these facilities to conduct groundbreaking research on dolphin acoustics, human/dolphin communication, dolphin brain function, hearing and echolocation, and behavior. Soon the public became more familiar with dolphins through shows at aquaria and from a popular TV show called "Flipper" in which a dolphin was portrayed as an intelligent family pet. With this heightened awareness, the public began to understand that dolphins were not large fish, but intelligent and friendly marine mammals. However, the image transformation inspired by animals at marine mammal facilities would soon become a public relations nightmare for the industry that first made these animals popular.

II. The Impact

The boom in aquaria and oceanaria experienced through the 1970s came to a near halt during the mid-1980s due to the growing debate over keeping cetaceans in human care. Pressure and sometimes inaccurate information from the animal rights lobby forced the closure of some existing facilities and prevented some new facilities from being opened. While the 1990s saw a decline in the number of facilities keeping cetaceans in Australia and some parts of Europe, there was an increase in the establishment of new marine mammal facilities in other parts of the world such as Asia and South America where there was little to no animal activist movement.

Compared with most terrestrial mammals, marine mammals are expensive and difficult to maintain in captivity. They require a good deal of logistical support, such as high-quality food sources, specialized medical care, large enclosures, and expensive water-quality maintenance systems. Cetaceans and sirenians (manatees and dugongs), being wholly aquatic, present greater logistic difficulties than other marine mammals. A few species predominate at these facilities because they have shown greater success in human care. Of these animals, those most often used in public performances include bottlenose dolphins, belugas or killer whales, and California sea lions (*Zalophus californianus*), whereas phocids such as harbor seals (*Phoca vitulina*), polar bears (*Ursus maritimus*), sea otters (*Enhydra lutris*), and sirenians are more typically maintained in exhibits. While a few facilities, especially those in developing countries, have fallen short of being able to maintain the highest standards of operation, most modern facilities successfully meet these challenges. However, there is word that many oceanaria are being planned to be built outside the control of effective regulations in the coming years—more than 13 in China alone. There is concern that many capture and holding facilities that are effectively unregulated and pretty much undercover are being built in the Philippines, Indonesia, and other places to supply the resulting demand for animals. It is on these types of facilities that we should focus.

Even if for only short periods of time, almost every species of marine mammal other than most of the great whales have been maintained at a marine mammal facility at some point. Animals are kept captive for different reasons: display in zoos and aquaria; military work; scientific research; and temporary maintenance for rehabilitation for injured or sick animals, although these categories are not mutually exclusive. Size and temperament are generally the limiting factors in keeping some marine mammal species for long periods of time. Most are kept in zoos or aquaria; some live in open ocean enclosures. However, many commercial facilities with cetaceans are not traditional zoological gardens but marine parks where there tends to be more emphasis on performances by animals. (Temporary restraint from a few minutes to hours for research purposes is not considered as captivity here.)

III. Regulations for Collection, Care, and Maintenance

A. International Regulations

In general, regulations dealing with marine mammals in human care cover collection, care and maintenance of animals, and movements of animals between countries. The extent to which existing laws are administered and enforced varies internationally. The INTERNATIONAL WHALING COMMISSION (IWC) is the central international instrument for the protection of whales; however, its effectiveness has been hotly debated. Both the prowhaling and the anti-whaling factions try to load the IWC to influence the outcome of voting, and qualifying animal activist groups are allowed to attend and lobby at annual IWC meetings.

The major instrument regulating the international trade in captive cetaceans is the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Most cetaceans are listed in CITES Appendix II, which provides a means of regulating and monitoring trade for species not threatened with extinction but which are vulnerable to overuse. This

listing allows for international trade with properly issued permits. The remaining species are listed in Appendix I of CITES indicating that they are either currently threatened with extinction or may be affected by trade. The smaller species/subspecies include the baiji or Chinese river dolphin (*Lipotes vexillifer*), Ganges river dolphin (*Platanista gangetica gangetica*), Indus River dolphin (*Platanista g. minor*), tucuxi (*Sotalia fluviatilis*), Indo-Pacific humpbacked dolphin (*Sousa chinensis*), Atlantic humpback dolphin (*Sousa teuszii*), finless porpoise (*Neophocaena phocaenoides*), and the vaquita (*Phocoena sinus*). With regard to marine animals, the CITES convention includes the requirement that suitable housing and care are available and, for Appendix I-listed animals, that they are not to be used for "primarily commercial purposes." Most nations keeping marine mammals in captivity are signatories to CITES. International agreements can regulate capture, but most trade in wild-caught animals now comes from a few nations with few or no regulations on capture, or with regulations that are ignored. International pressure on some nations (e.g., Iceland in 1989) has resulted in the closure of their capture industry.

In the United States, Congress passed unprecedented regulatory legislation in 1972 to bring under its protection all marine mammals within the borders of its jurisdiction. The legislation was called the Marine Mammal Protection Act (MMPA). Its intent was to protect marine mammals from human actions (predominantly fishing) that lead to extinction. However, the MMPA specifically authorized the collection of animals from the wild for scientific research and public display and education. Depending on the species involved, the collection of marine mammals is governed by a permit process administered by either the National Marine Fisheries Service or the Fish and Wildlife Service. The standards for the maintenance of marine mammals in research or public display facilities are established and monitored by the Animal and Plant Health Inspection Service under the U.S. Animal Welfare Act, and all marine mammal-related activities are monitored by the presidentially appointed Marine Mammal Commission. While collection is still permitted in the United States, there have not been any bottlenose dolphins collected for U.S. facilities since 1989 due to a self-imposed moratorium observed by the members of the Alliance of Marine Mammal Parks and Aquariums on the collection of bottlenose dolphins (*Tursiops truncatus*) from the Gulf of Mexico. In addition, there is a changing trend regarding holding and breeding bottlenose dolphins in North America. In 1976, 94% of the population of bottlenose dolphins were wild caught while 6% were captive born. From 1989 to 1996, no wild-caught animals were added to the captive population; all additions were a result of successful breeding programs. In 1996, 44% of bottlenose dolphins in North American facilities were captive born.

Several countries have legislated regulations or guidelines to govern the collection and keeping of marine mammals since 1972. New Zealand passed a MMPA in 1978, and in 1980, Australia passed the Whale Protection Act of Australia. In Australia, the state of Victoria banned the issuance of permits for keeping cetaceans for display or collecting them for export. Here, legislation does not absolutely preclude issuing a permit for the capture of free-ranging animals; however, general government policy, the legal requirement for public comment on an application for capture, and the need for signed Ministerial approval for capture permits mean that it is highly unlikely that permits will be issued. Canada developed guidelines that forbid the capture of killer whales and gives priority to Canadian institutions in considering permits for the capture of belugas. Legislation can interact with government policy and public opinion to affect the capture industry. For example, guidelines established in some countries such as the United Kingdom do not specifically prohibit the collection and display of marine mammals, but they effectively force closure of some facilities by making it almost impossible for facilities to meet building codes and specifications. This is perhaps epitomized by British cetacean display facilities, the last of which closed in 1991. Movements of cetaceans into and within the European Union are regulated under EU wildlife trade regulation, established to fulfill EU member nations responsibilities under CITES. Trade in animals listed under Annex A of this regulation (including all cetaceans) is permitted for "research or education aimed at the preservation or conservation of the species," breeding for conservation, and biomedical research (the latter is not relevant for cetaceans), but not simply for commercial use. Other places such as the Republic of South Africa still permit the capture and display of cetaceans.

In Japan, multispecies drive fisheries that combine capturing animals alive for aquaria and dead for food have, in some drives, exceeded their allowed quota of animals. United States legislation requires that captures be conducted humanely, effectively denying animals from the Japanese fishery to institutions in the United States.

Regional conservation agreements have also been developed. Several nations that are signatories to the Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas (ASCOBANS) are mandated to take part in conservation and research measures. Such measures include preventing the release of potentially harmful substances into the environment, developing fishing gear to reduce bycatch, and reducing the impact of other potentially harmful human activities. They are obliged to prohibit intentional killing of small cetaceans and to release immediately any healthy small cetaceans incidentally caught.

B. Care and Maintenance

The first published accounts of the behavior of captive cetaceans were provided by Charles Townsend in the early 1900s when he was the director of the New York Aquarium. His observations of a group of bottlenose dolphins described their social behavior and some sensory capabilities. Townsend understood the importance of developing health care and water treatment regimes to promote long-term survival. Requirements for the care and maintenance of marine mammals can vary dramatically between countries and between jurisdictions within a country. These requirements include regulations regarding pool dimensions and construction materials; food quality and feeding schedules; water quality; air quality; veterinary care; and educational message. There are countries (e.g., the United States) where the agency responsible for overseeing capture and international transport is different from that responsible for care and maintenance. United States regulations require that facilities importing animals from the United States

must meet U.S standards of care and maintenance. These standards should become the *de facto* standards anywhere importing animals from the United States.

A core aspect of the argument against maintaining captive cetaceans is that it is impossible to provide an adequate environment for cetaceans in captivity. The basic reasons put forward for this are that pools can never be of adequate size; that regardless of size, pool construction is inappropriate; and that it is impossible to keep animals in suitable social groups. Even the larger commercial facilities, for example, one that includes a complex of four linked (sand-bottomed, rock-lined) pools of 30,000,000 liters, with a maximum depth of 7.5 m, holding 12 bottlenose dolphins, are considered inadequate to some. Facilities differ greatly in their resources, and so the quality of their environment.

IV. Issues

A. Experiencing Captive Marine Mammals

Zoos and aquariums in North America alone are visited by over a hundred million people each year. A Roper Poll titled "Public Attitudes Toward Aquariums, Animal Theme Parks, and Zoos" taken in the United States in 1992 and again in 1995 revealed that more Americans visit zoos and aquariums in the course of a year than the total of those that attend all professional sporting events. The assumption is that people, having experienced living marine mammals in close proximity, will be more likely to develop (or enhance) their marine conservation ethic. It is clear that public support for marine mammal conservation increased substantially in the latter half of the 20th century. In many parts of the country, images of dolphins are stenciled near storm drains with a reminder that "I live downstream." The extent to which commercial aquaria contributed to this change is questioned by some of those calling for closures, as is the extent to which this remains true today. The public view of killer whales changed radically at the same time as they appeared in captivity, supporting the "captive animals as ambassadors" argument. Unfortunately, there is little current research (by either side) on the extent to which visiting aquaria affects peoples' conservation ethic.

Some anticaptivity proponents suggest that it would be better if people ventured out to the ocean to see cetaceans through commercial whale watching. Whether most people who visit aquaria would go whale watching if the aquaria did not exist is unknown. However, whale watching has become an industry in itself. In 1989, the whale-watching industry off the Atlantic seaboard of the United States alone brought in 23 million dollars. Along with the increasing popularity of these trips, there is also an increasing number of reports of inappropriate behavior of whale watchers and a growing need for regulation. At marine mammal facilities, it is much easier to monitor and guard against inappropriate human behavior than it is out in the open ocean. Additionally, the environmental impact of an extra several million people a year going whale watching has not been estimated, but could be substantial. Most opponents of captivity are in favor of whale watching. However, if viewing captive cetaceans enhances an inappropriate worldview (as opponents of captive cetaceans contend), can large-scale commercial whale watching do the same? The argument that equal or greater conservation benefit could be gained through multimedia presentations remains untested.

Most of this discourse is set in a Western context. Public awareness of marine mammals in most other nations is less developed than it is in the West. It may be that zoos and aquaria can make a significant contribution in these countries.

B. Scientific Value of Captive Marine Mammals

The value of studies conducted with captive marine mammals has also come under scrutiny. However, before field studies of living cetaceans burgeoned (after the late 1970s), captive animals were the major means by which scientists collected data on biology and behavior. Some phenomenon such as echolocation may still have been unknown if not for captive animals. Still today, the echolocation capabilities of most dolphin species remain unknown, and controlled experiments with captive animals are the only way by which we are likely to determine them. Because there are so many other questions that have not or cannot be answered using wild marine mammals, captive animals are still the primary source of data for several fields such as comparative psychology, cognition, physiology, acoustics, toxicology, immunology, reproduction, and medicine. The remarkable sensing abilities of dolphins and their perceived intelligence are, paradoxically, two of the arguments used against their maintenance in captivity.

Most of the opposition to the scientific value of captive marine mammals appears to disregard the value of experiments in biological research generally and of the capacity for "pure" research" to alter peoples' outlook on conservation issues. Interplay remains between work on captive and free-ranging animals. Recent experiments with captive dolphins have provided new insights into the role of bottlenose dolphins' whistle repertoires, allowing development of better focused studies of free-ranging animals. The role of animal language experiments generally in providing direct conservation benefit through redefining our view of humanity's place in the natural world is (like the conservation value of captive facilities or whale watching) difficult to estimate, but may be substantial.

More recently, open ocean training has made it possible to use captive animals to conduct some studies in the wild. Incorporating both wild and captive marine mammals is also gaining favor in recent years. In a report to the Marine Mammal Commission, international experts advised the use of "model [marine mammal] species that have been well studied and are readily available in captivity . . . [to] provide basic insight about the variability in and relationships between contaminants and basic health and physiological processes, biomarkers, reproduction, and survival. Such insight could prove critical to interpretation of contaminant impacts on wild marine mammal populations" (MMC, 1999). Ken Norris, a pioneer in the field of marine mammalogy—both captive and wild—contended that "Both kinds of study are crucial, really" (Norris, 1984).

C. Captive Breeding for Conservation

While some populations of wild marine mammals have been reduced or depleted as a result of high mortality, populations

of marine mammals in zoos, aquariums, and research facilities have increased as a result of successful breeding programs. Since the first birth of a bottlenose dolphin in an exhibit facility at Marine Studios in 1947, breeding programs have become more and more successful, increasing the number of animals at these facilities and providing animals to other marine mammal facilities. By 1996, 44% of bottlenose dolphins on exhibit in North America were a result of successful breeding programs. The success of bottlenose dolphin breeding programs is probably due in large part to the fact that more of these animals are available for breeding programs and more is known about the physiology and husbandry of this species than any other cetacean. Although there is still a paucity of data from free-ranging animals, it has also been shown that once acclimated, bottlenose dolphins in well-maintained facilities have survival rates comparable to those in the only free-ranging population that has been studied over a long time.

Breeding animals in zoological facilities has a role in the conservation of some endangered species. It has been suggested that such *ex situ* conservation supports the existence of aquaria. However, the development of such programs should not be an excuse to ignore our responsibility to implement conservation strategies to protect wild populations and their habitat.

There are major difficulties confronting those wishing to develop *ex situ* breeding programs for marine mammals, but the advances in reproductive technologies and the establishment of population management protocols will help overcome those challenges. After all, the successful 1999 birth of a giant panda at the San Diego Zoo in California was a result of artificial insemination. Even though the marine mammal species most commonly maintained in captivity are not endangered, knowledge and technologies developed with these animals can be applied to those that are at greater risk. While permits for the capture or importation of such animals may be difficult to obtain in some countries, demonstrating success with captive breeding programs may help overcome these difficulties.

Opponents to oceanariums worry that taking animals from the wild will threaten wild populations. To prevent this, no captures should be allowed unless stock structure is well understood and the takes can be shown to be sustainable. While in the 1990s, only seven cetaceans, three Pacific white-sided dolphins (*Lagenorhynchus obliquidens*) and four belugas, were collected from North American waters for public display and research in U.S. facilities, marine mammals in the wild are dying in large numbers. Gaskin (1982) warns, "If there is one lesson which modern ecological science has for us, it is that if one protects the habitat, then animal populations can show remarkable resilience in the face of other external pressures, even those such as intensive predation by man."

D. Rehabilitation

At times, free-ranging marine mammals that are ill, injured, or have suffered some misadventure require rehabilitation. In most cases, these are species that are not at risk of extinction, and so the issue is one of animal welfare, not conservation. An exception to this is the efforts made to rehabilitate Florida manatees (*Trichechus manatus latirostris*) where the rehabilitation and subsequent return to the wild of each individual manatee have demonstrable conservation value. Whether or not a species is endangered, with each rescue comes the possibility of acquiring new knowledge that will benefit all marine mammal species whether they be endangered or otherwise. Generally, zoos and aquaria provide needed support to rescue operations whether they be expertise, facilities, medicine, or food, and their role in rehabilitation has been rather significant.

E. Release

Perhaps due to the decrease in collecting animals from the wild, attention has now focused more on releasing those already in facilities. Several attempts have been made to release captive dolphins back to the wild. Following the closure of "Atlantis" in Perth, Western Australia, nine bottlenose dolphins were released in 1992. Animals were radiotracked after a gradual release back to the waters from which some had been caught 11 years previously (three were captive born). After a few weeks, three animals in very poor condition were returned to a sea pen, but the fate of most was unknown due to the failure of the radio tags. The animals that were recovered died of poisoning in late 1999.

The release program for Keiko, the killer whale that starred in the movie "Free Willy," encapsulates some of the issues regarding captivity. Caught as a calf by the Icelandic capture industry, he was imported to Canada and then to Mexico where he was held in an inadequate pool with no other members of his own species. Activists organized his importation to another captive facility in the United States where his condition improved before he was moved to Iceland for a planned release. At this writing, he is in a sea pen and is being trained to catch prey prior to his release. However, the example of the "Atlantis" release demonstrated that it is insufficient to teach cetaceans to catch prey—they need to be able to locate and capture their prey using less energy to do so than the prey provides. Although there are plans for Keiko to be fitted with a satellite tag, recovering him from oceanic waters off Iceland will be logistically challenging if there are indications that his health is deteriorating after release.

Just as the conservation value of zoos and aquaria should be questioned, so too should the value of release projects. Do the perceived benefits of using an individual animal as an ambassador to send a message about captivity outweigh the costs (e.g., funding for conservation projects foregone, greenhouse gas emissions used in the release) and possible risks of the project?

Too little money is available already for needy conservation programs, particularly for projects in developing countries. Clearly, people are more likely to be stirred into supporting a grandiose cause such as the Keiko release rather than more mundane low-profile projects with no immediate emotive attraction. Paul Watson, founder of the Sea Shepherd Conservation Society, stated: "Free Keiko, free Lolita, free Corky, free Hondo. These are wonderful and appealing ideals, but not all captive cetaceans can or should be freed. Not all facilities holding marine animals are the enemy. And the huge sums raised to free a few individuals could be more positively directed toward ending the slaughter of hundreds of thousands of nameless whales, dolphins, and seals on the world's oceans. Never in the history of the animal protection movement have so many

given so much for so few and so many given so little for such large numbers" (from the June 1995 edition of Animal People).

F. Funding

Just as some zoos and aquaria contribute significant funds and resources to rescue and rehabilitation programs, some agencies keeping captive marine mammals also support research programs. For example, most of the research into cetaceans' acoustic faculties has been funded through the U.S. Office of Naval Research (ONR). There have been suggestions that the significant contribution made by the ONR to funding cetacean research affects the capacity of scientists to comment openly on issues relating to the U.S. Navy, although this is disputed. Some captive facilities and groups opposed to captivity either employ full-time research staff or provide funding for research projects. The relative funding provided by the two groups varies dramatically between countries, and there are places where one or both of the groups contribute significantly to research efforts.

V. Conclusion

The ongoing debate continues over whether marine mammals, particularly whales and dolphins, should be kept in captivity. Basically the debate between pro- and anticaptivity groups boils down to one thing: does the benefit achieved by holding animals in captivity outweigh the costs involved—both to the individual animal and to the population from which the animal came if all parties view "benefit" as contributing to the conservation of free-ranging marine mammals. Both sides believe their positions to be valid and rational. Neither side can afford to lose sight of the need to identify what is, in fact, better for the animal as opposed to what makes the participants in the debate feel satisfied.

In this debate, scientific data are often ignored because the debate has become based more on personal philosophy than on science, or the value of the science is debated. If nothing else, the debate brings attention to marine mammals, not only to those in facilities, but to those in the wild as well. The passing of the MMPA in the United States effectively curbed the mortality of dolphins in tuna nets from over 400,000 dolphins before the MMPA to less than 4000 in 1995. This is most likely a reflection of a new-found feeling of stewardship for marine mammals evoked by both marine parks housing them and activists trying to release them. However, the ongoing debate may be hurting them as well. Energy and money spent on a debate that may never be resolved may be more helpful to the animals if spent on improving the quality of the oceans. Klamer *et al.* (1991) suggested "If the increase in ocean PCB concentration continues, it may ultimately result in the extinction of fish-eating marine mammals." Ocean warming and other anthropogenic changes in the oceans are also potential threats along with the undermining of legislation such as the Endangered Species Act. Reynolds and colleagues (2000) ask whether the natural world today is a healthier place to live than the captive environment. They state that there is evidence that humans have damaged coastal and marine environments so much that the well-being of some wild dolphins may be in greater jeopardy than collection animals.

Carnivora

Ronald E. Heinrich
Ohio University, Athens

Living members of the mammalian order Carnivora exhibit an incredibly diverse array of ecological and behavioral adaptations. Among the 11 families and 275 or so extant species are animals that range in body size from 35 g (the least weasel) to 3700 kg (elephant seals) and that exhibit locomotor specializations for terrestrial speed (e.g., cheetah), arboreality (e.g., kinkajous), marine environments (e.g., pinnipeds), and almost everything in between. The origin of this diversity is traced to the miacoids, a paraphyletic assemblage of small and medium-bodied carnivorans that appear in the fossil

record 65 million years ago. Miacoids possess carnassial teeth, the key diagnostic character of the order, involving the transformation of the last upper premolar and first lower molar into blade-like structures (Fig. 1 top), that enable carnivorans to effectively shear through the skin and flesh of prey. Carnassials are retained by nearly all members of the order, although they are greatly modified in some taxa such as pinnipeds where they resemble the premolars positioned in front of them (Fig. 1 bottom), an adaptation for grasping fish and other aquatic prey.

I. Diversity and Origin of Basal Carnivorans

Miacoid fossils are restricted to the northern hemisphere with the most abundant materials, primarily fragmentary jaws and isolated teeth, coming from localities in western North America, western Europe, and China. Nearly all of the proposed miacoid taxa are referred to one of two extinct families—Viverravidae and Miacidae—the common ancestor of which probably lived in the latest Cretaceous. Viverravids appear several million years earlier than miacids but are dentally more derived than miacids in having only two molar teeth rather than the primitive carnivoran condition of three. Viverravids ranged in size from as little as 150 g to about 10 kg and their skeletal anatomy suggests that they were predominantly terrestrial, although there is little doubt that at least the smallest members of the family could climb well. While similar in body size (estimates range from 1 to 10 kg), miacids were more arboreal than viverravids, possessing relatively larger and more powerful muscles that would have aided in climbing. The miacid fossil record extends to about 38 million years ago (mya) in North America, almost 10 million years beyond the last known occurrence of viverravids.

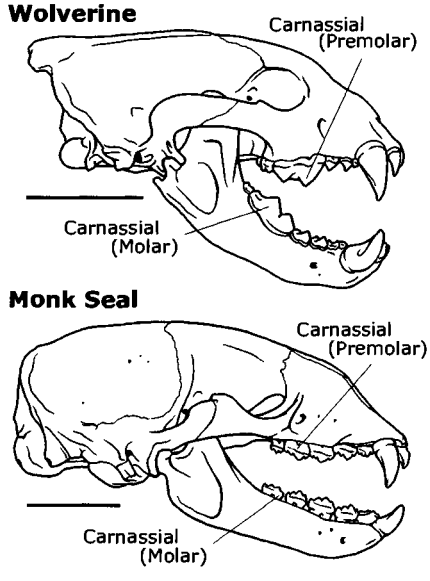

Figure 1 *Skulls of a wolverine* (Gulo gulo) *and a Caribbean monk seal* (Monachus tropicalis) *showing the typically enlarged and blade-like carnassial teeth of the wolverine in comparison to the highly derived and premolar-like carnassial teeth of the seal. Scale bar = 5 cm.*

The origin of miacoids and their relationship to other mammalian orders remains poorly understood. Among fossil taxa the extinct order Creodonta has long been considered to be the most likely candidate as sister taxon to Carnivora, but recent efforts by several workers have found little support for this hypothesis. Likewise, higher level molecular and biochemical phylogenies suggesting sister group relationships with such disparate mammals as lagomorphs (rabbits), pangolins (scaly anteaters), primates, chiropterans (bats), and artiodactyls + cetaceans (whales) have few supporters. At present the most likely candidate for sister group affiliations appears to be Lipotyphla (Wyss and Flynn, 1993), an apparently monophyletic group of insectivores that includes hedgehogs, tenrecs, shrews, and moles. None of the known fossil lipotyphylans ("palaeoryctids" and "leptictids" among others), however, appear to be any more closely related to Carnivora than creodonts.

II. Phylogenetic Relationships of Feliform and Caniform Carnivorans

Based largely on his studies of basicranial anatomy, W. H. Flower outlined a tripartite division of extant terrestrial carnivorans that has been retained with little modification since 1869. Morphologic, biochemical, and molecular analyses provide nearly unanimous support for the monophyly of these three groups (Aeluroidea, Cynoidea, and Arctoidea) and for the hypothesis that Cynoidea and Arctoidea are sister taxa (Fig. 2A). In addition, there is a growing consensus that the clade Cynoidea + Arctoidea is derived from Miacidae and that aeluroids are descendant from viverravids, phylogenetic relationships that have been formalized taxonomically using suborder designations Caniformia and Feliformia, respectively (Flynn, 1998). Familial level relationships within Caniformia and Feliformia have proven more difficult to resolve.

Included within Feliformia are the families Felidae (cats), Hyaenidae (hyaenas), Herpestidae (mongooses), Viverridae (civets and genets), and Nimravidae, an extinct family of cat-like carnivorans. Appearing in the late Eocene, nimravids bore striking similarities to modern felids in several dental, cranial, and postcranial characteristics and to sabre-toothed cats in particular because of the large, dagger-like canines possessed by many of the included taxa. While basicranial evidence clearly demonstrates the uniqueness of these Holarctic carnivorans, the phylogenetic position of nimravids is less clear and the family has been considered to be basal caniforms, the sister taxon to Caniformia + Feliformia, and, what is probably the best supported hypothesis, the sister group to living aeluroids (Fig. 2B).

Aeluroidea is primarily an Old World radiation with the earliest members represented by a diverse array of small-bodied (generally <5 kg) closely related forms from late Eocene–early Oligocene fossil localities in France and Mongolia. The basicranial morphology exhibited by these carnivorans is plesiomorphic for the group, and it was not until about 32 mya that carnivorans belonging to the extant families Felidae and Viverridae make their first appearance in the FOSSIL RECORD, with the earliest herpestids and hyaenids showing up closer to 18 mya (Hunt and Tedford, 1993). Felids are the only member of this Old World radiation to successfully colonize the New

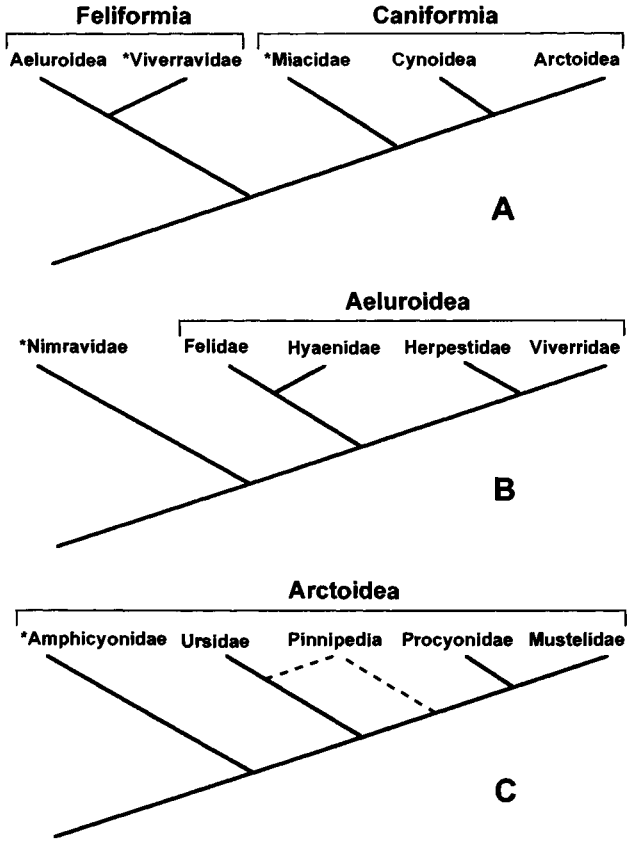

Figure 2 *Cladograms depicting several of the more strongly supported phylogenetic hypotheses of higher taxon relationships within Carnivora (A–C) and two hypotheses regarding pinniped relationships among arctoid carnivorans (C). See text for a discussion of alternative hypotheses. Asterisks denote fossil taxa.*

World, although one hyaenid lineage does appear in North America and Mexico about 3.5 mya. Attempts to resolve interfamilial relationships among these four families have resulted in at least some support for nearly every possible phylogenetic pairing. A recent analysis (Binida-Emonds *et al.*, 1999) combining nearly all known data sets bearing on the question of aeluroid relationships does corroborate some earlier studies in identifying sister taxon relationships between Felidae and Hyaenidae and between Herpestidae and Viverridae (Fig. 2B), as well as argue for a split between these two clades about 38 mya. There is also growing evidence, both morphologic and molecular, that *Nandinia binotata* (palm civet) is the sister taxon to all living aeluroids rather than a member of Viverridae as traditionally assumed (Flynn, 1996).

Caniformia includes the families Canidae (dogs), Ursidae (bears), Procyonidae (raccoons and their relatives), Mustelidae (skunks, weasels, badgers, and otters), the extinct Amphicyonidae, and the pinnipeds Odobenidae (walruses), Otariidae (fur seals and sea lions), and Phocidae (seals). There is little contention that canids (i.e., Cynoidea) are the sister group to the remaining caniforms (i.e., Arctoidea) and there is good documentation of the transition from middle and late Eocene miacids through the earliest canids such as *Hesperocyon*, a strictly North American taxon that appeared in the fossil record about 42 mya. The skeleton of hesperocyonids possesses several characteristics indicative of the increased cursoriality common to modern canids but retains several miacid features, suggesting that they had not completely abandoned arboreal habitats.

Arctoidea includes the smallest and largest of the terrestrial carnivorans as well as all marine-adapted members of the order. Its origins are traced to the late Eocene–early Oligocene and its distribution is Holarctic with fossil material coming primarily from western North America, France, and Mongolia. Many of these earliest forms are attributed to the extinct family Amphicyonidae (the bear-dogs), which have been variably considered basal members of the arctoid clade (Fig. 2C), the sister taxon to Ursidae, and the sister taxon to Cynoidea + Arctoidea. Amphicyonids appear almost simultaneously in the fossil records of North America and Europe, are taxonomically and morphologically diverse, attain an extremely large body size (>200 kg), and remain Holarctic in their distribution until disappearing between 7 and 9 mya (Hunt, 1996).

A number of recent molecular and morphological studies have addressed phylogenetic relationships among the extant arctoid families, and the result has been reduced support for what had been a nearly consensus view, that Arctoidea included two clades: Mustelidae + Procyonidae and Ursidae + a monophyletic Pinnipedia (Fig. 2C). All subsequent analyses have upheld pinniped monophyly (relationships among the three included families are not as clear), but several molecular studies have suggested that pinnipeds may be the sister taxon to the clade Procyonidae + Mustelidae rather than Ursidae (Fig. 2C). In contrast, other molecular and morphological studies indicate that Procyonidae may be the sister group to Ursidae or to a clade Ursidae + Pinnipedia. One of the keys to resolving arctoid relationships will be in deciphering phylogenetic relationships of *Ailurus fulgens* (the lesser panda), which has been variously included within Procyonidae, as the sister taxon to the clade Mustelidae + Procyonidae, and as the most immediate sister taxon to the clade Ursidae + Pinnipedia. As the number of species-level phylogenies increases in coming years, it seems likely that the resolution of Carnivora phylogeny may become even more problematic and more interesting as key taxa such as *Ailurus* and *Nandinia* are identified and analyzed.

Cephalorhynchus Dolphins

C. heavisidii, C. eutropia, C. hectori, and *C. Commersonii*

STEPHEN M. DAWSON
University of Otago, Dunedin, New Zealand

The four dolphins of the genus *Cephalorhynchus* are small, coastal species found only in Southern Hemisphere waters (Fig. 1). Haviside's dolphin (*C. heavisidii*) occurs off the west coast of South Africa and Namibia. Hector's dolphin (*C. hectori*) is found solely off New Zealand. The Chilean dolphin (*C. eutropia*) is found in the coastal waterways of Chile and along the exposed west coast. The remaining species, Commerson's dolphin (*C. commersonii*), has the strangest distribution. Its principal stronghold is in the inshore waters of Argentina and in the Strait of Magellan, but it also occurs at the Falkland Islands and has an isolated population 8500 km away at the Kerguelen Islands, in the Indian Ocean. The Kerguelen Commerson's dolphins are larger, retain the darker juvenile coloration into adulthood, and have some skeletal and genetic differences. It appears that this population was founded by only a very few individuals, perhaps as recently as 10,000 years ago.

Cephalorhynchus dolphins are among the smallest dolphins. Indeed, in length, Hector's dolphins from New Zealand's South Island (maximum 145 cm; ca. 50 kg) and South American Commerson's dolphins (maximum 146 cm; ca. 45 kg) are the smallest of all dolphins (franciscanas are longer, but weigh less). Both Hector's and Commerson's dolphins have isolated populations in which individuals grow larger. Commerson's dolphins at Kerguelen grow to 174 cm (86 kg), and the few North Island Hector's dolphins reach at least 152 cm (65 kg). In both these species females are 5–10% larger than males. Far fewer Haviside's and Chilean dolphins have been measured so it is not clear whether females are also larger in these species. Haviside's dolphins reach about 174 cm (ca. 75 kg), and Chilean dolphins reach at least 167 cm (ca. 63 kg).

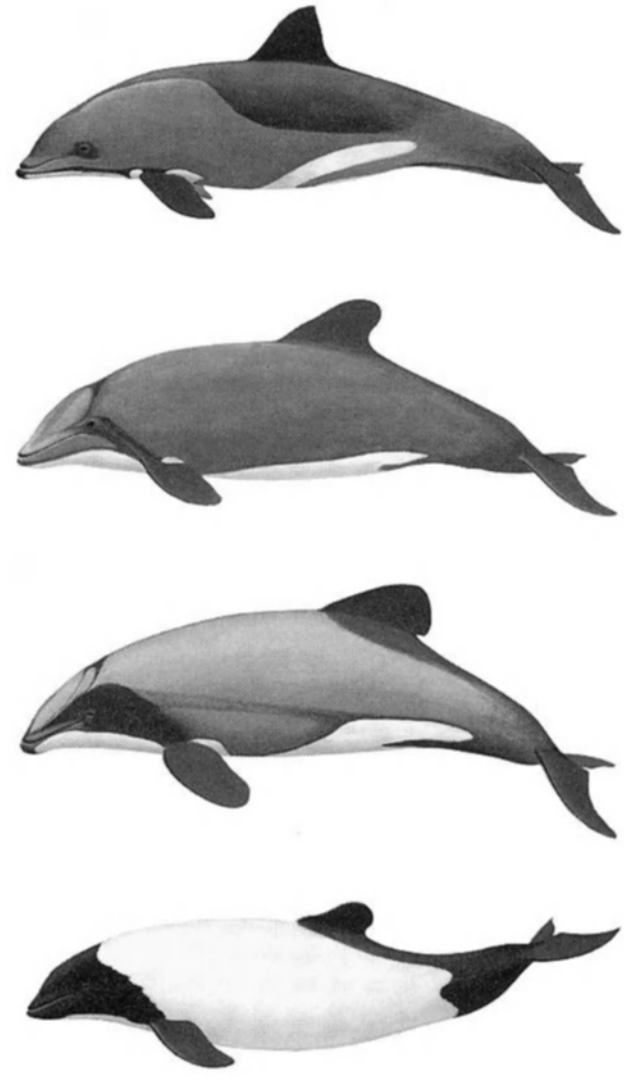

Figure 1 *The four* Cephalorhynchus *species, top to bottom: Haviside's, Chilean, Hector's, and Commerson's dolphins. Pieter A. Folkens/Higher Porpoise DG.*

All four species share similar morphology. They are all small, blunt-headed (hence the frequent mistake of calling them porpoises), chunky dolphins with rounded, almost paddle-shaped flippers. The most characteristic feature of the genus is the dorsal fin, which is proportionately large and with a rounded, convex trailing edge (like a Mickey Mouse ear; Hector's, Commerson's, and Chilean dolphin) or triangular (Haviside's dolphins). In color pattern, Chilean dolphins and Hector's dolphins are most similar.

I. Distribution and Abundance

Of the four species, only Hector's dolphin has been surveyed throughout its range. It is most common along the east

and west coasts of the South Island between 41° 30′ and 44° 30′S, with hot spots of abundance at Banks Peninsula and between Karamea and Makawhio Point. These South Island east coast and west coast populations are genetically distinct, as is the very small population occurring on the west coast of the North Island between 36° 30′ and 38° 20′S. An apparently isolated population exists in Te Wae Wae Bay, on the Southland coast. Recent surveys suggest South Island populations number ca. 1900 (east coast) and ca. 5400 (west coast). The species is rarely seen more than 8 km from shore. We have not seen it in water more than 75m deep.

South American Commerson's dolphins are found off the east coast between Rio Negro (40°S) and Cape Horn (55° 15′S) down into the Drake Passage (61° 50′S) and also at the Falkland Islands. They are common between Peninsula Valdez and Tierra del Fuego (42° to 54°S) and very common in the Straits of Magellan, where an aerial survey in 1984 suggested a population of around 3200. At Kerguelen, Commerson's dolphins are restricted to the immediate vicinity of the islands, where they are seen most frequently on the eastern side in the Golfe du Morbihan.

Haviside's dolphins are found on the west coast of Southern Africa from 17° 09′S) on the Namibian coast to around Cape Town (34° 13′S). Sightings are clustered between Walvis Bay and Cape Town. There are no estimates of abundance.

Chilean dolphins have been seen over a very wide latitudinal range, from Valparaíso (33° S) to near Cape Horn (55° 15′S), on both open and sheltered coasts. They are seen regularly in only a few places, however, including Valdivia, Golfo de Arauco, and near Chiloé. The total population appears to be very small (low thousands at most). Suggestions that the species is becoming very rare (Leatherwood, personal communication) are worrying and impossible to refute without dedicated survey work.

All *Cephalorhynchus* species favor waters of less than 200 m deep and are often seen in the surf zone, especially in summer.

II. Reproduction and Population Biology

Reproduction has been studied thoroughly only in Hector's dolphins and Commerson's dolphins, but the limited information available for Haviside's and Chilean dolphins suggests they are similar. Females bear their first calf between 6 and 9 years, in spring to late summer. Males reach sexual maturity between 5 and 9 years. MATING and calving occur in spring to late summer, and the gestation period is around 10–11 months. The maximum ages so far found in this genus are 20 (Hector's dolphin) and 18 (Commerson's dolphin).

Studies of individually identified Hector's dolphins suggest that mature females calve every 2–4 years. Late maturity, a relatively short life, and long intervals between calves inevitably result in a low population growth rate. Modeling studies have shown that Hector's dolphin populations, in the absence of human impact, would be expected to grow by about 2% per year.

III. Diet

All four species feed on a wide variety of coastal prey, focusing on benthic and small pelagic schooling fish and squid. The South American species supplement their fish/squid diet with crustaceans (mysids, euphausids, and *Munida* spp.) and, strangely, algae. Haviside's dolphins are apparently alone in preying on octopus to any significant degree. The DIET of Hector's dolphins is more varied on the South Island east coast, where eight species of fish and squid make up 80% of the diet by mass, than it is on the corresponding west coast (where four species make up 80%).

IV. Movement

Individual dolphins in this genus appear to be seasonally resident in a local area. Long-running studies on Hector's dolphins have shown that individuals usually range over about 30 km of coastline. In Haviside's, Commerson's, and Chilean dolphins, at least some individuals are found in local areas year-round, although inshore abundance is lower in winter. Individual Hector's dolphins have been resighted in the same general area year-round, but they tend to spread out, form smaller groups, and range further from shore in winter. There is no evidence for large-scale MIGRATION. Despite wide-ranging surveys over more than a decade, no two sightings of the same individual Hector's dolphin are more than 106 km apart.

V. Behavior

Small group sizes are characteristic of this genus. Although occasional sightings of more than 50 have been made, most sightings are of between 2 and 10 individuals. In high-density areas, there may be several such groups nearby. In Hector's dolphin, these often coalesce to form a large, temporary group of 25 or so. Large groups often show boisterous behavior, such as chases, leaps, and lobtailing. Sexual displays and copulation are also more common after groups have joined. Such large groups are usually short-lived; after 10–30 min they split into small groups again. Frequently groups lose, gain, or swap members in this process. Associations among adult Hector's dolphins are weak. It is likely that the other species are similar.

All members of the genus except Chilean dolphins are strongly attracted to boats and readily ride the bow wave. Chilean dolphins have been heavily hunted and their wariness of boats has probably been acquired. All species are thoroughly at home in turbulent water close to shore and are frequently seen surfing.

VI. Acoustic Behavior

Only Hector's dolphin has been recorded comprehensively in the wild with equipment that could capture the full range of its sounds. Almost all the sounds are short [ca. 140 μsec (roughly 1/7000 sec)], high-frequency (ca. 125 kHz) narrow-band, ultrasonic clicks (Fig. 2) that are used in "trains" of a few dozen to several thousand. Clicks may contain one, two, or three main pulses and appear to have a role in COMMUNICATION as well as sonar. Complex clicks are used disproportionately in social contexts, and a particular type of click is used preferentially in feeding. Click rates can be exceptionally high (maximum 1149 clicks/sec). Such high click rates generate an audible tone of the same frequency as the click rate (Fig. 3). These signals, which sound like a "cry" or "squeal," are strongly linked to

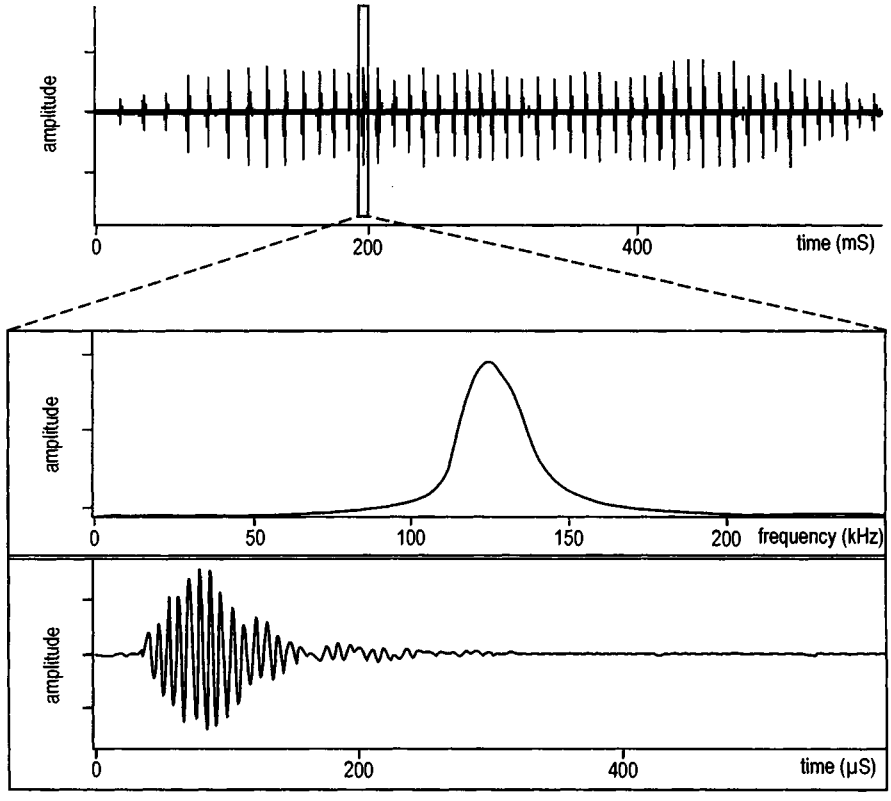

Figure 2 *A "train" of high-frequency Hector's dolphin clicks, with a "zoomed" section showing the waveform and spectrum shown for an example click.*

aerial behaviors and apparently indicate excitement. "Cry"-type sounds, and the lower emphases of occasional broadband clicks, are Hector's dolphins' only vocalizations that are audible to humans. Very similar click and "cry"-type sounds have been described from Commerson's dolphins.

Haviside's dolphin and Chilean dolphin both make the "cry" sounds just described. Neither has yet been recorded with equipment capable of recording ultrasonic frequencies. Given the close similarity of the sounds of Hector's and Commerson's dolphins, it is likely that the sounds of Haviside's and Chilean dolphins will be similar also.

VII. Threats and Conservation

All four species have, at some stage, been hunted for food or bait. The South American species have fared worst: they have been hunted extensively for bait for crab pots and are reported to be no longer common in areas frequented by crab fishers. As many as 1300–1500 Chilean dolphins may have been harpooned each year near the Western Strait of Magellan in the late 1970s and early 1980s. Such hunting is now illegal, but fishers in the area are poor, and the crab processing companies supply insufficient bait. Enforcement of this law in such a remote and convoluted area is practically impossible.

All four *Cephalorhynchus* species suffer some degree of incidental catch in fishing gear. In South America these animals are used as bait. Hence fishers have no motive to avoid areas where captures occur and may favor them. Numbers taken currently are unknown for any of the four species. It is clear, however, that gill nets pose a larger problem than any other fishing method. In the mid-1980s an average of 57 Hector's dolphins were caught each year in gill nets in the Canterbury region of the east coast of New Zealand's South Island. Given the low reproductive rate of this species, it was clear that this level of catch was unsustainable. An 1170-km^2 sanctuary, in which commercial gill netting is illegal and amateur gill netting is restricted to particular times and places, was established in 1989. The problem has not been entirely solved. Analysis of observed catches in the Canterbury region in 1997/1998 suggests that 18 Hector's dolphins were caught in gill nets to the north and south of the current sanctuary.

There appear to be fewer threats to Haviside's dolphin than to the others, and it seems that Commerson's dolphin, despite the impacts on it, is probably the most numerous member of this genus. The Chilean dolphin and Hector's dolphin need urgent consideration. Currently there is insufficient information to judge the conservation status of Chilean dolphins. Population surveys are needed before we can say even whether the species numbers hundreds (as the most dire of the warnings imply) or thousands. In a small population of slow-breeding animals, even a very low level of directed or incidental catch can be enough to continue the decline.

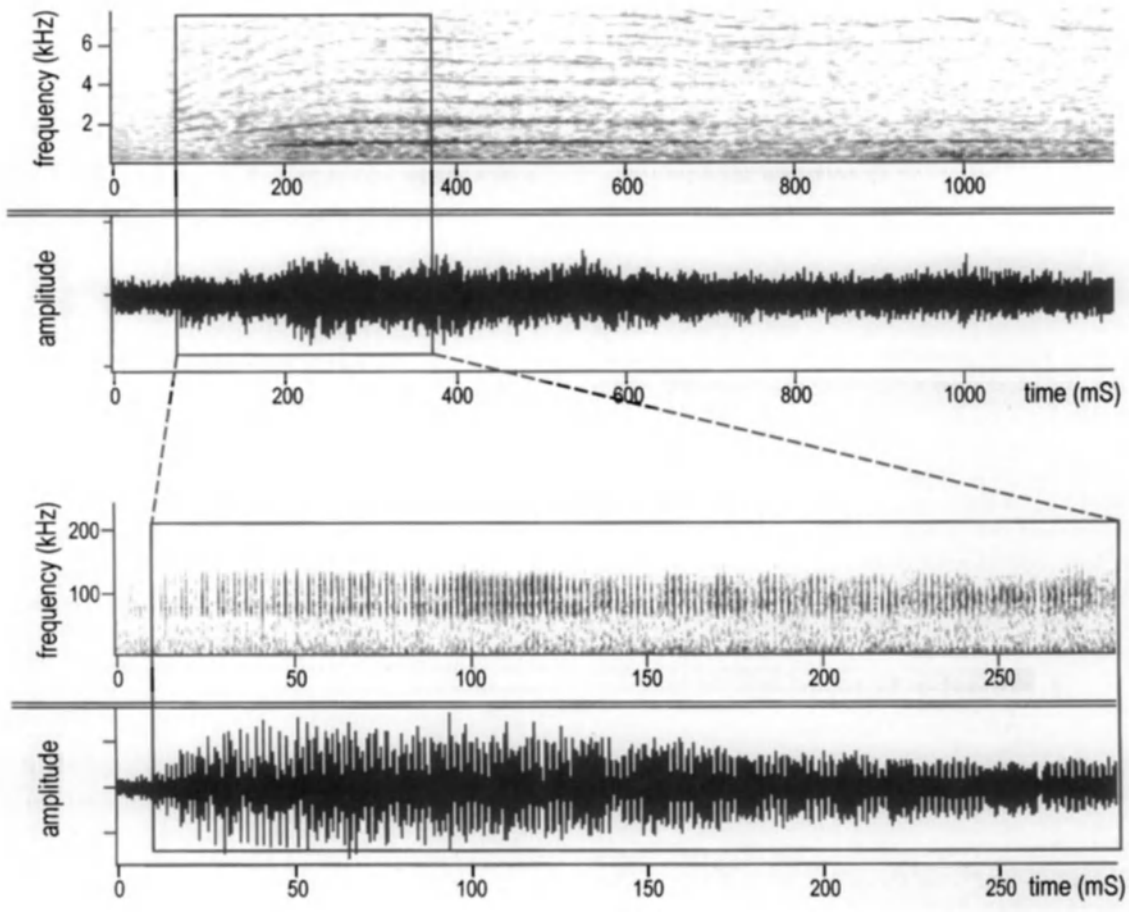

Figure 3 *Audible "cry" sound from Hector's dolphin. The "zoomed" section shows that the "cry" sound is made up of high-frequency clicks emitted at a very high rate (ca. 1000 clicks/sec)*

Hector's dolphin has at least received some direct conservation action, via the Banks Peninsula Marine Mammal Sanctuary. The latest modeling suggests that this population is still declining. Hector's dolphins off the North Island west coast are genetically as distinct from those off the South Island east coast as the South American Commerson's dolphins are from those 8500 km away at Kerguelen. Surveys suggest that the North Island west coast population may number fewer than 100 animals. Gill netting effort along this coast is high by New Zealand standards. Population models show that this population is declining rapidly. Unless effective conservation action is taken very quickly, the outlook for North Island Hector's dolphins is imminent extinction.

Cetacea, Overview

LAWRENCE G. BARNES
Natural History Museum of Los Angeles County; California

The most highly aquatically adapted group of marine mammals are the mammalian order Cetacea, which are commonly called whales, dolphins, and porpoises. Living cetaceans are a diverse group of mammals whose specialized anatomy and behaviors mask their origin from terrestrial mammals. Ranging from under 5 feet to over 90 feet in length, cetaceans are ecologically diverse; they live in rivers and oceans and in tropical and polar latitudes. About 78 species live today, classified in 13 or 14 families, and in the suborders Mysticeti (baleen whales) and Odontoceti (toothed whales, dolphins, and porpoises). Hundreds of fossil species are known, going back to the Middle Eocene, about 55 million years (Ma) ago, including members classified in an extinct third suborder, the Archaeoceti.

I. Suborder Archaeoceti: Archaic Cetaceans

The oldest Cetacea are the toothed, extinct suborder Archaeoceti, a paraphyletic group. Archaeocetes are clearly related to living Cetacea; they show typical cetacean features such as an elongate upper jaw with bony nostrils set back from the tip, a broad shelf of bone above the eye, lack the incisive foramina, incisors aligned anteroposteriorly, a dense outer ear bone (tympanic bulla), and an enlarged mandibular canal on the inner side of the lower jaw; later archaeocetes have an expanded basicranial air sinus, like living cetaceans. Archaeocetes lack the "telescoped" SKULL, in which bones of the snout and cranium slide over one another, as in the later odontocetes and mysticetes.

Sinuous eel-like bodies have been depicted by authors and artists, especially for the later archaeocetes, but this would be contradictory to the vertical tail movements and caudal flukes typical of other cetaceans. A quite whale-like body shape can be reconstructed around the skeletal outlines of even the longest of the basilosaurine archaeocetes. Stomach contents of *Basilosaurus cetoides* suggest that it was an ambush predator on bony fishes and small sharks in shallow water. There is fossil evidence that most, if not all, archaeocetes had external hindlimbs. Early archaeocetes have well-developed pelves, sacral vertebrae, and hindlimb bones. The smaller yet still-functional hind limbs of *Basilosaurus isis* may have aided locomotion in shallow waters. Archaeoceti also have a primitively mobile elbow joint, with a long humerus and less streamlined foreflipper than in extant Cetacea. The more primitive forelimbs might indicate that they were semiamphibious-like pinnipeds.

Most older archaeocete fossils are from India and Pakistan, in sediments deposited around the ancient Tethys Seaway, which extended between India and Africa to the south and Eurasia to the north. Since 1980, new fossils have greatly expanded our knowledge of protocetids and other early archaeocetes.

A. Family Pakicetidae: Amphibious Early Cetaceans

Nalacetus is mainly known from isolated teeth, which show that it is the most primitive cetacean. *Pakicetus* was a small archaeocete with eyes on top of its head. Oxygen isotope ratios in its tooth enamel indicate that it drank only fresh water.

B. Family Ambulocetidae: Walking Whales

Ambulocetus had feet that were much longer than its hands and a long tail that probably was without flukes.

C. Family Remingtonocetidae: Gavial-Convergent Cetaceans

Remingtonocetus and *Andrewsiphius* had a long and narrow skull, very tiny eyes, and a long symphysis (junction) between the two lower jaws.

D. Family Protocetidae: First Pelagic Cetaceans

Indocetus had large molars that have a complex, primitive morphology. *Rodhocetus* was approximately 3 m long and had nostrils near the front of the snout. It retained a large pelvis and small hind legs. *Protocetus* had a skull that lacks the complex tooth crowns and expanded basicranial air sinuses of later archaeocetes. It had a small pelvis and flexible posterior part of the trunk.

E. Family Basilosauridae: Zeuglodonts

Basilosaurus was a large whale (approximately 20 m). It had cheek teeth with many small denticles (saw-tooth like) and had enlarged air sinuses around the ears. *Basilosaurus* also had large and elongate vertebral centra and short hindlimbs.

Sometimes included in the basilosaurids, but sometimes treated as a separate family are the Dorudontinae, including *Dorudon*, *Saghacetus*, and *Zygorhiza*.

II. Suborder Mysticeti: Baleen Whales

Mysticetes are small to very large filter-feeding whales with a loose mandibular symphysis and a type of jaw articulation that allows the mandible to open widely for bulk feeding. All mysticetes also have a smooth ventral surface of the maxilla (the palate), which in the baleen-bearing species has grooves that hold the blood vessels that nourish the baleen plates, an infraorbital plate of the maxilla ventral to the eye, and a laterally projecting antorbital process of the maxilla. Mysticeti are a natural clade that originated from the Archaeoceti. The oldest mysticete is Late Eocene in age and the group survives today, having been represented throughout most of its history by at least five or six contemporaneous family-level groups.

Just a few years ago, it would have seemed paradoxical to need to differentiate between baleen-bearing mysticetes and tooth-bearing mysticetes, the latter seemingly a misnomer. However, this need was brought about largely by the discovery of the Aetiocetidae and other Late Eocene and Oligocene whales that are transitional between the toothed Archaeoceti and the later baleen-bearing mysticetes. There is as much recognized diversity now at the family level among both named, and known but undescribed, fossil tooth-bearing mysticetes as there is among the fossil and living baleen-bearing mysticetes.

The primitive, extinct tooth-bearing mysticetes had heterodont dentitions, differentiated into incisors, canines, premolars, and molars, and these animals are classified in the families Llanocetidae, Kekenodontidae, Mammalodontidae, and Aetiocetidae, and in possibly two other undescribed families. Some of these families had skull characters that were very much like those of archaeocetes, thus confirming the origin of baleen whales from them.

More highly evolved toothed mysticetes, such as the Aetiocetidae, had skulls and jaws that were similar to the later baleen-bearing mysticetes, e.g., the cetotheriids, so they represent a transitional morphology. In many ways, the "intermediate" structure of aetiocetids helps us understand how baleen-bearing mysticetes might have evolved from archaeocetes. A possibly unanswerable question is which toothed mysticete taxon was the first to have rudimentary baleen plates between its teeth. It is most parsimonious to assume that baleen originated only once in cetacean evolution.

General evolutionary trends among the later Mysticeti include the acquisition of large body size, shortening of the intertemporal region as anterior and posterior parts of the skull "telescope" over and under each other, reduction of the coronoid process and mandibular foramen, lateral bowing of the mandibles, and shortening of the neck. Mysticetes are virtually cosmopolitan in their distribution, being found both in the past and now from polar to equatorial latitudes, with fossils known from all ocean basins. The great increase in size among baleen-bearing mysticete whales was a phenomenon of Miocene and later time, with the largest known species being among the living species.

A. Family Llanocetidae: Archaic-Toothed Mysticetes

Llanocetus had a large triangular braincase and its brain was shaped much as in later mysticetes. It had a deep mandible with widely spaced, large, multicusped teeth.

B. Family Kekenodontidae: Toothed Mysticetes

Kekenodon had long-rooted, multicusped cheek teeth, with large accessory cusps.

C. Family Mammalodontidae: Southern Ocean-Toothed Mysticetes

Mammalodon was a toothed mysticete with a strangely abbreviated and blunt rostrum. The posterior end of its mandible was deeper and more heavily built than that of the more highly derived Aetiocetidae. It had more than the primitive eutherian number of teeth per jaw (11). The teeth crowded each other, were implanted somewhat obliquely in the mandible, and had small accessory cusps.

D. Family Aetiocetidae: Small-Toothed Mysticetes

Aetiocetidae had heterodont denitions that were differentiated as incisors, canines, premolars, and molars, with small cuspules on comparatively small molar and premolar crowns. *Chonecetus* had a small braincase and relatively narrow rostrum. *Morawanocetus* had large molars, a wide and dorsoventrally flattened braincase, large tympanic bullae, and small, anteroposteriorly compressed cervical vertebrae. *Aetiocetus* was of relatively large size, with wide flat rostrum, anteroposteriorly foreshortened intertemporal region, and large zygomatic process of the squamosal. Some Aetiocetinae had increased numbers of teeth (as do embryonic modern baleen whales) and smaller teeth, possibly indicating the transition to incipient baleen plates.

E. Family Cetotheriidae: Primitive Baleen-Bearing Mysticetes

Cetotheriidae were flat-snouted, edentulous, baleen-bearing mysticetes. Their palates had characteristic grooves marking the courses of blood vessels that nourished the baleen plates, and fossil baleen has even been found with some specimens. The dentaries were elongate and relatively slender and had nutrient foramina along the dorsal border marking the previous locations of dental alveoli. Cetotheres had relatively small heads compared to their body size, similar in this regard to Recent rorquals of the family Balaenopteridae.

Herpetocetus and *Nannocetus* are characterized by their dentary-squamosal articulation: the zygomatic process of the squamosal is elongate anteroposteriorly and deepened dorsoventrally, and the angular part of the dentary projects posteriorly ventral to the postglenoid process and the ear region.

F. Family Balaenopteridae: Rorquals and Relatives

Balaenopterids have a deep transverse sulcus between the rostral portion of the maxilla and the supraorbital process of the frontal. They also have an elevated cranial vertex (relative to the supraorbital process of the frontal), a tapered and somewhat twisted (in derived taxa) horizontal ramus of the dentary, and a large, spheroid mandibular condyle. They also lack any transverse exposure of the parietals at the apex of the skull posterior to the nasal bones.

G. Family Eschrichtiidae: Gray Whales

Eschrichtius robustus is characterized by a relatively narrow and dorsally arched rostrum with large nares that are located at the apex of the curve, two tuberosities on the braincase near the nuchal crest, and a massive mandible with a low coronoid process and a large rounded mandibular condyle.

H. Family Balaenidae: Right Whales, Bowheads, and Relatives

Morenocetus, a fossil, probably had an upper jaw that was narrow and arched. Living balaenids have extremely long baleen plates, similar to those of the extant *Balaena mysticetus.*

I. Family Neobalaenidae: Pygmy Right Whales

Extant *Caperea marginata* is very small, has expanded ribs, an extremely large occipital shield of the braincase, a short and tapered rostrum, and tapered and twisted mandible.

III. Suborder Odontoceti: Toothed Cetaceans

Odontocetes are echolocating toothed cetaceans that have extensions of the basicranial sinuses, around their ears, into

other parts of the skull. The large pterygoid sinus extends anteriorly around the sides of the nasal passages and, in derived taxa, in front of them. The Odontoceti are known as far back as the Eocene–Oligocene boundary, approximately 35 Ma.

Odontoceti are commonly called "toothed whales," but this is a bit of a misnomer because all of the Archaeoceti, some of the primitive fossil Mysticeti, and all fetal baleen-bearing mysticetes are toothed, whereas some Odontoceti had undergone dramatic tooth loss. Therefore, "presence of teeth" is not diagnostic of the Odontoceti. The earliest odontocetes have a primitive dental formula, differentiated into incisors, canines, premolars, and molars. Later odontocetes have all teeth alike, homodonty, and some taxa have additional teeth (polydonty) whereas others have reduced numbers of teeth.

Similarly, Odontoceti are commonly thought of as having asymmetrical crania, but this is not true for all Odontoceti, especially many of the fossil species, and, again, is not diagnostic of the group. Cranial asymmetry, a derived character state, is related to the development of complex echolocation abilities involving the production of both high- and low-frequency sound. Different odontocete species have either symmetrical or asymmetrical crania, and asymmetry is a derived character state that apparently has been independently acquired within different lineages at different times. In most odontocetes having asymmetrical crania, the skew is to the left side, but the skulls of members of the extinct kentriodontid delphinoid subfamily Pithanodelphinae are skewed to the right side.

The type of cranial bone telescoping of odontocetes differs from that of the mysticetes; the maxilla extends posteriorly *over* the supraorbital process of the frontal and there is no laterally projecting antorbital process of the maxilla. The pterygoid sinus fossa in Odontoceti extends from the ear region anteriorly around the nasal passage to invade the posterior part of the palatine bone. In the earliest Odontoceti, the nasal bones primitively were elongate, flat, and overhung the posterior part of the narial opening, as in the derived Mysticeti. In later Odontoceti, the nasal bones are reduced, being knob-like and retracted posterior to the nasal opening. All Odontoceti have a premaxillary foramen, a branch of the infraorbital foramen system, located in each premaxilla anterior to the narial opening. Around or anterior to the narial opening is a widened and flattened part of the premaxilla where the premaxillary sac, a diverticulum of the dorsal nasal passage, lies. This flat part of the premaxilla is called the premaxillary sac fossa or the spiracular plate.

Odontocetes have the ability to echolocate and to selectively take individual prey items. This separates them from the Mysticeti, which cannot echolocate and are bulk feeders. During echolocation, high-frequency sound, in the form of clicks, is produced by the movement of air, recycled within the diverticula, sacs, and valves of the nasal passages. The sound is focused by the melon on the face, which is an acoustic lens, and projected into the environment. Sound is reflected off of objects and animals in the water and is returned to the odontocete. The external acoustic meatus is closed; sound is instead transmitted to the ears via the side of the face, through the thin posterior part of the dentary, through a fat body, and thence to the ear region. Directional hearing is possible because the ear bones are isolated in fat bodies, and the sound arrives at each ear at a different time. Even the earliest odontocetes had spiracular plates and enlarged peribullary sinuses, and this implies that they could actively echolocate, at least to some extent.

Throughout their history, odontocetes have been more diverse taxonomically than mysticetes, with several different families existing simultaneously. Different families of odontocetes are diagnosed particularly on details of sutures around the bony nostrils and the base of the rostrum, the basicranial sinuses, and the ear region. Trends among odontocetes include the evolution of paedomorphism (adults showing a spectrum of juvenile-like features), repeated convergent evolution of very long rostra, increasing facial asymmetry, development of more complex basicranial sinuses, and shortening of the neck.

A. Family Agorophiidae: Primitive Toothed Whales

Agorophius was a medium-sized odontocete with heterodont dentition, wide mesorostral groove, elongate nasal bones, very large temporal fossae bordered by large cranial crests for the attachment of very massive jaw musculature, and a relatively elongate and narrow intertemporal constriction.

B. Family Physeteridae: Giant Sperm Whales

In physeterids the periotic is distinctive, having a large posterior process, a round internal acoustic meatus, and a part of the outer whorl of the bulla (called the "accessory ossicle") that is attached to the anterior process of the periotic. The teeth of all physeterids are homodont. *Ferecetotherium* had both upper and lower functional teeth. *Diaphorocetus* had a skull with the distinctive physeterid type of supracranial basin.

Scaldicetus had a relatively long, slender rostrum, large zygomatic arches, large tympanic bullae, prominent occipital condyles, and a forward-sloping occipital shield that is deeply emarginated laterally by large temporal fossae. It appears to have had 12 teeth on each side of the mandible. The living sperm whale, *Physeter macrocephalus*, lacks upper teeth.

C. Family Kogiidae: Pygmy and Dwarf Sperm Whales

Kogiids and physeterids share highly asymmetrical crania, supracranial basin, derived lachrimal-jugal structure, and a large mastoid process. Kogiids differ from physeterids by having lesser development of the melon and thus a less concave facial skeleton. In addition, the kogiid skull has a blunt and squared zygomatic process of the squamosal and an anteroposteriorly aligned bony crest or eminence in the middle of the facial basin of the skull.

Extant *Kogia* have skulls that are largely composed of spongy and inflated bone, with very short and tapered rostra, no upper teeth, an elevated cup or basin on the sagittal crest in the supracranial basin, and the orbit placed posteriorly within the temporal fossa.

The latest Miocene fossil pygmy sperm whale, *Praekogia*, differed from the Recent species of *Kogia* by having dense rather than spongy (=oil-filled) cranial bone, cranial crests that are not so elevated, and the orbit situated anterior to the end of the zygomatic process of the squamosal (the typical cetacean condition), not posteriorly within the temporal fossa.

Scaphokogia had an elongate and narrow skull, a long, parallel-sided, thick, dense snout, and nearly circular supracranial basin.

D. Family Ziphiidae: Beaked Whales

Ziphiidae have reduced the number and size of teeth. Male modern ziphiids generally retain one or two prominent teeth in the lower jaw, but primitive species showed rows of small dolphin-like teeth.

E. Family Squalodontidae: Shark Toothed Dolphins

Squalodontidae were medium-sized to large, dolphin-like cetaceans with long rostra and a relatively primitive, heterodont dentition composed of incisiform anterior teeth and premolars and molars commonly with triangular crowns and two roots. Their skulls were fully telescoped, the narial openings being located between the eyes, and the premaxillae and maxillae extending posteriorly to reach the cranial vertex. In *Patriocetus* and *Kelloggia*, the skull had a narrow intertemporal region. In *Squalodon* and related genera, the skull had a more disk-like facial region.

F. Family Eurhinodelphinidae

Eurhinodelphinidae (also called Rhabdosteidae) were medium to large sized and have fully telescoped skulls with extremely long, narrow rostra bearing many small, homodont teeth with single roots and conical crowns. The vertebrae are elongate and the neck is flexible. The lower jaw was shorter than the upper jaw. The front part of the upper jaw that overhung carried no teeth.

Argyrocetus and *Rhabdosteus* had narrow facial regions, but *Eurhinodelphis* had a wide, rounded facial region. *Macrodelphinus* attained the size of a living killer whale.

G. Family Waipatiidae

Waipatia was a dolphin-like cetacean with heterodont teeth and a relatively wide rostrum. The cranial vertex was slightly asymmetrical.

H. Family Squalodelphinidae

Squalodelphinids were medium-sized cetaceans with stout rostra bearing homodont denititions composed of conical-crowned teeth that somewhat resembled those of modern dolphins, but which had somewhat rugose enamel caps. The cranial vertex was asymmetrical and there was a moderate-sized elevated crest aligned anteroposteriorly over each orbit.

I. Family Dalpiaziniidae

Dalpiazinia had a nasal region and cranial vertex that were symmetrical, the rostrum was relatively short, and the dentition was homodont.

J. Family Acrodelphinidae

Acrodelphinids (also called Eoplatanistidae) were medium-sized cetaceans with relatively large vertebrae and pectoral limbs, and on the skull there was a relatively low anteroposteriorly aligned crest on top of the supraorbital process of the frontal. The pterygoid bone was continuous with the alisphenoid bone to form a thin, vertically oriented sheet of bone within the back of the orbit (similar to platanistids, a so-called "reduplicated pterygoid). The lower jaw was the same length as the rostrum and had an elongate groove on each side, mirroring a similar groove on each side of the rostrum. Such grooves are also present in some Pontoporiidae.

K. Family Platanistidae: Indian River Dolphin (*Platanista gangetica*) and Relatives

Platanistidae have a generalized vertebral column, but a highly modified foreflipper. The skull has tiny eyes with reduplicated pterygoids. The narial region and cranial vertex show strong left-skew asymmetry. The jugal is thick, and the zygomatic process of the squamosal is dorsoventrally expanded and medially excavated. The maxillary crests are large and form a parabolic surface on the facial region, "accessory ossicles" surround bulla and periotic, and the rostrum is long and transversely compressed with elongate anterior teeth and short back teeth.

L. Family Iniidae: Amazon River Dolphin and Relatives

Inia geoffrensis has a delphinid-like basicranium and ear region, but its combination of elevated maxillary crests, premaxillary eminences, asymmetrically left-skewed narial region, elevated cranial vertex, and elongate zygomatic processes of the squamosals differentiate it from other families of Odontoceti.

M. Family Pontoporiidae: Franciscana and Relatives

Pontistes, *Pliopontos*, and the living *Pontoporia blainvillei* have symmetrical crania and long rostra. *Brachydelphis* was extremely short snouted, but its cranium was otherwise similar in construction to those of the Pontoporiinae and was symmetrical around the narial region. *Parapontoporia* (also classified as a lipotid) was extremely long snouted and had 77 to 88 teeth on each side of the slender rostrum and mandible. Fossil species are known from 8 to 3 Ma ago in the North Pacific.

N. Family Lipotidae: Yangtze River Dolphin

Lipotes vexillifer shares important derived characters of the cranial vertex and facial region with *Parapontoporia*. Its postcranial morphology is relatively primitive, but its skull has several unique derived characters, including crests on the supraorbital process of the maxilla over the orbit, a stout rostrum, a left-skewed highly asymmetrical nasal region, and a highly elevated asymmetrical cranial vertex.

O. Family Kentriodontidae: Primitive Delphinoid Dolphins

Kentriodontids were small to medium-sized fossil dolphins. The cranial vertices of all kentriodontids, with the exception of *Pithanodelphis* and *Atocetus*, were symmetrical, the skulls were fully telescoped, and their dentitions were more or less homodont. *Kamptholophus* was relatively large, with a large skull that bore prominent cranial crests, and large teeth with vestiges of heterodonty—the posterior teeth had accessory cups. *Kentriodon* was similar in body form to the small living dolphins. *Pithanodelphis* and *Atocetus* displayed cranial asymmetry: the cranial vertex was skewed to the right side. This skew was in the opposite direction of that present in all other odontocetes

with an asymmetrical skull. These two genera were also characterized by having exceptionally large and elevated nasal bones. *Lophocetus* and *Hadrodelphis* had large and elevated nasal bones, which were constricted medially between the posterior ends of the maxillae.

P. Family Albireonidae

Albireo was a *Tursiops*-sized dolphin that had a large, massive skull with an up-turned rostrum containing many large, conical-crowned teeth, a large brain, and an extensive basicranial air sinus system. Its flippers resembled those of *Platanista gangetica* and the stout body form that of *Lagenorhynchus* spp. It had numerous thoracic and lumbar vertebrae and these bear long processes.

Q. Family Odobenocetopsidae: Walrus-like Whales

Odobenocetops had asymmetrical, posteroventrally directed tusks, the right much longer than the other, similar to those of a narwhal, and a blunt snout. There were no other upper teeth. The facial region retained the odontocete nasal morphology, but lacked the bony indications of nasal sacs and air sinuses. The optic nerve tracts were exceptionally large for a cetacean.

R. Family Monodontidae: Belugas, Narwhals, and Relatives

Delpninapterids have a relatively narrow and slightly downturned snout like modern beluga (*Delphinapterus leucas*). *Delphinapterus* and *Monodon monoceros* have similar skulls, but the latter bears a large tusk. *Denebola* was a strange fossil monodontid of temperate latitudes that had a broad skull and a snout that was wide, flat, and blunt.

S. Family Delphinidae: True Dolphins

Delphinidae are characterized by skull osteology, especially details of the left-skewed asymmetrical cranial vertex and narial region, the basicranium, and the periotic. Delphinids range from small to large species with long or short rostra, and narrow or broad rostra, and are the most diverse living family of Cetacea.

T. Family Phocoenidae: Porpoises

Phocoenids have a raised eminence on each premaxilla anterior to the narial opening, a lobe of the pterygoid air sinus extending dorsal to the orbit between the frontal and maxillary bones, and anteriorly retracted posterior premaxillary terminations. The short rostra, rounded crania, and spatulate teeth of living phocoenids are paedomorphic characters that only appear in the more recent members of the group, known from the Late Pliocene and more recently. Late Miocene phocoenids had longer snouts, more prominent cranial crests, and conical tooth crowns. *Piscolithax* was a large phocoenid, approximately the size of extant *Tursiops truncatus*, and had relatively large pectoral flippers.

Cetacean Ecology

LISA T. BALLANCE
Southwest Fisheries Science Center, La Jolla, California

Ecology is the study of the natural environment and of the relationships of organisms to each other and to their surroundings. From its natural history beginnings in the late 1800s, the field of ecology has blossomed into a broad discipline, encompassing empirical and theoretical research in fields as diverse as mathematics, conservation, physiology, geography, and behavior. The study of cetacean ecology is very much in its infancy, however. Until fairly recently, most of what was known about cetacean ecology was largely composed of anecdotes and observations handed down by early whalers (Herman Melville's "Moby Dick" provides for classic examples). Studying whales or dolphins in their natural environment is a formidable challenge. This is due to the logistical constraints of attempting to study highly mobile, oceanic animals that spend nearly all of their lives underwater, as well as the political and legal constraints of working on protected species, which include most cetaceans.

Cetaceans are a diverse group that includes some 83 species. They range in size from less than 1 m long for a newborn vaquita (*Phocoena sinus*) to 33 m in an adult blue whale (*Balaenoptera musculus*); they occupy water whose temperatures range from −2 to over 30°C; they exhibit a diverse array of life history strategies. Consider the sperm whale (*Physeter macrocephalus*), which can remain beneath the water for over an hour and dive to depths of several thousand meters; the Indian river dolphin (*Platanista gangetica*), which inhabits fresh water so turbid it is functionally blind; beaked whales of the genus *Mesoplodon*, which are so pelagic and so elusive that new species are still being described; the gray whale (*Eschrichtius robustus*), which an-

nually migrates some 15,000 to 20,000 km between breeding and feeding areas; and the bowhead whale (*Balaena mysticetus*), which uses its rostrum to break ice in the Arctic.

One of the challenges of ecology is to search for pattern within diversity. Despite their diversity of form, behavior, and habitat, all cetaceans have some key features in common that underscore the fact that they are secondary marine forms, derived from terrestrial ancestors. That they are all air-breathing, live-bearing homeotherms provides a unifying theme. This article provides an overview of cetacean ecology with the ultimate goal of identifying some unifying principles in the ways that cetaceans interact with each other and with their environment.

I. Habitat

A. Where Do Cetaceans Live?

On a global scale, cetaceans have invaded a large proportion of the ocean's habitats. They inhabit coastal waters up to and including the surf zone (gray whale; some populations of bottlenose dolphins, *Tursiops truncatus;* harbor porpoise, *Phocoena phocoena*; Commerson's dolphin, *Cephalorhynchus commersonii*), neritic waters over continental shelves (long-beaked common dolphin, *Delphinus capensis*; *Lagenorhynchus* spp.; *Cephalorhynchus* spp.; *Phocoena* spp.), and the most oceanic of systems (sperm whale; Fraser's dolphin, *Lagenodelphis hosei*; beaked whales). They are found in tropical waters (pantropical spotted dolphin, *Stenella attenuata*), temperate seas (Risso's dolphin, *Grampus griseus*), and polar oceans, up to and within pack ice (beluga, *Delphinapterus leucas*; bowhead whale). They utilize much of the water column, some being confined to relatively shallow depths (most dolphins and baleen whales), and others diving to thousands of meters (sperm whale, many beaked whales). They have also invaded several of the world's major river systems (Ganges, Indus, Amazon/Orinoco, Yangtze).

Cetaceans in different habitats might be expected to show differential development of adaptations that reflect selective pressures of the environments in which they function. For example, species in polar seas must conserve heat and so bowhead whales have relatively large bodies, thick BLUBBER layers, and short appendages. Deep-diving species (sperm and beaked whales) must conserve oxygen and might be expected to have large blood volumes, a high hematocrit, and a well-developed diving response. Species that forage in low-light conditions (night feeders, deep divers, species living in turbid rivers) should have well-developed ECHOLOCATION abilities relative to those that function in habitats with greater light levels and better visibility. To date, these types of comparative studies have been rare and are a promising line of future investigation.

The geographic range of cetaceans runs from cosmopolitan to extremely local. For example, the killer whale (*Orcinus orca*) can be found throughout the world's oceans and, with the exception of humans, is the most wide-ranging animal on earth. At the other extreme is the vaquita, a tiny porpoise that occupies a few hundred square kilometers in the northern Gulf of California. Why some species are habitat generalists and others specialists remains largely a mystery.

On a smaller spatial scale, we are beginning to identify those features that correlate with centers of distribution for some species and so possibly identify what may be called critical habitat. For example, some species associate with ice edges (beluga), some with continental shelf edges or seamounts (beaked whales), and some with shorelines (gray whale, bottlenose dolphin, harbor porpoise). For oceanic species, habitat preferences are often defined by less obvious features: physical and chemical characteristics of the water itself, which define water masses and current boundaries. So, for example, some species associate with cold-water currents (Heaviside's *Cephalorhynchus heavisidii*, Commerson's, Peale's *Lagenorhynchus australis* dolphins). Blue whales in the eastern Pacific are found in relatively cool, upwelling-modified waters with high primary and secondary productivity. In the eastern tropical Pacific, pantropical spotted and spinner (*Stenella longirostris*) dolphins segregate from common dolphins according to thermocline depth and strength, sigma-t (a measure of seawater density computed from surface temperature and salinity), and surface water chlorophyll content. These differences are statistically significant, and these species-specific distribution patterns track oceanographic variation on a seasonal and interannual basis.

We know very little about why these species-specific preferences exist. Most often, habitat preferences are suggested to relate to prey abundance or availability, which in turn are determined by physical oceanographic patterns. In fact, a number of studies have linked general distribution and movement patterns of cetacean species (humpback, *Megaptera novaengliae*; fin, *Balaenoptera physalus*; long-finned pilot whales, *Globicephala melaena*; Atlantic white-sided, *Lagenorhynchus acutus*; bottlenose and common dolphins, *Delphinus* spp.) with those of their prey. In a very few instances, physical features have been directly linked with the processes that cause them to aggregate prey or increase productivity, and indirectly with cetacean distribution. This is a productive area for future investigation.

B. How Do Cetaceans Use Their Habitat?

Home range can be defined as an area of regular use that typically provides for all of an animal's requirements. The size of these areas ranges from 125 km^2 for bottlenose dolphins along the west coast of Florida, to 600 km^2 for minke whales (*Balaenoptera acutorostrata*) off the west coast of north America, to thousands of kilometers for many baleen whales, which annually migrate between the tropics and polar seas (and can be thought to occupy two home range areas, separated by large distances). Particularly for odontocetes, very little is known about home range size, but there are indications that it can be quite large. Bottlenose dolphins along the coast of Mexico and California regularly traverse 900 km. Pelagic spinner and pantropical spotted dolphins have been tracked over 500 and 1800 linear km, respectively, in a single year.

Within these home ranges, many cetaceans have well-defined habitat use patterns. This is perhaps best exemplified in species that migrate. These individuals move from high latitudes in the winter to low latitudes in the summer, distances spanning thousands of kilometers in some cases. They feed in their high-latitude habitat, where waters high in nutrients combined with seasonal sun produce a strong bloom in productivity and superabundant food. They mate and calve in their

low-latitude habitat, where little feeding occurs because prey are scarce.

Differential habitat use patterns have also been identified for some non-migratory cetaceans. For example, island populations of spinner dolphins use sheltered bays to rest during the daytime and move to deep waters offshore during the night to feed. Coastal bottlenose dolphins feed in some areas of their range preferentially, sometimes with a seasonal shift, presumably in response to prey movement. Most knowledge of habitat use patterns comes from coastal or neritic species; little is known about how or if pelagic species differentially use their habitat.

II. Food, Feeding, and Foraging

One of the most striking differences between marine and terrestrial ecosystems has to do with the form of primary producers. Whereas terrestrial ecosystems tend to be dominated by large macroscopic plants that are long-lived and provide substantial resources to other organisms in the form of food and physical structure, macroscopic plants are almost completely absent in marine ecosystems. In contrast, marine primary producers are dominated by microscopic, short-lived plants. This has profound implications. Marine herbivores are dominated by small, often microscopic animals themselves, whereas the majority of large marine animals are carnivores, including all cetaceans. Because the vast majority of oceanic habitat is pelagic, i.e., without any benthos, primary producers, herbivores, and consumers tend to be patchy in space and time. Thus the form of marine primary producers affects community composition, resource distribution, and so food, feeding, and foraging of cetaceans.

A. What Do Cetaceans Eat?

Most of what is known about the food of cetaceans comes from data collected from dead animals, through directed fisheries, incidental mortality, or strandings. Prey of cetaceans fall into four general categories. The first prey type consists of small individuals that school at relatively shallow depths (surface to several hundred meters). These are primarily planktonic crustaceans (euphausiids, copepods, amphipods) and small fish [e.g., herring (*Clupea*), sardine (*Sardinops*), anchovy (Engraulidae), sandlance (Ammodytidae)]. They tend to occur in temperate or polar seas or in those tropical latitudes that are associated with unusually high productivity. They generally occupy low trophic levels, have small body sizes, and occur in dense aggregations. Accordingly, the cetaceans feeding on them capture multiple individuals simultaneously, have large body sizes, and have evolved filtering mechanisms (baleen) to strain prey items from the water. All mysticetes feed on this prey type.

The second prey type is composed of larger organisms that also school at relatively shallow depths (surface to several hundred meters) or migrate up to shallow depths during the night. This includes many pelagic fishes [e.g., hake (*Merluccius*), pollock (*Pollachius, Theragra*), myctophids (Myctophidae)] and schooling squids (*Loligo, Dosidicus*), which occur throughout the world's oceans. Because these prey are larger, they generally occupy higher trophic levels and are captured individually. Their cetacean predators typically have smaller body sizes. They include all of the large-schooling dolphins (e.g., dusky, *Lagenorhynchus obscurus*; common, striped, *Stenella coeruleoalba*; spotted dolphins) and some small-schooling or solitary species (e.g., bottlenose, Commerson's, Indian river dolphin). These cetaceans tend to have a high tooth count, pointed TEETH, and pointed snouts, all adaptations for pursuing fast, individual prey.

The third prey type is composed of large, solitary squid (e.g., *Gonatus*). These are most often found in deep waters throughout the world's oceans. Because of their size and solitary habits, they are captured individually. Cetacean predators of these prey include the sperm whales (*Physeter, Kogia* spp.), all of the beaked whales (Ziphiidae), and pilot whales (*Globicephala* spp.). They are deep divers and tend to have reduced dentition, rounded heads, and well-developed melons, the latter perhaps indicative of the importance of echolocation for prey detection in the dark depths.

The final prey type includes species at high trophic levels that are themselves top predators. These include predatory fishes [e.g., tunas (Scombridae), sharks, salmonids], marine birds, pinnipeds, and cetaceans, including the largest of whales [rorquals (*Balaenoptera* spp.) and sperm whales]. Few cetaceans are able to take these prey items. They include the killer whale and, possibly, false killer whale (*Pseudorca crassidens*), pygmy killer whale (*Feresa attenuata*), and pilot whales. Two distinct forms of killer whales occur in waters off the west coast of North America: those that take fish and those that take mammals and birds. There is some indication that these two forms are found in Antarctic waters, and perhaps throughout the world's oceans.

B. How Do Cetaceans Capture Prey?

Cetaceans have two main types of feeding apparatus: baleen and teeth. Baleen is used for straining prey items from the water or, in the case of the benthic-feeding gray whale, from the sediment. Teeth are used for catching individual prey items. Species with a high tooth count use them to grasp individual prey; those with a low tooth count tend to be suction feeders (see later).

We know the most about prey capture strategies for cetaceans that feed on small prey that school at relatively shallow depths (the mysticetes). This is because it is relatively easy to observe these animals feeding in the wild. Mysticetes have BALEEN plates suspended from the roof of their mouths, which they use to strain prey items from the water. The number of baleen plates, their length, and the density of baleen fibers per plate vary between species and are correlated with prey size. Right whales (Balaenidae) and sei whales (*Balaenoptera borealis*) have the greatest number of plates with the finest filtering strands and feed mainly on tiny copepods. Blue whales and most other rorquals have an intermediate number of plates with coarser filtering strands and feed on larger prey items such as euphausiids and small fishes. Gray whales have the fewest number of plates with the coarsest strands and are largely bottom feeders, sifting benthic infauna from muddy substrate.

In addition to specializing on different prey sizes, baleen whales have specialized feeding methods that also correlate with the morphology of their baleen. "Skimmers," the right whales, swim slowly with their mouths open through dense

clouds of slow-swimming copepods. "Gulpers," including most rorquals, lunge into dense schools of euphausiids or fishes with their mouths open, closing them rapidly to trap their prey. All rorquals have throat grooves that run along the ventral surface of the mouth and throat, which allow the buccal cavity to expand during a lunge, taking in huge quantities of water and, with this, prey (Fig. 1). A variation of this type of feeding is used by humpback whales when they form "bubble nets": streams of bubbles emitted from the blowhole as the whale swims in a circular pattern toward the surface. The bubbles form an ascending curtain, which concentrates prey inside. Most of these cetaceans are solitary feeders but they regularly aggregate in areas of high-prey density and, when prey are extremely dense, will feed cooperatively at times, through bubble-net feeding or in staggered echelon formations (Fig. 2).

Cetaceans that feed on larger fish and squid that school at relatively shallow depths capture individual prey items and swallow them whole. High speed is important, as is vision. Typically these predators forage cooperatively, herding prey into tight aggregations and capturing them in turn. Acoustic signaling is presumably important for the coordination of schooling activities. Some cetaceans in this group feed as individuals, particularly those found in coastal areas. They show a wide range of prey capture behaviors, including slapping fish with their flukes and deliberately stranding themselves on the beach in pursuit of fishes.

Cetaceans taking large, solitary squid feed at depth, in partial to full darkness. For this reason, not much is known about how they capture prey. They probably do not feed cooperatively because their prey do not school and because most of these cetaceans occur in small schools and are slow swimming. Most have reduced dentition, and evidence indicates that they are suction feeders, using the gular muscles and tongue in a piston-like action to suck prey into their mouths. How they are able to get close enough to their prey to suck them in remains a mystery. One intriguing idea is that they are able to partially stun prey with echolocation bursts. To date, this hypothesis remains largely untested.

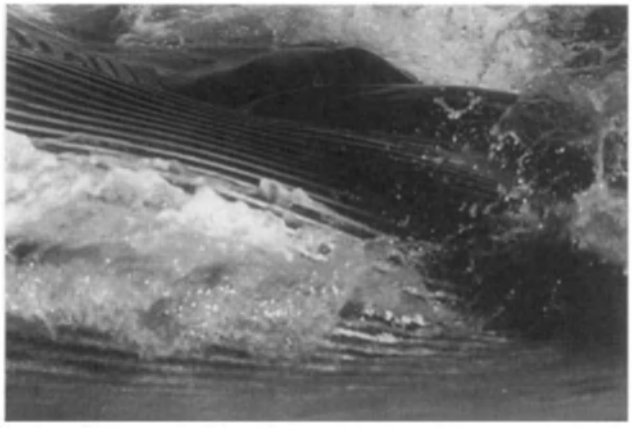

Figure 1 *A lunge-feeding fin whale* (Balaenoptera physalus) *with throat grooves expanded to allow water into the buccal cavity. Note the animal's eye (top, center).*

Figure 2 *A pair of lunge-feeding fin whales* (Balaenoptera physalus) *in echelon formation. The animals are moving left with right sides to the surface. Baleen can be seen attached to the upper jaws and the throat pleats are expanded.*

Cetaceans that prey on top predators show a wide range of prey capture methods: hunting as individuals when prey are small and cooperatively in groups when prey are large. For example, killer whales may take pinnipeds by beaching themselves intentionally to grab adults and pups from ROOKERIES but hunt cooperatively to take dolphins and large whales. Cooperative behaviors include prey encirclement and capture, division of labor during an attack, and sharing of prey.

C. How Do Cetaceans Locate Prey?

Most cetaceans are visual predators, at least in part. For odontocetes, echolocation is equally important in locating and targeting prey, more so than vision in some species. Although only confirmed for a handful of captive species, all odontocetes are assumed to be able to echolocate and to use this sense extensively when foraging. At present, there is no evidence that mysticetes have the ability to echolocate, although they do produce low-frequency sounds that travel long distances (hundreds of kilometers). The long wavelengths of these pulses cannot resolve fine features and are transparent to most schooling prey, so it is doubtful that they could be used to locate and target prey patches.

The effective range of VISION and echolocation is a function of water clarity and the specific echolocation abilities of a species, but both are probably limited to distances on the order of hundreds of meters to a few kilometers. On a larger spatial scale, patchiness and variability in space and time are characteristic of most marine ecosystems and little is known about how cetaceans locate prey in such environments. Presumably, many species simply travel large distances in a continuous search. Here, schooling may increase the chances of encountering a patch (the more eyes and ears, the better), and dolphin schools have been observed moving through the water in wide line-abreast formations, apparently searching for prey.

However, there are circumstances under which prey occur predictably in space and time, and it is likely that cetaceans search for and exploit these opportunities. For example, oceanographic

features (e.g., boundaries between currents, eddies, and water masses) increase prey abundance or availability by enhancing primary production, by passively carrying planktonic organisms, and by maintaining property gradients (e.g., fronts) to which prey actively respond. Topographic features (e.g., islands, seamounts) are also sites of prey aggregation. Therefore, a good foraging strategy is simply to locate these physical features, and many species of cetaceans (right, blue, fin, humpback, sperm, killer whales, spinner, Risso's, common, Atlantic spotted *Stenella frontalis* dolphins) have been found to associate with them.

Many species of cetaceans locate and associate with predictable point sources of prey. For example, killer whales aggregate around pinniped rookeries when young seals and sea lions are weaning. Rough-toothed dolphins (*Steno bredanensis*) associate with flotsam in the oceanic tropics, which serves to aggregate communities of animals at a wide range of trophic levels. A wide variety of cetaceans associate with fishing operations to take their discards or their target species.

And there are times when prey are more accessible than others. The pelagic community of fishes and invertebrates, which live at depth during the day but migrate to the surface at night, provides an opportunity for cetaceans to predictably locate prey near the surface, and some dolphins (spotted, spinner, dusky, common) are known to feed on organisms in this community at night.

III. Cetacean Predators

By far the most important predator of cetaceans is the killer whale (Fig. 3). Its pack-hunting behavior allows it to take everything from the fastest dolphins and porpoises to the largest whales, including blue and sperm whales. Other predators known to occasionally prey on smaller or weakened individuals include large sharks, and possibly false killer, pygmy killer, and pilot whales. Polar bears (*Ursus maritimus*) take cetaceans along the ice edge.

The ecological significance of this predation pressure in the lives of whales and dolphins is difficult to assess, but it may be significant. Individual large whales often show signs of killer whale tooth rake marks on their flippers, fins, and flukes, and up to one-third of the bottlenose dolphins off eastern Australia bear shark bite scars, suggesting that they regularly encounter predators. It has been hypothesized that large whales may undergo their annual migrations in order to reach calving grounds in areas of lower killer whale densities (i.e., the tropics). Aggregative behavior is a common defensive strategy among prey species and it is possible that schooling evolved in dolphins primarily as a defense mechanism against predators (see later). These kinds of behavioral adaptations have cascading effects influencing not only distribution and abundance, but also social structure, timing and mode of reproduction, foraging strategies, and speciation patterns. Predation therefore could play a major role in shaping cetacean communities and life history strategies.

IV. Schooling

Like many other animals, cetaceans form aggregations for two main reasons: feeding and protection. Feeding can bring animals together as passive aggregations in areas of high resource abundance. Alternatively, animals may actively seek others to take advantage of benefits provided by other school members. Schools also serve to protect members from predation, by providing cover for individual members, by confusing predators with synchronized movements of many individuals, by reducing the probability of predation on any one individual, by increasing the chance of detection of a predator, and by providing for coordinated defense. Although occurring in large groups also increases the potential for social interactions, including reproduction, this may only be a secondary benefit of schooling.

The majority of cetaceans occur in schools, although there are some species that regularly occur solitarily or in very small groups of pairs or trios (many mysticetes, large male sperm whales, most beaked whales, *Kogia* spp., and river dolphins). Most schooling species have characteristic school sizes (although they can vary somewhat area to area). For example, rough-toothed dolphins typically occur in groups of 10–20, pilot whales occur in schools of dozens, and some oceanic dolphins (*Stenella* spp., *Delphinus* spp.) regularly occur in groups of hundreds or thousands (Fig. 4).

School size correlates with feeding habits: species that form large schools are almost all shallow-diving species that feed mainly on schooling prey, whereas those that occur in school sizes of 25 or fewer tend to be (a) deep-diving species that feed mainly on larger squids or (b) coastal species feeding on dispersed prey. School size also correlates with predation pressure; large cetaceans, presumably subject to lower predation pressure than small species, occur only in small groups, whereas small cetaceans, subject to higher predation pressure, occur in schools whose size correlates with the openness of habitat: the more open, the larger the school size. School size should correlate with resource availability and will affect reproductive strategies, although the nature of these relationships remains largely unexplored.

Although most schools are monospecific, several species regularly occur in mixed-species schools. Some of these associations appear to be opportunistic: bottlenose dolphins, for ex-

Figure 4 *A school of long-beaked common dolphins* (Delphinus capensis) *in the Gulf of California. These schools typically include thousands of individuals.*

ample, have been recorded to occur with over 20 different species of whales and dolphins. Other associations appear to be more prescribed: spotted and spinner dolphins regularly occur together in mixed schools. Risso's, Pacific white-sided (*Lagenorhynchus obliquidens*), and northern right whale (*Lissodelphis borealis*) dolphins are commonly found in association. The nature of these interactions (e.g., why these species-specific associations occur, how these species avoid competition) is unknown.

V. Communities and Coexistence

Studies of communities typically focus on identifying member species and their interactions and then address mechanisms for their coexistence. These kinds of studies comprise a large part of the ecological knowledge for many terrestrial species. In contrast, almost nothing is known about this aspect of the ecology of cetaceans.

We do know that there are regularly occurring species assemblages (Fig. 5). For example, pantropical spotted and spinner dolphins are frequently found in mixed-species schools in association with yellowfin tuna (*Thunnus albacares*) and are accompanied by large and speciose flocks of seabirds; this association is particularly prevalent in the eastern tropical Pacific, as opposed to other tropical oceans. We know that there are variations in typical co-occurrence patterns. In the Gulf of Mexico, for example, five species of *Stenella* coexist in a relatively small area, more *Stenella* species than any other tropical ocean. The nature of the interactions between species in these assemblages, why they associate, and the reasons for variations in community membership patterns are almost completely unknown.

Coexisting species, particularly those that are closely related or have similar ecological roles, potentially compete for resources. An often cited example is the Southern Ocean, where the relative abundances of cetaceans, pinnipeds, and seabirds, all krill consumers, have been reported to have changed between pre- and postwhaling years. One plausible explanation is competitive release: the decrease in biomass of cetacean predators released a huge prey base of krill to pinnipeds and seabirds, both of which were able to increase in abundance. However, available data on prey biomass, predator consumption, and population status are largely lacking, so the purported changes are in question. In fact, there is little hard evidence to indicate the degree, or existence, of competition between ecologically similar cetaceans.

Ecological theory states that stable communities of coexisting species must differ in resource utilization in some way: prey species or size specialization, differential habitat use, or diel pattern. Such niche partitioning is fairly clear for cetaceans on a broad scale. For example, there are species that feed on fish and those that feed on squid. There are species feeding in shallow water and those that feed at depth. Some cetaceans feed at night and others during the day.

On a smaller scale, one of the best known examples of niche partitioning is for baleen whales. In this group, there is a fair degree of prey specialization that presumably allows for niche partitioning in areas of sympatry. Blue whales feed almost entirely on euphausiids; fin whales and humpbacks feed mainly on fishes but take euphausiids when they are abundant; and right whales and sei whales feed mainly on copepods. Odontocetes provide additional possible examples. Bottlenose, short-beaked common (*Delphinus delphis*), pantropical spotted dolphins, and harbor porpoises exhibit diet specialization among age, sex, and reproductive class, although this diet specialization could be due to differing energy requirements. Aside from these examples, very little is known about how or if cetaceans partition resources.

Ultimately, in order to understand community structure, the mechanisms by which species partition resources, not merely the presence of differences in resource use, are of principal interest. The question then becomes, given that there are differences, what mechanisms can explain them? Community ecologists have identified interference and exploitative competition, mutualism, morphological or physiological factors, and habitat structure as potential mechanisms for maintaining resource utilization differences. This is an area that remains

Figure 5 *A feeding assemblage of long-beaked common dolphins* (Delphinus capensis), *skipjack* (Euthynnus affinis), *brown pelicans* (Pelecanus occidentalis), *Heerman's gulls* (Larus heermanni), *and brown boobies* (Sula leucogaster) *chasing schooling fishes in the Gulf of California.*

almost completely unexplored for cetaceans and the communities in which they are found.

VI. The Role of Cetaceans in Marine Ecosystems

What role do cetaceans play in marine ecosystems and what is their significance? Most cetaceans are apex predators. As such, they take tons of prey from the ecosystem. (Some estimate that cetacean consumption equals or exceeds that of fisheries in the Georges Bank, the continental shelves of the northeastern United States, the northwestern Mediterranean, and the Southern Ocean ecosystems.) In so doing, it seems likely that cetaceans affect the life history strategies and population biology of their prey, as well as organisms at other trophic levels that interact in various ways with these prey. Little is known about the details of these dynamics, although this may be the most significant way in which cetaceans impact marine ecosystems.

More specific effects have been documented. For example, benthic feeders such as gray whales alter habitat by regularly turning over substrate (between 9 and 27% of the benthos in the northern Bering Sea) and therefore significantly affect the species composition of benthic communities. Feeding cetaceans provide feeding opportunities for seabirds by driving prey to the surface, sometimes injuring or disorienting it; in one study, up to 87% of all feeding individuals from four seabird species in the Bering Sea associated with gray whale mud plumes. Large whales dying at sea may sink to the bottom and provide rare but superabundant food and habitat for deep-water species. There is evidence that mollusc communities may have specialized on these resources for the past 35 million years, and some speculate that whale carcasses may have been instrumental in the dispersal of hydrothermal-vent faunas. Feces of some cetaceans, particularly large whales in areas of low productivity, may play a significant role in nutrient cycling. Cetaceans are host to a variety or commensal or parasitic species; in some cases (Cyamid WHALE LICE), these species are completely dependent on cetaceans through all life stages.

VII. Concluding Remarks

The field of cetacean ecology is very much in its infancy. Technological advances and heightened interest will undoubtedly bring greater insight to this discipline in the near future. However, any attempts to make ecological sense of cetaceans as marine organisms and to interpret their distribution patterns, foraging ecology, community structure, and role in ecosystems must take into account the fact that many cetaceans today exist as remnant populations that have been reduced drastically through anthropogenic effects: commercial exploitation, incidental mortality, and habitat destruction. This means that cetacean ecologists must also add conservation biology to the list of disciplines that will likely affect our search for ecological patterns.

Cetacean Evolution

R. EWAN FORDYCE

University of Otago, Dunedin, New Zealand

I. Patterns of Evolution

Fossils show that cetaceans arose from terrestrial ancestors more than 50 million (M) years ago. They have evolved to become the dominant group of marine mammals in terms of both taxonomic and ecological diversity and geographic range. Fossils provide the only direct evidence of cetacean evolution and extinction, revealing many changing patterns over time, but rarely details of rates, modes, and mechanisms of ancestor-to-descendant transitions. Structural, genetic, and ecological patterns in living species also elucidate how Cetacea have evolved. At the species level, evolutionary

processes include natural selection, sexual selection, coevolution, founder effects, vicariance, and hybridization. At larger scales, the distribution and abundance of global food resources have also played major roles in evolution, for there are strong links between changes in ocean structure and ocean ecosystems on one hand and structural/ecological patterns among Cetacea on the other.

II. Paleoecology and Evolution

Ecology encompasses the sum of interactions that species have with their environment, biological, physical, and chemical, whereas paleoecology explores such relationships for the past. At the scale of geological time, evolution and paleoecology are inextricably linked, for evolution occurs through natural selection and adaptation to the environment. An appreciation of paleoecology thus helps understand the history of Cetacea. Several ecological factors have been considered repeatedly in accounts of cetacean evolution (Fig. 1), including feeding and predator/prey interactions, migration, thermal adaptations, and habitat shifts.

For any ancient species, paleoecology can be inferred several ways. A common approach, termed "taxonomic uniformitarianism," assumes that a fossil species had similar ecological strategies to its closest living relatives. Thus, fossil sperm whales presumably were deep divers, and fossil mysticetes were filter feeders. Fossils show that all cetacean lineages have evolved through a long-term change in structure. If such evolution is caused by ongoing adaptation to changing environments, then even within a lineage, ecological strategies will change. For these reasons, taxonomic uniformitarianism must be supported by other methods.

In groups that lack close living relatives, ancient ecologies may be inferred by analogy. The bizarre extinct Peruvian *Odobenocetops* species, or walrus whales, have no structural equivalents among living Cetacea, but their jaw form was remarkably similar to that of the unrelated living walrus, *Odobenus rosmarus*. A comparable style of suction FEEDING on molluscs is inferred. This approach to paleoecology can be expanded by studying functional morphology, which includes reconstructing soft tissues onto fossil bones using known conservative patterns of muscle, nerve, and vessel to bone. Finally, geological evidence (sediment patterns) and geochemical signals (isotopes) can identify the ancient environments in which cetaceans lived, sometimes indicating dramatic or novel ancient ecologies.

Changes in structure and diversity of fossils reveal major functional, ecological, and taxonomic shifts in cetacean history. In particular, these involve an Eocene radiation of archaeocetes and an Oligocene radiation of Neoceti. Ecological shifts in the

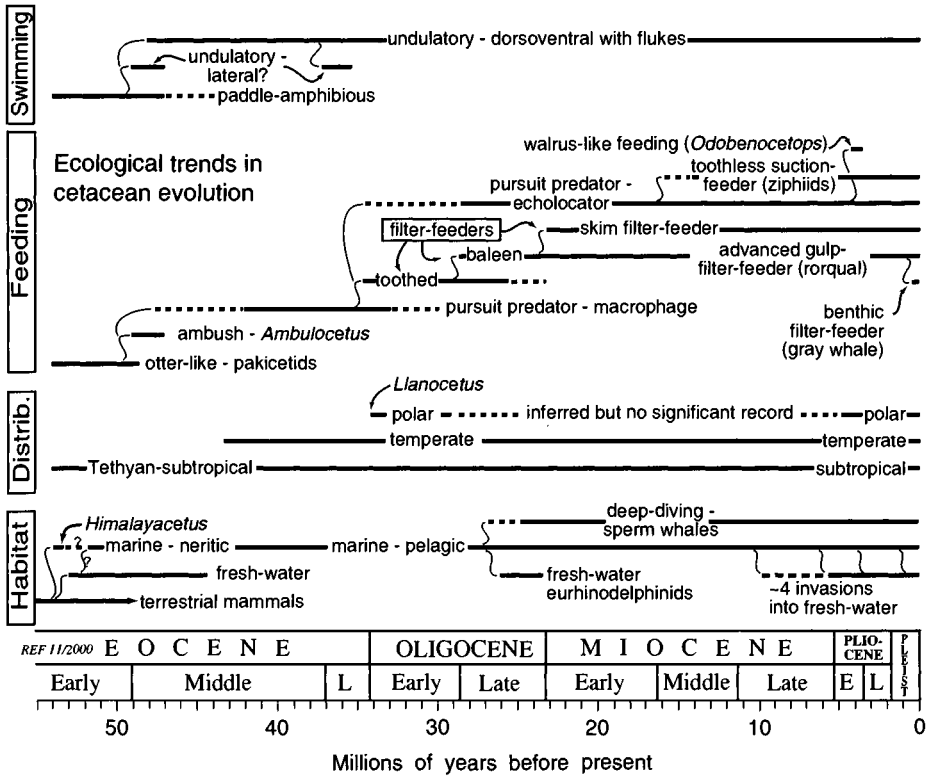

Figure 1 *Summary of inferred ecological strategies important in cetacean evolutionary history. Paleoecology is inferred mainly using taxonomic uniformitarianism (see text). Only selected taxa are shown.*

later Miocene radiation of some odontocetes and mysticetes are less clear.

III. Major Phases of Cetacean Evolution

The fossil record reveals three major radiations in cetacean history (Fig. 2). First, cetaceans diversified in near-tropical shallow waters of the Tethys seaway between India and Asia about 45–53 million years before the present, (Ma), spreading into midtemperate waters by 40 Ma. Presumably this early phase of evolution was influenced by local marine productivity. Up to 6 species in three families of Archaeoceti (stem or basal Cetacea) were present at some times, and >35 species have been reported for the interval 35–53 Ma. This initial radiation of archaeocetes involved shifts from riverine and nearshore marine settings to fully oceanic habits, linked with changes in, for example, locomotory and hearing mechanisms. In terms of structural variation (and, by inference, ecology), these early cetaceans were comparable with living mysticetes and did not show the wide disparity seen among living odontocetes. Archaeocete diversity dropped late in Eocene times, foreshadowing the rise of Neoceti.

The second major radiation, involving the Neoceti or crown group Cetacea, occurred early in the Oligocene. ECHOLOCATING odontocetes and FILTER-FEEDING mysticetes arose from Late Eocene (~35–36 Ma) archaeocetes, which neither echolocated nor filter-fed, and diversified rapidly in about 5 M years. (No certain archaeocetes are known from the Oligocene.) Concurrent events included the final breakup of Gondwanaland, opening of the Southern Ocean, cooling and increased tropics-to-polar temperature gradients, and changes in ocean ecosystems and productivity. Probably, cetaceans radiated in direct response to new ecological opportunities in rapidly changing oceans. By the Late Oligocene interval (23.5–~29 Ma), there were 13+ families and probably >50 species, with some species ranging into polar and fresh waters.

Third, in about the middle of the Miocene (12–15 Ma), seven extant families of mysticete and odontocete appeared. Balaenopterid whales radiated to become the most speciose mysticetes, concurrent with a decline in archaic grades of mysticete ("cetotheres"). Delphinoids—dolphins and relatives—diversified dramatically, particularly the family Delphinidae, but also the Phocoenidae and Monodontidae. Two extinct delphinoid families (Odobenocetopsidae, Albireonidae) appeared briefly. Some archaic cetacean groups, including the Eurhinodelphinidae and Squalodontidae, went extinct at about this time, and the superfamily Platanistoidea (which includes the Squalodontidae) declined almost to extinction. Evolutionary patterns during the Quaternary ice ages (<2.5 Ma) are not clear because of a patchy fossil record. It has been suggested that many north–south species pairs evolved late in Quaternary times, but molecular studies point to older evolutionary events (see later).

IV. Processes: Mechanisms of Evolution

Darwin's original evolutionary mechanism, natural selection, is the process that leads to the adaptation or "fine-tuning"

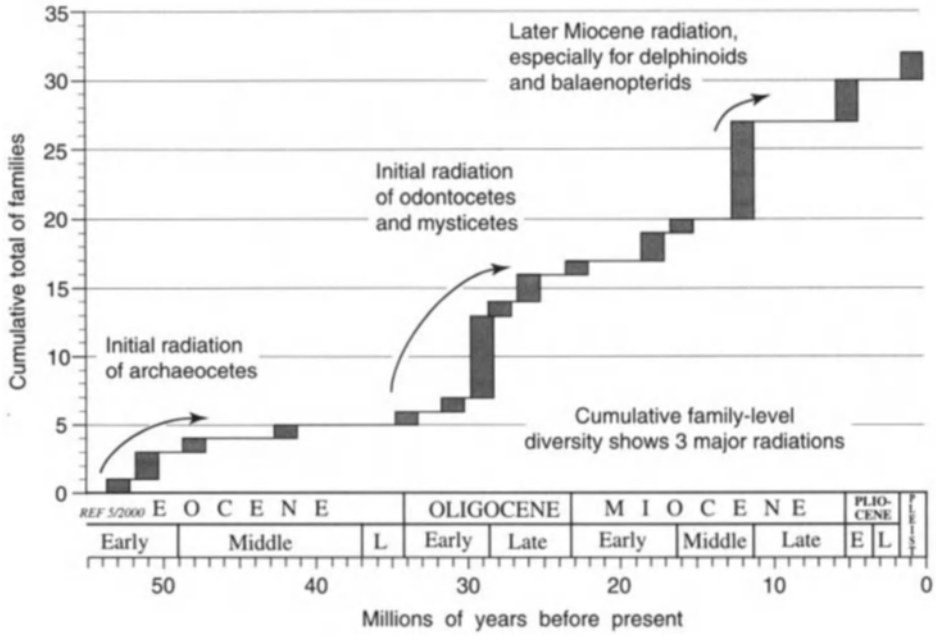

Figure 2 *Cumulative graph of changes in family level diversity over time based on the cetacean fossil record. Three major radiations are apparent. Most of the earliest records for families are based on individual specimens with likely age errors of ±1 million years. With ongoing refinement of dating and the breakup of family level grades, more families are likely to be added in the future, some families of crown group Cetacea will be pushed more firmly back into the Oligocene, and dating errors will be reduced.*

of organisms to the environment through beneficial structure or behavior, resulting in differential reproductive success. Natural selection alone does not, however, explain the origins of novel structures. It is inescapable that the process occurs, although it is not the only one significant in evolution.

Intra- or interspecific competition for limited resources, especially food, has long been viewed as fundamental in evolution. Many cetologists have suggested or implied that competition for food is important among species of baleen whales and between baleen whales and other plankton-eating vertebrates, with implications for the origins of the species involved. However, there is little direct evidence for this. The structure of the feeding complexes of baleen whales, mode (behavior) of feeding, and geographic distribution indicate that niche overlap and thus competition are limited between species. Perhaps previous competition among ancestral species led to taxonomic and ecological divergence seen today. Among fossils, platanistoid dolphins declined in diversity later in the Miocene, as the delphinoids diversified about 12 Ma; this pattern of extinction in one group and radiation in another could indicate that delphinoids outcompeted platanistoids. However, differences in skull structure, especially involving the jaws, imply different ecological requirements, and thus limited competition, between the two groups. Perhaps changing oceanic circulation and climate at about this time caused the extinction of platanistoids and allowed the radiation of delphinoids.

Darwin identified sexual selection as a mechanism in evolution. Here, one sex chooses a specific member of the other sex as a mating partner. Sexual selection might explain the origin of marked SEXUAL DIMORPHISM, particularly in structures involved in display, and has been linked with polygamous mating systems. Dimorphic and possibly sexually selected examples among male Cetacea include the large dorsal fin in *Orcinus orca*, conspicuous mandibular teeth in many ziphiids, prominent foreheads in species of *Hyperoodon* and *Globicephala*, the genital hump in some species of *Stenella*, and the prominent tusks in *Monodon monoceros* and the extinct *Odobenocetops leptodon*. Perhaps the marked size dimorphism in some species also results from sexual selection; examples include male *Physeter macrocephalus*—with its grossly enlarged forehead—and female *Balaenoptera* species.

Hybridization is potentially important in the origin of new species, and cetacean hybrids are known, for example, in *Balaenoptera*, between *Phocoenoides* and *Phocoena*, and between several genera of Delphinidae. However, no convincing cases for evolution by hybridization have been identified in Cetacea.

Coevolution, especially involving mimicry, predator/prey, and host/parasite interactions, has an acknowledged role as an evolutionary process. For cetaceans, mimicry, which graphically illustrates natural selection, is seen in pygmy and dwarf sperm whales, *Kogia* spp.; these have a remarkably shark-like form complete with underslung jaw and pigmented false gill slit. Presumably, to look like a predator will lessen the chance of being preyed upon. Predation has other roles in evolution. The presence or absence of predators (such as the killer whale, *Orcinus orca*) has been used to explain species-specific DISTRIBUTION patterns, including the distinctive and presumably ancient migration patterns of mysticetes from polar to warmer waters for breeding.

Convergent evolution occurs when species show similarity not inherited from a common ancestor. Mimicry is a form of convergence. Among Cetacea, the "river dolphins," long discussed as if they form a real group, encompass species in four different families and in two superfamilies. However, *Platanista* is convergent in its riverine habits, small body size, and long rostrum with the three delphinoid genera *Inia*, *Pontoporia*, and *Lipotes*. In the past, the now-extinct Eurhinodelphinidae included some riverine or lacustrine species, also with long rostra. For living species, the southern delphinid *Cephalorhynchus hectori* is similar in body form and some aspects of ecology and behavior to the unrelated porpoise *Phocoena phocoena* (Phocoenidae). Unrelated groups have convergently reduced and lost teeth, as seen in Physeteridae, Ziphiidae, and some Delphinidae (e.g., *Grampus*).

In biology, there is great interest in the developmental mechanisms leading to rapid evolutionary change in structure. A widely discussed mechanism is heterochrony, which involves a change in timing or rate of development of structures relative to the equivalent processes in an ancestor. Thus, some features might arise when juvenile structures persist into adult stages (paedomorphosis), whereas others arise when structures develop "beyond" that of the ancestral adult stage (peramorphosis). Either process could generate new structures. Apparent paedomorphic features in cetaceans include the shortened intertemporal region and longer vomer and mesorostral groove in Neoceti, the rounded cranium and persistent interparietal bone on the skull of many Delphinidae and Phocoenidae, and the down-turned rostrum and relatively symmetrical SKULL in Phocoenidae. Possible peramorphic features include extra body parts (e.g., increase in number of vertebrae, as in Dall's porpoise, *Phocoenoides dalli*, or phalanges) generated through a delayed halt in development.

V. Geography and Evolution

Darwin realized that speciation is often related to geography. The range of a species may be split by a change in physical habitat (namely, split by a vicariant event) or can be expanded by dispersal beyond normal limits. Populations that become geographically isolated through such events can diverge and, via allopatric speciation, may become new species. Most discussion of such ideas focuses on terrestrial habitats, but there are clear marine parallels. During 50+ M years of cetacean history, geographic changes have included the closure or opening of some straits and ocean basins, dramatic swings in continental shelf habitat area through sea level fluctuations, and major shifts in current systems, upwellings, and latitudinal water masses. Oceanic temperature regimes changed in parallel. This physical evolution of the oceans probably influenced cetacean evolution at many levels. The distributions of modern and fossil Cetacea indicate an important role for geography in evolution (Fig. 3).

Some living species have obvious northern and southern populations or closely related north–south species pairs, but do not occur in the tropics (Fig. 3). Such bipolar or antitropical distributions probably arose allopatrically when populations became isolated either side of the tropics through

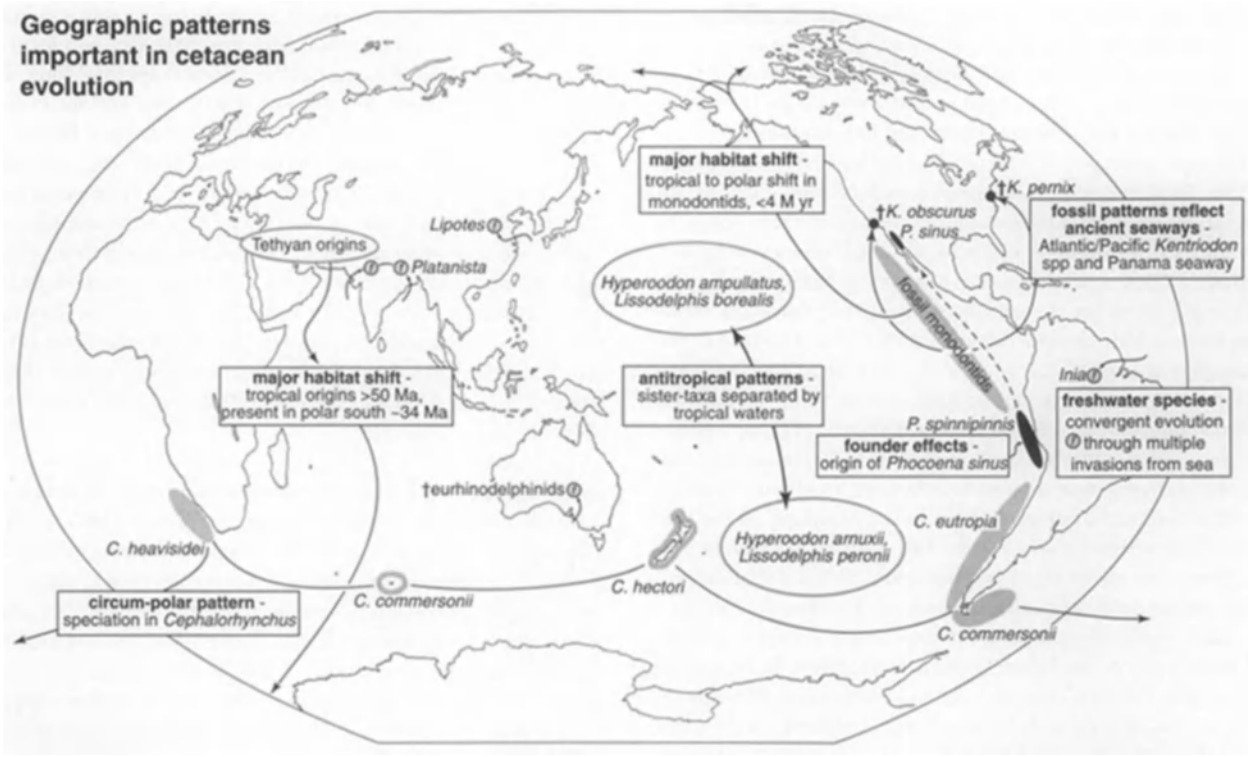

Figure 3 *Distribution patterns illustrating the possible role of geography in cetacean evolution. Patterns indicated include antitropical and circum-Antarctic distributions, allopatric species pairs between oceans, founder effects, convergent origins for various freshwater dolphins, habitat expansion in general for Cetacea (tropical origins, followed later by spread as far as the poles), and geologically recent changes in habitat. Only selected taxa are shown. Fossils are marked with a dagger.*

changing sea temperatures or current regimes, sometimes leading to speciation. Antitropical distributions are marked in populations of rorquals (*Balaenoptera*), species of right whales (*Eubalaena*), some beaked whales (Ziphiidae; species of *Berardius*, *Hyperoodon*, and *Mesoplodon*), porpoises (Phocoenidae), and dolphins (Delphinidae, e.g., *Lissodelphis* species).

Among delphinids, molecular studies reveal that six antitropical species of *Lagenorhynchus* split at varying times, not just during the geologically recent (<2.5 Ma) ice ages, and that these species represent two or more different lineages. At least one genus appears to have speciated around an ocean: four species in the small delphinid genus *Cephalorhynchus* occur around the circum-Antarctic Southern Ocean (Fig. 3). There is some fossil evidence for allopatric species pairs. Closely related species of the small archaic dolphin *Kentriodon* that occur in Miocene strata in California and Maryland perhaps evolved from an ancestor that ranged through the central American seaway before the uplift of Panama.

For porpoises, the endangered vaquita (*Phocoena sinus*), from the Gulf of Mexico, perhaps originated when a few of Burmeister's porpoise, *Phocoena spinipinnis*, crossed the equator only tens of thousands of years ago (Fig. 3). The vaquita, with its limited distribution and low genetic variability, illustrates founder effects; a new population, for example, in an isolated region on the limits of a normal range, may be established by only a few original founders, which are not genetically representative of the original population.

Sea level fluctuations have changed the extent of continental shelf habitat dramatically, especially during cycles of glaciation and cooling over the last 2.5 M years. At peak glaciation, the sea level was >100 m lower than at present, leading to fragmentation or loss of shelf habitat for long intervals, along with colder conditions. This sort of habitat change could lead to extinctions. However, if species' durations typically exceed 100,000 years, as is very likely, then most living cetaceans have survived several of these fluctuations. The record of Late Pliocene and Early Pleistocene Cetacea includes a few species from shallow-water habitats (the dolphin *Parapontoporia*, and cetothere *Nannocetus*), which are now extinct, perhaps as a result of Pleistocene climate changes and/or habitat loss.

Some cetacean groups show significant change in range, even in geologically recent times. The beluga and narwhal (family Monodontidae) are now restricted to cold north polar waters, but during warmer Pliocene times (~4 Ma), closely related extinct monodontids occurred far south in temperate to subtropical waters. Further evidence for changing geographic ranges comes from archaeocetes, which, for about 10 M years after their origin, were subtropical to tropical. In contrast, the maximum diversity for Cetacea is now in temperate waters.

Allopatric speciation results from lineage splitting, or cladogenesis. New species could also evolve by anagenesis, which in-

volves transformation from an ancestral to descendant species without lineage splitting. Anagenetic change would produce a fossil record with several species in unbranched succession and might be expected in lineages containing geographically wide-ranged species. (Species with limited ranges seem more likely to experience allopatric speciation.) Among living Cetacea, the sperm whale *Physeter macrocephalus* and the killer whale represent genera with a single abundant and widely distributed species with no immediate relatives (sister species), and anagenesis might be considered in explaining their history.

Freshwater settings were important in the early transition of cetaceans from land to sea in the Tethys (Fig. 1). Early archaeocetes were amphibious, with well-developed hindlimbs, and they include species from strata deposited in freshwaters. Freshwater habits for some archaeocetes are indicated by oxygen isotopes from TEETH. Fossil Neoceti also show several reinvasions of freshwaters. For example, one unnamed Late Oligocene species of Eurhinodelphinidae occurs in freshwater sediments of central Australia. The dolphin shows no obvious structural adaptations to a riverine or lacustrine habitat, but it is represented by several specimens of slightly differing geological age, indicating a significant long-term occupation of freshwaters. A single large ziphiid fossil is known from Miocene freshwater sediments of Kenya. All the living "river dolphins" arose from marine ancestors, some well known from fossils, which invaded freshwaters in Asia and South America in up to four separate events. Mysticetes seem never to have occupied river systems.

VI. Life History Strategies

In terms of life history traits, cetaceans appear to be *K* strategists. That is, compared with many other mammals, cetaceans are large animals that have slow reproductive rates, produce a single offspring, show significant PARENTAL CARE of young, have long reproductive lives, and have relatively low mortality rates. This rather inflexible reproductive strategy has been linked, in an evolutionary sense, to the nutritional requirements of both the young and parents and thus to food availability. Physical disturbance of the environment and biological effects, such as predation, might be less important in cetacean evolution. The FOSSIL RECORD of cetaceans, which shows major evolutionary change linked to oceanic change, supports the idea that food resources have been fundamental in cetacean history.

VII. Taxonomic Duration

How long do species and genera persist? The fossil record shows that few, if any, species have ranges longer than one geological stage (a stage is a time unit of variable length, mostly 4–5 M years). For extinct Cetacea, the close-spaced succession of Eocene archaeocetes points to species' durations of 1–2 M years. Living species can be traced back into the Pleistocene but not reliably longer, i.e., <2.5 Ma. Molecular studies provide estimated dates for separation of lineages of living species, including 1.9–3 and 3.8–9.6 M years for species of *Lagenorhynchus* and >5 M years for *Balaenoptera musculus* and *B. physalus*. Dates for lineage separation, however, are not necessarily the same as dates for species' durations. For groups beyond the species' level, some living genera have reliable fossil records back to the Early Pliocene or Late Miocene (~5 Ma), including *Balaenoptera, Megaptera, Balaena, Eubalaena, Delphinus* and *Mesoplodon*. Generally, though, generic ranges are uncertain because of inconsistent taxonomic concepts among paleontologists.

VIII. Rates of Evolution

Little is known about rates of evolution in Cetacea. The fossil record identifies phases of rapid radiation, and presumably rapid evolution, in the Early Oligocene and late Middle to early Late Miocene. Unlike the situation for some terrestrial mammals, the cetacean fossil record is not dense enough to reveal quantifiable change in structure over time. For living species, no speciation event has been dated reliably enough to clearly reveal evolutionary rate, but some species (vaquita, *Phocoena sinus*; gray whale, *Eschrichtius robustus*) probably evolved over tens, rather than hundreds, of thousands of years.

IX. Diversity and Disparity

Diversity is the number of species within a taxon such as a genus or family (effectively, an index of taxonomic richness), whereas disparity indicates the variation in structure or basic design within a taxon. Diversity is easy to assess, particularly now that advances in the philosophy and practice of classification have produced a widely accepted species level classification of living cetaceans, but the study of disparity is still developing.

A comparison of the two living clades Odontoceti and Mysticeti reveals quite different patterns of diversity (Fig. 4) and disparity. Mysticetes include 12 species in three or four families. The Balaenopteridae is most speciose, with 8 species in two genera (*Balaenoptera*, 7; *Megaptera*, 1). Broadly speaking, species of *Balaenoptera* vary in size, distribution, and behavior, but species boundaries may be blurred. Species are distinguished mainly on aspects of the feeding apparatus (baleen size and spacing, size and shape of the upper jaw), and skeletal differences are rather minor. Thus, disparity appears low. The gray whale, *Eschrichtius robustus*, is structurally quite different (disparate) from other mysticetes and is placed in its own monotypic family. The gray whale probably arose geologically recently (~0.5 Ma?) among the balaenopterids and might be classified with that family despite its different form. In this case, disparity does not indicate taxonomic distance.

Odontocetes include 71–72 species in 10 families. With its 36 species, Delphinidae is the most diverse family of cetaceans, and disparity seems much higher than, for example, within Balaenopteridae. Among delphinids, there is a greater variation in body size and proportion, skull form, proportions of the feeding apparatus and teeth, and distribution of air sinuses in the skull base. Among beaked whales (Ziphiidae; 20 species), the genus *Mesoplodon* has 13–14 rather similar species in which only adult males are separated easily. Disparity here appears low and awaits explanation in terms of evolutionary ecology within the genus. Among other odontocetes, 4 species of small long-beaked "river dolphins" each represent a single family (Iniidae, Pontoporiidae, Lipotidae, and Platanistidae). Although

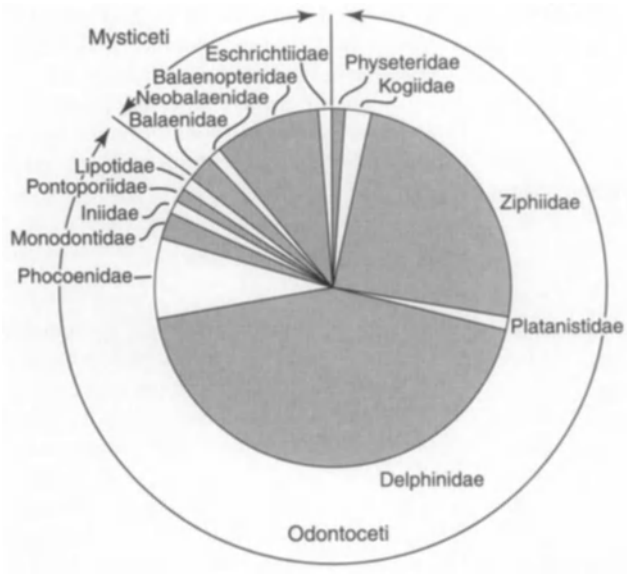

Figure 4 *Patterns of species' diversity at the family level among living Cetacea. Traditionally, families are clusters of species and genera with a similar body plan; thus, families usefully reveal disparity at high levels within the Cetacea. Mysticetes are less speciose and less disparate than odontocetes; delphinids and then ziphiids are the most speciose and most disparate of the odontocetes. Species' counts are derived from Rice (1998).*

these "river dolphins" are superficially similar externally, they are highly disparate in terms of skull form; this disparity supports the separation into 4 families. Of note, Iniidae, Pontoporiidae, and Lipotidae are related closely to delphinoids, whereas *Platanista gangetica* is a highly disparate species in its own family (Platanistidae), in turn in the ancient and once diverse superfamily Platanistoidea, which originated about 30 M years ago. For *Platanista,* Platanistidae, and Platanistoidea, diversity is low (1 living species of *Platanista*, with no fossil record) and disparity is high.

As a group, odontocetes are clearly quite disparate. Huge variation is seen in the skull, involving the shape, size, and sometimes basic construction of the feeding apparatus and teeth, facial region, including bony origin for nasofacial muscles implicated in echolocation, nasal passages, acoustic system, and air sinuses in the skull base. Disparity might be viewed as caused by reduced constraints on body form, allowing specialization in many different directions. This explanation for disparity, however, does not explain the ultimate origin of structural diversity.

X. Extinction

EXTINCTION, the disappearance of lineages, is a fundamental complement to evolution. Extinction obviously occurs when the number of individuals and geographic range drops to nil. The fossil record reveals that extinction is inevitable and, for lineages, usually terminal; only a few species go extinct by evolving into descendants. Among different styles of extinction, there is no evidence that cetaceans have been involved in mass extinction comparable to that affecting dinosaurs. Taxonomic extinction (the disappearance of a real group or taxon) has occurred, as shown by the fossil record of such well-defined clades as the odontocetes Eurhinodelphinidae and Squalodontidae, and the *Cetotherium* group mysticetes. As noted earlier, environmental change might explain the demise of such groups through loss of habitat or food or of intolerance of cold. Most extinction has probably involved the piecemeal extinction of single species, but the cetacean fossil record is too patchy to expect pattern or cause to be clear. Species susceptible to extinction are those in low-diversity clades (e.g., one or two species in a genus, with no close relatives) occurring in geographically limited physical settings that are unstable over geological time; for Cetacea, this means particularly the "river dolphins." Conversely, widely distributed oceanic species would seem resistant to extinction by other than human agencies.

Patterns of extinction beg a question that ecologists might consider unthinkable: are there vacant modern niches that formerly were occupied by Cetacea? For example, Platanistidae lived in shallow marine settings until about 10 Ma and now occur only in freshwaters, whereas species of Squalodontidae and Eurhinodelphinidae were widely distributed before their demise in the later Miocene. Judging from the functional complexes seen in the latter fossils, there are no modern equivalents to these groups. Functional studies are needed to see if some extant taxa may be the ecological equivalents of the extinct forms.

Cetacean Life History

SUSAN J. CHIVERS
Southwest Fisheries Science Center, La Jolla, California

A species' life-history strategy is defined by parameters that describe how individuals allocate resources to growth, reproduction, and survival. The allocation of resources presumably results from natural selection maximizing the reproductive fitness of individuals within a species. Biologists studying life-history strategies collect data to answer questions about how long individuals of a species live, the ages at which they become sexually mature and first reproduce, and where and when they travel to find sufficient food to survive (Fig. 1). In search of answers, these biologists may be found in a laboratory estimating an individual animal's age, at a computer modeling growth rates, or at sea observing animals in their natural habitat.

Among cetacean species, the life-history strategies are diverse and differ markedly between the two cetacean suborders: baleen whales (suborder Mysticeti) and toothed whales (suborder Odontoceti). This diversity demonstrates the range of successful strategies that have evolved and enable cetaceans to live in a completely aquatic environment as well as the influence of their phylogeny on adapting them to a particular niche. Reviewing the strategies of species within each suborder reveals that the baleen whales share more similar life-history characteristics. All species are large and long-lived, and all of the baleen whales, except the bowhead whale (*Balaena mysticetus*) and Bryde's whale (*Balaenoptera edeni*), make long-range annual migrations between breeding grounds in tropical waters and feeding grounds in temperate or polar waters. However, the life-history patterns observed among odontocetes are more varied. These species range in size from the small, relatively short-lived (<24 years) harbor porpoise (*Phocoena phocoena*) to the large, relatively long-lived (>70 years) sperm whale (*Physeter macrocephalus*) and occupy diverse habitats, ranging from pelagic and coastal ocean waters to estuarine and fresh waters.

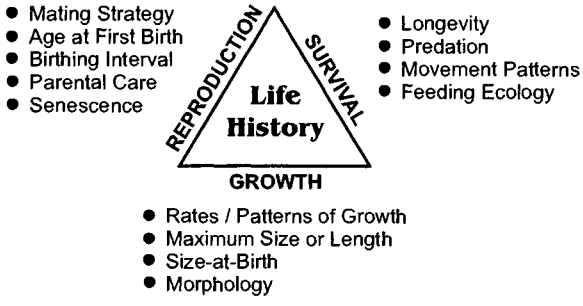

Figure 1 *Studies of cetacean life history integrate data describing an individual animal's allocation of resources to growth, reproduction, and survival. Compiling data from many individuals allows the parameters listed next to each category to be estimated, which in turn describes the growth, reproduction, and survival strategies of a species. Life-history data may be collected by observing individual animals in directed photo identification, tagging, marking, or telemetry studies or by necropsying animals to collect teeth for aging, body length measurements for quantifying growth rates, gonads for determining reproductive condition, and skin for estimating individual relatedness or determining "local" adaptations using molecular genetic techniques.*

The life-history strategies for relatively few cetacean species are known in detail. Most of the biological data available for baleen whales were collected during whaling operations, whereas odontocetes have been studied from animals incidentally taken during fishery operations, taken in directed fisheries, found stranded on the beach, or observed in the wild or in captivity. Among the most well-known cetacean life histories are those of the humpback whale (*Megaptera novaeangliae*), fin whale (*B. physalus*), common bottlenose dolphin (*Tursiops truncatus*), and killer whale (*Orcinus orca*). Three of these species—the humpback whale, common bottlenose dolphin, and killer whale—have each been the subject of long-term studies, which have provided unique data about the natural variability of a species' life-history strategy based on the observed demographics of individual animals. Our knowledge about the life-history strategies of cetacean species is still incomplete, particularly for rarely encountered species, but our knowledge is expanding rapidly as more specimens are collected and new techniques are developed.

I. Characteristics of Cetacean Life Histories

Although a diversity of life-history strategies is exhibited by cetacean species, there are a few common characteristics that are likely the necessary adaptations for life in a completely aquatic environment. All species give birth to single, large, and precocial young. The presence of multiple fetuses or multiple births has been documented only rarely, and there are no known cases of successfully reared multiple offspring. Gestation times are approximately a year. Among the baleen whales, the estimates for gestation range from 10 to 12 months, and among the odontocetes, estimates range from 10 months for the harbor porpoise (Gaskin *et al.*, 1984) to 14 or 15 months for the sperm whale (Best *et al.*, 1984) and 17 months for the killer whale (Olesiuk *et al.*, 1990; Baird, 2000). Most of the small delphinids (e.g., *Stenella* spp.) have gestation periods of 11 to 12 months (Perrin and Reilly, 1984). The length of the gestation period in part balances the cost of producing a large neonate. Additionally, all cetaceans are relatively long-lived. Among odontocetes, estimates of longevity range from approximately 2 decades for the harbor porpoise to up to 7 decades for the sperm whale, and for the baleen whales, estimates of longevity range from 6 decades for the common minke whale (*B. acutorostrata*) up to 9 or 10 decades for the fin whale. Additional generalizations about life-history strategies are presented in Section III.

II. Methods of Studying Life Histories

Longitudinal and cross-sectional studies of cetacean species have provided data necessary for understanding their life-history strategies. Longitudinal studies are rare but valuable because they provide unique data on the variability of individual demographics. Three species—the humpback whale (Clapham, 1996), the common bottlenose dolphin (Wells and Scott, 1990), and the killer whale (Olesiuk *et al.*, 1990)—have been the subject of ongoing studies that originated during the 1970s. These studies are possible because individuals are relatively accessible and easily distinguishable in the field by natural markings. These studies have quantified individual variability in reproduction and survival through time and have provided unique insights into the species' life-history strategy by incorporating observations of the species' social behavior and ecology. However, most of our knowledge about cetacean life-history strategies is the result of cross-sectional studies. In these studies, data are collected from individual animals sampled primarily from directed or incidental takes. The primary advantage of these studies is that a complete suite of morphological and biological data can be collected, which allows explicit determination of reproductive and physical maturity as well as an estimate of age. Estimates of age are made from the layering patterns evident in the ear plugs or ear bones of baleen whales (Lockyer, 1984; Christensen, 1995) and in the teeth of odontocetes (Perrin and Myrick, 1980). Accurate determination of reproductive maturity in both sexes requires examination of the gonads. In females, the presence of one corpus or more in the ovaries indicates sexual maturity, and in males, the presence of spermatazoa and large seminiferous tubules in histologically prepared testes tissue indicates sexual maturity (Perrin and Reilly, 1984). Physical maturity is determined in both sexes by examining the vertebral column for evidence of fusion. That is, when the vertebral epiphyses are fused with the centrum, an animal is considered physically mature.

Life-history studies are designed to collect data on body size, age and reproductive and physical maturity from many individuals in order to estimate parameters that characterize a species' allocation of resources to growth, reproduction, and survival. Estimated parameters may include age-specific growth and pregnancy rates, the average age at attainment of sexual maturity, calving interval, and longevity. Age is the primary independent variable for all studies because age explicitly demonstrates the trade-off in resource allocation to growth and reproduction during an individual animal's life. The expected pattern of resource allocation from birth through attainment of sexual maturity is primarily for growth and then for reproduction once sexual maturity is attained. Also, the probability of an individual surviving to the next age class increases with increasing age after weaning until sexual maturity is attained and then remains high throughout the individual's reproductive years. Data on age-specific growth and reproductive rates, combined with estimates of age-specific survival rates, are essential to comparing and contrasting the life-history strategies of different species.

III. Cetacean Life-History Patterns

Neonates of all cetacean species are relatively large when compared to those of other mammal species. In fact, neonate size ranges from approximately 29% of the female's asymptotic total body length in most of the baleen whales to between 40 and 48% of the female's length in odontocetes. The large size of neonates, combined with their ability to swim and grow rapidly immediately after birth, increases their probability of survival. The lactation period for the baleen whales lasts only about 6 months, and the young grow rapidly during that period because the fat content of the milk is high. However, the calves of odontocetes grow more slowly, and the lactation period lasts approximately a year or more. The difference in calf growth rates between the two suborders of cetaceans is probably due to the transfer of energy to the young through the milk. Oftedal (1997) estimated that the energy output through milk ranges from 0.40 to 1.06 $MJ/kg^{0.75}$ for mysticetes and from 0.09 to 0.17 $MJ/kg^{0.75}$ for odontocetes. For species with a lactation period of more than a year, the additional investment likely further increases the calf's probability of survival by facilitating the learning of social behaviors [e.g., common bottlenose dolphin, short-finned pilot whale (*Globicephala macrorhynchus*)].

Patterns of growth differ between the sexes of many cetacean species, resulting in some degree of sexual dimorphism. Both males and females have high growth rates while suckling, but growth slows after weaning and again after reaching sexual maturity. However, the sex that grows largest tends to grow for a longer period of time and may have higher growth rates after weaning. Among baleen whales, females attain lengths that are generally 5% larger than males. Similarly, among odontocetes, females are slightly larger than males in the porpoises and river dolphins. However, for other odontocetes, males are larger than females. Sexual dimorphism is most marked in sperm whales, in which males are 60% larger than females. Among the smaller delphinids, such as the common bottlenose dolphin, pantropical spotted dolphin (*Stenella attenuata*), and common dolphins (*Delphinus* spp.), males are approximately 2 to 10% larger than females.

The breeding cycle for all cetacean species has three parts: a gestation period, a lactation period, and a resting, or anestrous, period. This cycle is 2 years or more for most cetacean species. Exceptions are the minke whale and harbor porpoise, which can breed annually. The breeding cycle of blue (*B. musculus*), Bryde's, humpback, sei (*B. borealis*), and gray (*Eschrichtius robustus*) whales includes an 11-month gestation period, a 6- to 7-month lactation period, and a 6- to 7-month resting, or anestrous, period for a minimum of a 2-year cycle, while the breeding cycle for the bowhead and right whales (*Eubalaena* spp.) is 3 to 4 years starting with a 10- to 12-month gestation period. Furthermore, the breeding season of baleen whales is synchronized with their migration cycle. These species travel long distances to breed in tropical waters. Exceptions are the Bryde's whale, and the pygmy Bryde's whale, which spend all year in tropical waters and do not breed synchronously (Lockyer, 1984). Several hypotheses have been proposed for the adaptive significance of the large-scale migrations of baleen whales. Although the phenomenon remains unexplained, hypotheses of increased survival rates for neonates in tropical waters by reducing thermoregulatory demands or the risk of predation by killer whales have been proposed (Corkeron and Connor, 1999).

Similar to other life-history characteristics, the breeding cycle for odontocetes is more variable than that of mysticetes. Porpoises have the shortest breeding cycle, which is approximately 1 year and includes a 10-month gestation. In fact, annual breeding among porpoises has been well documented for the harbor porpoise. The smaller delphinid species seem to have 2- to 3-year calving intervals, which include an 11- to 12-month gestation and a 1- to 2-year lactation period. However, larger odontocetes, such as the killer whale, short-finned and long-finned (*G. melas*) pilot whales, and sperm whale, have calving intervals of >3 years, which includes a 12- to 17-month gestation period and a 2- to 3-year, or longer, lactation period. Breeding synchrony also varies among odontocetes. Species inhabiting temperate waters, such as the harbor porpoise, have been found to have more synchronous breeding seasons than species inhabiting tropical waters. For example, studies of the pantropical spotted dolphin (Fig. 2) and the striped dolphin (*S. coeruleoalba*), which inhabit tropical waters in the Pacific Ocean, found that young are born throughout the year, although most births occur during the spring and fall (Perrin and Reilly, 1984).

Age at attainment of sexual maturity is delayed in all cetacean species as would be expected for large, long-lived mammals. However, the range of ages is quite broad and reflects the unique set of adaptations that characterize the life-history strategy of each species. The range in age of sexual maturity among baleen whales is from approximately 4 years for the bowhead and humpback whales to approximately 10 years for fin and sei whales (Lockyer, 1984). Among odontocetes, the range in age at attainment of sexual maturity is about the same as that observed for baleen whales and seems to be correlated to a degree with longevity and body size. The youngest age at attainment of sexual maturity is 3 years for the harbor porpoise, which is among the smallest odontocetes and is estimated to live approximately two decades (<24 years). However, many of the larger odontocetes reach sexual maturity at ages of 10 years or more and live for four or more decades (Perrin and Reilly, 1984).

Reproductive success varies throughout the life of female cetaceans. Initially, reproductive success is relatively low, peaks several years after the age at attainment of sexual maturity, and then declines as the female ages. This phenomenon is also characteristic of large terrestrial mammals and is probably due in part to a trade-off in costs between reproduction and growth that must occur because physical maturity is attained several years after sexual maturity and to learning to care for young. Evidence for low reproductive success among newly matured females has been documented in the common bottlenose dolphin and the fin whale. Lower reproductive rates for older females have also been documented in the common bottlenose dolphin as longer interbirth intervals for older females that include a 3- to 8-year lactation period. Postreproductive females with senescent ovaries have been identified in only a few odontocetes, including the short-finned pilot whale (Marsh and Kasuya, 1986) and the pantropical spotted dolphin (Myrick *et al.*, 1985), but senescence has not yet been identified in any of the baleen whales. The adaptive significance of senescence is not yet understood but likely contributes to increased reproductive success. For example, several species that exhibit senescence also have fairly complex social structures (e.g., sperm whale, short-finned pilot whale), and the role of postreproductive females in their societies may be associated with increased survival rates of the young by these females participating in the care of young that are not their own.

IV. Characteristics of Male Life Histories

The life-history characteristics of males are less well known than those of females, primarily because this knowledge is less critical to understanding a species' reproductive potential and population dynamics. In this sense, females are the limiting sex. However, knowledge about the life-history strategies of males provides a more complete picture of a species population dynamics and provides information about the species' breeding strategy and social structure.

One of the major differences between the life-history strategies of male and female cetaceans is the age at attainment of sexual maturity. In species with the greatest degree of sexual dimorphism, the difference in age at attainment of sexual maturity for males and females is greatest. This difference reflects the additional time required to grow to about 85% of their asymptotic length, which is the approximate size at which all mammals become sexually mature. For example, sperm whale males reach sexual maturity at a much later age than females. The estimated age at attainment of sexual maturity for the female sperm whale is from 7 to 13 years and for males is approximately 20 years (Rice, 1989; Best *et al.*, 1984). The difference is similar in the killer whale and the short- and long-finned pilot whales (Baird, 2000; Lockyer, 1993). However, the smaller delphinid species that show less sexual dimorphism

reach sexual maturity at more similar ages. In fact, the difference in age between the sexes is about 3 years for the common bottlenose dolphin, pantropical spotted dolphin, and spinner dolphin (*S. longirostris*), with males reaching sexual maturity at the older age (Perrin and Reilly, 1984).

Sexual dimorphism has been used as a predictor of cetacean mating systems. For example among odontocetes, the degree of sexual dimorphism exhibited by the sperm whale, short-finned pilot whale and killer whale has been hypothesized to indicate male-male competition in a polygynous mating system. The presence of scars inflicted by other males provides evidence of male-male competition in sperm whales. However, fairly recent data that the short-finned pilot whale and killer whale have limited male dispersal from natal pods and likely breed promiscuously suggests that sexual dimorphism may have evolved for reasons other than mating. One interpretation of these data is that the presence of large males in their natal pod enhances their reproductive fitness by improving, for example, the foraging efficiency of the pod (Wells *et al.*, 1999).

V. Life-History Parameters and Demography

Knowledge of a species' life-history strategy provides the foundation for understanding the species' demography because their life-history characteristics reflect the species' adaptations to a particular niche, which is bounded by constraints of the environment as well as their morphology and physiology. Whereas life-history studies focus on individual variability in traits that express these adaptations, each study can usually only focus on a particular group of animals within the species. The comparison of studies made on different groups of animals within a species' range, however, reveals variability in life-history parameters. For example, pantropical spotted dolphins north and south of the equator have different breeding seasons, and the estimates of asymptotic length for animals in the western Pacific are 4 to 7 cm longer than those from the eastern Pacific (Perrin and Reilly, 1984). Similar examples exist for other cetacean species. There are also examples in the literature of cetacean populations responding to changes in the availability of resources through time. This is called density dependence. For example, changes in the age at attainment of sexual maturity for fin, sei, and minke whales through time have been reported and are presumed to be a response to increased per capita resource availability following reductions in population abundance that resulted from commercial whaling (Lockyer, 1984). Similarly for the striped dolphin and the spinner dolphin, changes in the age of sexual maturity and pregnancy rates have been reported and explained as responses consistent with increased resource availability that resulted from decreased population abundance (Perrin and Reilly, 1984). In addition to understanding a species' life-history strategy and its inherent variability, recognition of these types of population-level responses is important to consider when developing conservation and management plans.

Estimates of age-specific reproductive rates and survival rates are critical to quantifying a species' demography. However, for nearly all cetacean species, age-specific survival rates are unknown and are likely to remain so. Because demographic studies must include age-specific survival rates, unique solutions have been sought to allow the estimation of survival rates based on imperfect knowledge (Barlow and Boveng, 1991). Longitudinal studies like those of the common bottlenose dolphin and the humpback whale provide the only source of data to estimate survival rates, and these data are generally used as a guide for estimating survival rates for other species with similar, but less well-known, life histories.

VI. Life-History Studies and the Future

Several new technologies are being actively applied to studies of cetacean species and contribute to our knowledge about the adaptive significance of their life-history strategies. Specifically, the expansion of molecular genetic techniques and the development of satellite and VHF (Very High Frequency) tracking technology allow more detailed data collection on individual animals. For example, the application of molecular genetic markers as tags for individuals has been demonstrated successfully with the humpback whale data set (Palsbøll, 1999). Application of this technique to cetacean species whose individuals cannot be recognized readily by natural marks may facilitate life-history studies for those species. Additionally, the results of molecular genetic studies on several cetaceans, including the beluga whale (*Delphinapterus leucas*) and Dall's porpoise (*Phocoenoides dalli*), have confirmed hypotheses of male-biased dispersal (O'Corry-Crowe *et al.*, 1999; Escorza-Treviño and Dizon, 2000). Although this is not a surprising result because male-biased dispersal is common among large terrestrial mammals, molecular genetics provided the tool to examine large enough data sets to ask this question for cetacean species. In addition to the expansion of molecular genetic analy-

Figure 3 *A pantropical spotted dolphin* (Stenella attenuata) *wearing a radio tag and time-depth recorder to study diving behavior. Photograph by M. D. Scott.*

ses to studying cetaceans, the development of satellite and VHF tracking technology is continuing. There have been notable successes in the use of satellite tags to study beluga whales in the Arctic (Martin *et al.*, 1998) and blue whales in the North Pacific (Mate *et al.*, 1999). Broader application of this technology to study more individuals of more species has been limited in part by problems with tag attachment, but this technology, together with the expansion of molecular genetic techniques, will provide us opportunities for new insights into the life-history strategies of more cetacean species (Fig. 3).

Cetacean Physiology, Overview

ROBERT ELSNER
University of Alaska, Fairbanks

> Though whales are the strangest of all mammals—the farthest out from the mainstream of mammalian life—they have no structures fundamentally new but only familiar ones reworked.
> —V. B. Scheffer, "The Year of the Whale," 1969.

Dolphins, porpoises, and whales occupy a special place in human interactions with the world of nature. Our fascination with them has its origins in a distant past. However, despite that long association, they remain the least accessible and least known of the mammals. Important pioneer investigations have been successfully applied to small captive cetaceans, but the obvious constraints of sheer magnitude have prevented all but the most rudimentary physiological studies of great whales.

The obligate cetacean aquatic lifestyle imposes environmental constraints with physiological consequences vastly different from those of terrestrial mammals in their atmospheric environments. However, most, if not all, of their adaptations are extensions of or variations on the general mammalian theme. The physical properties of water dominate these considerations:

water is 1000 times more dense than air, its viscosity is 60 times greater, heat is transferred through it at a rate about 25 times that of air, light penetration is much reduced, and the salt concentrations in sea water are substantially higher than those of the body fluids. Cetacean lungs, characteristically mammalian, are designed for aerial respiration. Without looking further, one may well suspect intuitively that living in water can have big disadvantages, imposing severe problems on respiration, foraging in long and deep dives, temperature regulation, vision, and navigation.

In contrast, what advantages are there in aquatic residence for a mammal that evolved originally from land-dwelling ancestors? Virtual weightlessness, for one; generally abundant and easily obtained food sources, for another. Whatever potential problems in the transition to the sea have been well dealt with by evolutionary natural selection. Cetacean adaptations range over the wide gamut of physiology and affect the responses of species from small porpoises to the blue whale (*Balaenoptera musculus*), the largest mammal ever to have lived, a range in body mass of more than 2000-fold. These adaptations for swimming, diving, maintaining temperature and salt equilibrium, navigating, and foraging endow the cetaceans with extraordinary facility in the sea. We have only the most rudimentary knowledge of the physiological mechanisms underlying these adaptations. Expressions of behavior are intimately related to these questions, and many physiological reactions are shaped by behavioral aspects of cetacean life (Wells *et al.*, 1999).

The long history of human interactions with cetaceans has been marked with wonder and mystery (Matthews, 1978). We admire the exploits of dolphins, and we have engaged in titanic battles for the harvest of great whales. Human exploitation of whales dates at least from the 12th century. They have been major suppliers of oil, food, and BALEEN—the "plastics" of previous ages. In addition to active hunting, whale carcasses that washed ashore in prehistoric times were doubtless used for whatever food value could be salvaged. Consumption, rather than study, has been the major preoccupation with this animal resource. However, incidental examinations of anatomy aroused curiosity of how these massive bodies operated.

Captive smaller cetaceans have been studied to good advantage (Irving *et al.*, 1941; Kanwisher and Ridgway, 1983; Williams *et al.*, 1993), but the massive size of whales severely limits their experimental manipulation. Even simple observations in their natural habitats challenge our ingenuity. Speculations about relations between structure and function have dominated our approach to understanding how whales work. With a few exceptions, we still engage in free deduction from morphology for our best guesses. The practice of extrapolation from anatomy to mechanism, functional morphology, has a long history. It works sometimes, but its indulgence must always be regarded with care because it can lead to misconceptions and error. Nothing beats controlled experimentation, in the field or laboratory, for the elucidation of physiological mechanisms and the regulatory processes that govern them.

Experimental physiological investigations of how the living cetaceans function are gradually becoming a reality, and they offer an especially promising research frontier in which field and laboratory studies will be advantageously combined. Accordingly, with the prospect of a new era in cetacean physiology in the offing, it can be useful to review briefly what we know and to consider the prospects for improved investigative efforts.

I. Diving

Clearly, the ability to dive, whether by brief and shallow breath holding or in long and deep submergence, is essential for productive existence in the oceans. We have some information about the dive durations and depths of which cetaceans are capable, but with the exception of relatively few studies on small cetaceans, we know only very little about the mechanisms that sustain them. Most of what we do know about marine mammal DIVING PHYSIOLOGY is derived from studies of seals, especially the phocid, or earless, seals [e.g., harbor (*Phoca vitulina*), elephant (*Mirounga* spp.), Weddell (*Leptonychotes weddellii*) and gray (*Halichoerus grypus*) seals], but there is no obvious rationale for simple extrapolation from that knowledge to diving cetaceans. However, the similarities among diving responses of many mammals and birds in resisting the effects of diving suggest that the cetacean responses are variations on that central theme (Kooyman, 1989; Elsner, 1999).

Cessation of respiration and increased pressure are conditions of submergence. It is reasonable to suspect that the cardiovascular system plays an important role in dives because of the observed lowering of heart rate (bradycardia) while diving that has been observed in several studies of captive small cetaceans. Protection against the problems of high pressure experienced during deep dives are poorly understood, but the structure of thorax and lung suggests some adaptive reactions. Protective lung collapse that prevents absorption of lung gases in deep dives has been demonstrated in captive dolphins and in excised whale lungs. However, these are but the beginnings of what research will be required for the comprehensive understanding of reactions to such dives.

The consequence of breath holding during submergence is an unrelenting depletion of the oxygen stores that are primarily sequestered in muscle myoglobin and blood hemoglobin, both of which are augmented in most cetacean (and pinniped) species when compared with oxygen stores of terrestrial mammals. Decreased oxygen availability (hypoxia) is accompanied by other important consequences of breath holding: increasing levels of carbon dioxide (hypercapnia) and steady accumulation of the acid by-products of anaerobic metabolism (acidosis). This combination—hypoxia, hypercapnia, and acidosis—is defined as asphyxia, and it is this steadily progressing condition that ultimately limits the duration of the dive.

II. Temperature Regulation

Of all the world's marine mammals, only sirenians (manatees and dugongs) and cetaceans remain immersed in water throughout their lives, and they venture onto land only at their peril. The sirenian requirement for warm water contrasts with the more thermally robust nature of cetaceans and requires restriction to warm coastal tropic seas, but cetacean species are found in all of the world's oceans and in several tropical freshwater rivers. Some species are regularly exposed to the high heat transfer characteristics of cold polar water, and this con-

dition raises questions about how they maintain body temperature. Other questions concern the ability of great whales to avoid overheating while exercising.

The thermal characteristics of the aquatic medium raise questions about the maintenance of body temperature. The high conductivity and convective heat transfer of water require marine mammals to have effective insulation, in cetaceans consisting mostly of subcutaneous BLUBBER. Body size becomes an important consideration here because heat loss is determined in part by the relationship of body mass and surface area. The geometry of great whales and their blubber thickness reveal that they have more insulation than they need for purposes of maintaining body temperature (Kanwisher and Ridgway, 1983; Hokannen, 1990). The enormous variations in size among cetaceans, and related surface/volume variations, imply that a simple extrapolation of thermal relationships from the small to the large species is invalid. The countercurrent circulatory structures in the tail and flippers indicate a variable heat regulatory function (Scholander and Schevill, 1955), but we lack evidence of how they operate in the living animal.

III. Metabolism

The enormous adult sizes of some whales and their apparently phenomenal growth rates are dependent on the vast quantities of small zooplankton animals that make up their diet, or a large part thereof. Food consumption is enormous, of course, as has been acknowledged in casual observations of the vast stomach contents revealed on the flensing decks where whale carcasses have been processed. However, actual metabolic determinations are limited almost exclusively to small toothed whales from the few reported observations on captive animals maintained in oceanaria. Rare indeed are determinations of food intake and growth in baleen whales. Two juvenile gray whales (*Eschrichtius robustus*) have been maintained in captivity for 1 year and released. Some of their metabolic and rather extraordinary growth characteristics have been described (Wahrenbrock *et al.*, 1974).

The metabolic reactions of cetaceans vary, just as they do in other mammals, depending on body size and surface area. These, in turn, will determine food requirements. Some controversy exists about the issue of possible metabolic consequences of lifelong immersion in water and whether metabolic rates of small cetaceans are elevated to maintain body temperature. Subcutaneous blubber represents a substantial metabolic storage, and whale migrations are supported by this resource and whatever relatively modest feeding may occur along the way. The detailed consequences, however, of the associated several month's fasting are unknown. The present state of knowledge of marine mammal metabolism and energy budgets has been well reviewed by Costa and Williams (1999).

IV. Migration and Navigation

Some cetaceans perform prodigious MIGRATIONS from regions of polar food abundance toward the more moderate climates where birth, nurture of newborn animals, and breeding occur. The energetic costs of such travel and its navigation techniques are poorly understood, but even more pertinent are questions relating to the reasons for migrations, especially in view of controversies derived from speculations and calculations relating to feeding, thermal insulation, and heat production (Hokkanen, 1990; Wells *et al.*, 1999).

Some whales travel by the season between polar and temperate or tropic regions with the result that whales of one hemisphere migrate poleward, where prey is generally more abundant, whereas those of the opposite hemisphere congregate in warmer waters. Apparently little or no food is consumed during these excursions. The possible reasons for these regular long migrations have been the source of extended speculations. It is probable that the energetic storage represented by massive quantities of subcutaneous blubber serves another function than what is required for thermal insulation. Calculations suggest that this fat reserve can provide enough metabolic energy to last several months, even including the requirement for maternal nurture of newborn calves (Kanwisher and Ridgway, 1983).

V. Osmotic Considerations

Consumption of marine food resources, especially zooplankton and other invertebrates, is accompanied by obligatory salt intake. What little we know of the composition of cetacean blood indicates that it conforms approximately to the concentrations of terrestrial mammal blood, i.e., the osmotic pressure of sea water is about three times that of whale blood. Obligatory sea water intake accompanying food consumption requires that excess salts be excreted by kidney concentration of urine. Human kidneys cannot handle such salt loads, but cetaceans have a better capability for excreting salt and for conserving water. Incidentally, even that facility is far exceeded by desert rodents that are confronted with more extreme requirements for water conservation.

VI. Sensory Systems

Vision and olfactory senses are modified and reduced in some cetaceans, although just how compromised these abilities are is poorly understood. Sound production is common among them, and hearing is acute. Some species are especially vocal, and there is good evidence that echolocation is highly developed in at least some of these. Training techniques applied to captive animals have been especially useful in support of these studies (Wartzok and Ketten, 1999), but many questions remain concerning how the senses are employed in navigation, for aging, and social interactions.

Other topics excite our interests. For example, how long do whales live? Evidence indicates the extraordinary old age of some bowhead whales (*Balaena mysticetus*), even exceeding 150 years (George *et al.*, 1999). Reproductive physiology and newborn responses are other fields fertile for new research (Boyd *et al.*, 1999). Digestive processes are little known. Physiological responses interact with behavioral reactions and their combined study yields important insights that can clarify environmental influences on animals. Mammalian responses are governed by neural and humoral mechanisms and their interactions, and our understanding of cetacean physiology will be only superficial without knowledge of these regulatory mechanisms.

Healthy populations of marine mammals are indicators of healthy marine ecosystems, as revealed by their dependence on prey abundance, minimal water pollution, and lack of disturbance. However, the ecological physiology upon which that state of health depends is not well defined. Some cetacean populations, northern right whale (*Eubalaena glacialis*) and Chinese river dolphin (*Lipotes vexillifer*), for example, are critically endangered. Their survival will depend on many factors, not the least of which will be our understanding and appreciation for optimum physiological adaptations to their habitats.

VII. Research Prospects

Research on whatever can be recovered from dead whales during processing has historically depended on the good will of commercial whale-harvesting companies. However controversial that activity may be, it is undeniable that new knowledge of cetacean physiology has been forthcoming from that source. Investigations of this kind have been limited in the past, with the exception of a few like that of Scholander (1940), but important new work is being done on whale metabolism and digestion (Folkow and Blix, 1992; Olsen *et al.*, 2000). Other resources and occasional access to captive animals for benign observations are being utilized through the cooperation of public display oceanaria. Contemporary techniques of cell biology and genetics can be applied usefully in studies related to the expression of some physiological characteristics as revealed by tissue sampling from wild animals. Such sampling has been accomplished successfully at sea and by the cooperation of both commercial and Native cetacean harvests (Haldiman and Tarpley, 1993).

As for future research prospects, we are justified in believing that marine mammal science is on the threshold of new prospects for understanding whale physiology. Among the many prospective challenges for the new millenium, one stands out as especially attractive: the extension of the techniques and understandings that work so well in other, more manageable species to the great whales. Indeed, the possibilities for new discoveries regarding the physiology of whales are not beyond the realm of dreams; they are practical and realistic. New knowledge continues to be steadily derived at an ever-increasing rate from attachment of instrumentation and tracking operations that reveal much about the activities, lifestyles, diving, feeding, and migratory habits of whales. These await further application of ingenuity for recording more and detailed variables relating to the adaptions of free-ranging whales.

However successful and ingenious the instrumentation of free-swimming marine mammals may be, those techniques are insufficient for detailed and controlled investigations of cell chemistry, neurophysiology, energetics, and other topics necessary for the full understanding of cetacean physiology. We know from experience with the captive cetaceans that management of very large animals in CAPTIVITY is limited only by imagination and funding. In addition to long-term healthy captivity for study and conventional public display, one can foresee the more restricted capture for days or weeks of research and later release of whales at sea. These procedures will require exploration of what is practical, but such an approach is not beyond the realm of possibility and would open a new era of research into how these animals function.

Circulatory System

PAUL J. PONGANIS
Scripps Institution of Oceanography, La Jolla, California

Although the circulatory systems of marine mammals follow the general mammalian plan, they are most notable for features associated with the diving response, thermoregulation, and large body mass. This article emphasizes anatomical and functional aspects of the circulatory system in these animals. The cardiovascular reflexes and adjustments that occur during diving are reviewed in other articles. Specific features of the circulatory system vary with orders, families, and species. These adaptations include large blood volumes, large capacitance structures (spleens and venous sinsuses), venous sphincter muscles, vascular adaptations for thermoregulation, aortic windkessels, and vascular retia. The heart, arterial and venous systems, and blood volume are discussed first. Then specific structural adaptations of the circulation in various groups are considered.

I. General Anatomy

A. Heart

The basic structure and size of hearts in pinnipeds and cetaceans are typical of mammals. The four-chambered heart, with right ventricular outflow to the lungs and left ventricular output to the systemic circulation, weighs 0.5–1% of body mass in most pinnipeds and small cetaceans. In the great whales, relative heart mass is smaller, about 0.3–0.5% of body mass. Chamber size, stroke volume, and resting cardiac output and heart rate (where measured) are also in the general mammalian range and in agreement with mammalian allometric equations. Both the foramen ovale and the ductus arteriosus are closed in adult seals and cetaceans as in other mammals. Therefore, utilization of an intermittent fetal circulatory pathway does not appear to be a mechanism to bypass a potential increase in pulmonary vascular resistance during diving.

B. Arterial/Venous Systems

General aspects of the arterial and venous systems in marine mammals are remarkable for several features. First, dense sympathetic nerve innervation of proximal as well as distal arteries in seals may represent a mechanism by which the intense sympathetic vasoconstriction of the dive response can be maintained independent of local tissue metabolite-induced vasodilatation in the periphery. Angiography during forced submersions of seals supports this model. Second, venous capacitance is highly developed, especially in phocid seals and whales. This includes a large hepatic sinus and inferior vena cava, the latter of which in seals has been estimated to be capable of storing a fifth of the seal's blood volume. Presumably, this large venous capacitance is related to the large blood volume of seals.

In some species, the spleen appears to be a significant storage organ for red blood cells. Increased splenic volumes in several pinniped species, and extensive sympathetic nerve innervation and smooth muscle development in the splenic capsule, are consistent with this storage role. Fluctuations in hematocrit between resting and diving states, or anesthetized and stressed states, also support such a role for the spleen in seals. It has been estimated that 30% of the blood volume can be stored in the spleen in Weddell seals (*Leptonychotes weddellii*).

Another feature of the venous system, again well developed in both seals and whales, is the extradural venous system. This system, located within the vertebral canal and above the spinal cord, receives blood flow from the brain, back, and pelvic regions. It is linked with both the inferior and the superior vena cava via paravertebral communicating veins. The direction and magnitude of flow within the extradural vein is complex, varies with the respiratory cycle, and bears further investigation. In seals and cetaceans, the extradural vein is the primary venous drainage of the brain; the internal jugular vein is poorly developed or absent. The function of such a prominent vertebral venous system in these animals is unclear. In humans, it has been noted that extradural vein flow may participate in brain temperature regulation, and that, in the upright posture, the vertebral veins, kept open by attachment to the bony walls of the vertebral canal, are the primary cerebral venous drainage as blood flow decreases in the jugular veins due to venous collapse in the upright posture.

C. Blood Volume

Blood volumes are elevated and contribute to increased blood oxygen stores in marine mammals. On a mass-specific basis, most measurements indicate that blood volumes are two to three times the 70-ml kg^{-1} human value and that blood volume is greater in more active and in longer-diving species. The largest blood volumes (200–260 ml kg^{-1}) have been found in some of the best divers, including elephant seals (*Mirounga* spp.), Weddell seals, and sperm whale (*Physeter macrocephalus*).

II. Structural Adaptations

A. Vascular Thermoregulatory Adaptations

The parallel pattern of counterflowing arteries and veins, characteristic of counter current exchange units, is present in the flukes and flippers of cetaceans. Such arrangements, characteristic of blood vessel patterns in the limbs of many animals, are considered to conserve body heat by transferring heat from warm, outgoing arterial blood to cool venous blood returning from the limb. A superficial venous system, which does not return in conjunction with outgoing arteries, also occurs in the skin. These veins, which have well-developed muscular walls, have been considered to represent a route by which heat could be dissipated to the environment during periods of thermal stress.

Another structural adaptation observed in pinnipeds is the presence of numerous arteriovenous (a-v) anastomoses in the skin. These structures are connections between distal arteries and veins through which blood bypasses tissue capillary networks, and instead shunts directly from the arterial to venous system. The a-v anastomoses are distributed uniformly over the

body surface of phocid seals, but, in otariids, are found in greater densities in the flippers. It is presumed that flow through these vessels allows heat exchange at the skin surface.

More recently, countercurrent anatomy has been observed in the reproductive organs of dolphins and pinnipeds. It has been proposed that the return of blood from the skin via vascular anastomoses allows relatively cool venous blood to prevent overheating of these organs. Temperature patterns along the length of the colon in the dolphin have been consistent with this hypothesis.

B. Aortic Bulbs/Windkessels

In pinnipeds, again particularly in phocid seals, the aortic root (ascending aorta) is dilated, forming the so-called aortic bulb. The bulb can accommodate the stroke volume ejected by the heart, and it is more distensible than the distal aorta. It has been proposed that the aortic bulb acts as a windkessel: the bulb expands and accepts blood ejected from the heart; then, gradual contraction of the bulb due to elastic fibers within its wall contributes to the maintenance of blood flow, especially to the brain and heart during diastole (relaxation phase of the cardiac cycle).

The ascending aorta, aortic arch, and proximal carotid arteries of whales are also very compliant and have also been hypothesized to act as a windkessel and preserve blood flow during diastole. This is especially important in whales because long diastoles accompany slow heart rates. Low heart rates can occur in whales due to the slow heart rates found in animals of large body mass and due to the bradycardias (decreased heart rates) that occur during diving.

The maintenance of blood flow and pressure during a long diastole is of course critical to the brain, but also to the heart. This is because coronary perfusion occurs during diastole when the heart is relaxed. Myocardial flow is dependent on the diastolic blood pressure as the driving pressure. Thus, species that are either large or have more profound diving responses are likely to have some form of an aortic windkessel.

A compliant ascending aorta may also contribute to a reduction in the impedance that the left ventricle must pump against during the peripheral vasoconstriction of the diving response. This reduction in afterload will decrease the work and oxygen consumption of the heart, which is of course beneficial to a diver with a limited oxygen supply.

C. Vascular Retia

The retia mirabilia (wonderful nets) of cetaceans have long been noted by anatomists. These plexuses of anastomosing arteries and veins occur along the vertebrae and base of the skull and are especially prominent in the thorax. The vascular retia are well developed in dolphins, in fact, more so than in large whales; they are also found in sirenians.

The thoracic rete is supplied by vessels from the aorta, which anastomose to form a complex, spongiform structure beneath the dorsal thoracic wall. This vascular tissue extends around the vertebrae into the vertebral canal and forms the primary arterial blood supply to the brain in cetaceans. The carotid arteries are vestigial or absent. The spinal meningeal artery in dolphins extends from the rete to the brain. Although mean blood pressure in the spinal meningeal artery of dolphins is equal to the aortic pressure, it is notable that the pressure is nonpulsatile; there is no systolic peak or diastolic trough. Thus, the cetacean brain appears to receive nonpulsatile blood flow. The significance of such a flow pattern, as well as the function of the retia, is unknown.

Large venous retia have also been reported in the abdomens of whales. Hypotheses about the role of the retia have included windkessel functions, intrathoracic vascular engorgement to prevent "lung squeeze" during diving, thermoregulation, and modification of composition of the blood.

D. Inferior Vena Caval Sphincter

In most pinnipeds, the inferior vena cava is associated with a striated muscle sphincter at the level of the diaphragm. Again, this is most well developed in phocid seals. The sphincter is innervated by the right phrenic nerve and is located cranial to the large hepatic sinus and inferior vena cava. Relaxation/contraction of the sphincter has been observed angiographically during forced submersions, and it is assumed that this is a mechanism to regulate venous return to the heart during diving bradycardias. Vena caval sphincters are also described in whales; they presumably regulate blood return from the large venous capacitance vessels in the abdomen (inferior vena cava and venous rete).

Another venous structure, especially developed in phocid seals, is the pericardial venous plexus. This extensive venous network drains the pericardium (membrane surrounding the heart) and empties into the inferior vena cava just cranial to the vena caval sphincter. It is especially developed in the better diving seals such as elephant seals. Its significance is unknown, although it has been reported to be associated with brown fat and has been hypothesized to function in thermoregulation.

Classification

Dale W. Rice
National Marine Mammal Laboratory, Seattle, Washington

Four clades of placental mammals (class Mammalia: cohort Placentalia) independently evolved adaptations for life in the oceans. These are the still-living pinnipeds (sea lions, walruses, and seals), cetaceans (whales, dolphins, and porpoises), and sirenians (manatees and dugongs) and the extinct desmostylians. The pinnipeds are amphibious animals capable of terrestrial locomotion and must haul out on shore to give birth. The cetaceans and sirenians (except for a few primitive Eocene species) are totally aquatic, having lost their hindlimbs and evolved huge muscular tails with terminal flukes for swimming. The extinct desmostylians were quadrupedal amphibious creatures. The pinnipeds and cetaceans are carnivorous, and the sirenians and desmostylians are herbivorous. Although primarily oceanic, several members of each of the three living groups have secondarily invaded freshwater habitats. The systematics of all of these sea mammals, living and fossil, is a flourishing field of research; many details are currently contested, and several paraphyletic groupings await resolution, so changes in the prevailing classification (Table I, McKenna and Bell, 1997) may be anticipated (Fordyce and Barnes, 1994; Rice, 1998; Berta and Sumich, 1999).

I. Pinnipeds

The pinnipeds were long classified as order Pinnipedia, separate from but closely related to the terrestrial carnivores of the

NOTE: See Species List.
[a]From McKenna and Bell. 1997. Extinct taxa are marked with a dagger, and taxa that appear to be paraphyletic are marked with an asterisk. Abbreviations: E. early, M, middle, L, late; Eoc., Eocene; Olig., Oligocene; Mico., Miocene; Plioc., Pliocene; Pleist, Pleistocene; Rec., Recent.
[b]Allocation of the family Odobenocetopsidae to the order Cetacea is disputed.

order Carnivora. In recent years, cladistic analyses of both morphological and and molecular data have clearly shown them to be members of the suborder Caniformia of the order Carnivora.

Two strongly differentiated groups of living pinnipeds were long recognized: the eared seals, or sea lions and fur seals (family Otariidae), and the earless, or true, seals (family Phocidae); the walruses (family Odobenidae) were usually associated with the former group. Some taxonomists maintained that pinnipeds are a diphyletic assemblage and that the eared seals shared a common ancestry with the bears (family Ursidae), whereas the true seals were most closely related to the weasel group (family Mustelidae) or, more specifically, the otters (subfamily Lutrinae). Those authorities allocated the pinnipeds to two superfamilies: Phocoidea for the family Phocidae and Otarioidea, which included the extinct families Enaliarctidae and Desmatophocidae, and the extant Otariidae and Odobenidae. The Enaliarctidae included several late Oligocene and early Miocene genera that were postulated to have given rise to the other three families of otarioids in the Miocene (Repenning and Tedford, 1977).

With the advent of cladistic methods, a different picture emerges. All of the molecular analyses and most of the morphological analyses have supported the hypothesis that all pinnipeds shared a common ancestry. However, the position of the pinnipeds within the suborder Caniformia is still disputed. Although most investigators favor a sister group relationship to the Ursidae, a few studies (Bininda-Emonds and Russell, 1996) do support a closer affinity to the Mustelidae. One analysis placed the genus *Kolponomos* as the sister taxon of the pinnipeds. *Kolponomos*, an amphibious bear-like creature that lived along the coasts of Washington and Oregon during the Miocene, is currently listed in the family Amphicynodontidae, a paraphyletic group from which the Ursidae descended. With the present preponderance of evidence, the most appropriate classification is that of McKenna and Bell (1997), who rank the pinnipeds as the superfamily Phocoidea and the bear-like terrestrial carnivores as the superfamily Ursoidea, both under the parvorder Ursida, and place the mustelids in parvorder Mustelida; those authors also included all the genera of amphicynodonts as unallocated stem groups of the Phocoidea.

The cladistic studies have also reopened the question of interfamilial relationships of pinnipeds. A total evidence analysis indicated the following "phyletic sequence": Desmatophocidae–Phocidae–Odobenidae–Otariidae. The traditional pairing of the Odobenidae with the Otariidae was likewise supported by molecular and morphological analyses of the living taxa (Árnason *et al.*, 1995; Bininda-Emonds and Russell, 1996). However, a comprehensive morphological analysis (Berta and Wyss, 1994) affirmed the paraphyletic nature of the Enaliarctidae and arranged the other families in the following phyletic sequence: Otariidae–Odobenidae–Desmatophocidae (paraphyletic)–Phocidae. Berta and Wyss (1994) proposed a new classification, but did not assign formal Linnean ranks to all of their suprageneric taxa; their taxon Pinnipedimorpha equals McKenna and Bell's Phocoidea minus the amphicynodontids.

Mention must be made of three other fossil genera of "otter-like seals" or "seal-like otters." These are *Potamotherium* with two species from freshwater Oligocene and Miocene deposits in Europe and North America, *Semantor macrurus* from freshwater Miocene or Pliocene deposits of Kazakhstan, and *Necromites nestoris* from a marine Pliocene stratum of Azerbaijan. The latter two are known only by the hinder halves of their skeletons. All three have been proposed as primitive pinnipeds or phocids, but their phylogenetic placement remains totally problematic.

II. Cetaceans

Whales differ so much from other placental mammals that their evolutionary relationships long remained conjectural. The marked anatomical dissimilarities between baleen whales and toothed whales led a few earlier cetologists to question the monophyly of the Cetacea, but none of them ever proposed an explicit hypothesis of diphyly (Rice, 1984). However, many recent studies, both morphological and molecular, overwhelmingly confirm the monophyletic origin of cetaceans and indicate that their closest living relatives are the even-toed ungulates (order Artiodactyla). A comprehensive cladistic analysis of morphological data from fossil and living taxa showed the cetaceans (order Cetacea) and the extinct mesonychids (order Acreodi) as monophyletic sister groups, which together constitute the sister group to the monophyletic Artiodactyla (O'Leary and Geisler, 1999). The mesonychids were cursorial, wolf-like creatures whose feet had five toes that bore hoof-like claws; they lived throughout the Holarctic from the early Paleocene to the early Oligocene.

During the past two decades a remarkable series of Eocene fossil cetaceans have been unearthed, mostly near the shores of the ancient Tethys Sea in Pakistan, India, and Egypt (Thewissen, 1998). These finds document the origin of the early cetaceans from the terrestrial mesonychids and their rapid evolutionary transition from amphibious quadrupeds to fully aquatic forms during the interval from 54 to 34 million years ago (Ypresian through Priabonian). The phylogenetic relationships among these primitive Eocene cetaceans have yet to be fully resolved. For the interim they are allocated to six families, some of which are paraphyletic; the entire assemblage is traditionally included in the paraphyletic suborder Archaeoceti. The close relationship between mesonychids and cetaceans led McKenna and Bell (1997) to include both in order Cete and to

reduce Acreodi and Cetacea to subordinal rank; they further divided the Cetacea into two infraorders, Archaeoceti and Autoceta, with the latter including the Mysticeti (baleen whales) and Odontoceti (toothed whales) as parvorders.

In several cladistic analyses of molecular data, the Cetacea have appeared as the sister taxon to various subclades within the order Artiodactyla—most often the hippos (family Hippopotamidae) (Gatesy *et al.*, 1999; Nikaido *et al.*, 1999; Shimamura *et al.*, 1999). The strongest support for these hypotheses was claimed to come from short interspersed elements in the genomes, but their potential for resolving this problem has been questioned (Buchanan *et al.*, 1999). The veracity of these conclusions is further suspect because of the unavailability of molecular data from mesonychids, archeocetes, and any of the other extinct clades of ungulates. As noted earlier, the morphological analysis of living and fossil taxa by O'Leary and Geisler (1999) showed the Artiodactyla as well as the Cetacea as monophyletic clades, but when they repeated their analysis without the fossil species, the Cetacea appeared nested within a paraphyletic Artiodactyla, as they had in the molecular studies. Another critical assessment of morphological and molecular data from living taxa likewise corroborated the monophyly of the Artiodactyla (Luckett and Hong, 1998). The rich FOSSIL RECORD of the artiodactyls has provided no evidence whatever that would support the derivation of cetaceans from hippos or any other subclade within the Artiodactyla. Some authors now group the living orders Artiodactyla and Cetacea under a supraordinal taxon Cetartiodactyla, which with the addition of several extinct taxa becomes approximately equivalent to mirorder Eparctocyona of McKenna and Bell (1997).

The more advanced post-Eocene cetaceans are postulated to have descended from an archeocete, most plausibly a member of the family Dorudontidae. The monophyly of each of the two modern suborders, Mysticeti and Odontoceti, is strongly corroborated by a suite of complex morphological synapomorphies. Some years ago much publicity was given to a contradictory idea, based on molecular data, that sperm whales (superfamily Physeteroidea) are phylogenetically closer to baleen whales than they are to the other toothed whales. In addition to the overwhelming morphological evidence, subsequent molecular studies have corroborated the conventional hypothesis of odontocete monophyly (Luckett and Hong, 1998; Messenger and McGuire, 1998; Gatesy *et al.*, 1999).

The oldest fossil cetacean allocated to the suborder Mysticeti is *Llanocetus denticrenatus* (family Llanocetidae) from the end of the Eocene of the Antarctic Peninsula. It and several Oligocene genera of the families Aetiocetidae, Mammalodontidae, and Kekenodontidae all possessed teeth rather than baleen. The first toothless, baleen-bearing cetaceans appeared in the late Oligocene; they are assigned to the family Cetotheriidae, a paraphyletic assemblage from which the four living families descended.

The earliest members of the suborder Odontoceti appeared in the late Oligocene. During that epoch lived a number of unusual genera whose phylogenetic relationships remain unresolved. One distinctive superfamily, the Eurhinodelphinoidea, or long-snouted dolphins, diversified and then died out during the Miocene. All of the living odontocetes other than the peculiar river dolphins clearly fall into three superfamilies—Physeteroidea (sperm whales), Ziphioidea (beaked whales), and Delphinoidea (dolphins, porpoises, etc.)—all of which first appeared in the late Oligocene (Muizon, 1988, 1991). Beaked whales were long thought to be closely related to sperm whales, but a majority of recent cladistic analyses suggest that they are closer to the delphinoids. Studies of river dolphins have come up with no consistent phylogenetic pattern, other than an emerging consensus that the Platanistidae are only distantly related to the others, and are closer to the family Squalodontidae, or shark-toothed porpoises, that lived during the Miocene. The Iniidae, Lipotidae, and Pontoporiidae appear to constitute one or more branches from the ancestral lineage of the Delphinoidea.

Other putative cetaceans are *Odobenocetops peruvianus* and *O. leptodon*, bizarre, tuskbearing sea mammals unearthed from Pliocene deposits on the coast of Peru; they have been allocated to a new family (Odobenocetopsidae) and are thought to be related to the narwhal (family Monodontidae), but their cetacean affinities are disputed.

III. Sirenians and Desmostylians

Because of their superficially whale-like physique, many 19th century naturalists classified the sirenians as the "herbivorous cetacea." Modern studies have revealed that the Sirenia, along with the extinct Desmostylia, are marine members of a supraordinal group called the Tethytheria, which also embraces elephants (order Proboscidea) and several other extinct groups. The earliest sirenians had four limbs and appeared capable of terrestrial locomotion. The early to middle Eocene *Prorastomus* (family Prorastomidae) probably swam only with its hindlimbs, but the middle Eocene *Protosiren* (family Protosirenidae) probably used its well-developed tail as well. The latter genus thus foreshadowed the still-living Dugongidae and Trichechidae, fully aquatic forms that lost their hindlimbs and swim by means of caudal flukes (Domning, 1996). The affinities of the Oligocene and Miocene desmostylians long remained problematic because they were known only from skulls, but many authors classified them as a suborder of the Sirenia. The discovery of complete skeletons finally showed them to be quadrupedal hippopotamus-like animals, sufficiently different from sirenians to be ranked as a separate order. The most recent cladistic analysis places the Desmostylia closer to the Proboscidea than to the Sirenia. If true, this would imply that sirenians and desmostylians acquired their aquatic adaptations independently. McKenna and Bell (1997) demoted the Tethytheria to a suborder of their new order Uranotheria, under which they ranked Sirenia as one infraorder, and also included the Desmostylia and Proboscidea as parvorders under the infraorder Behemota.

IV. Other Marine Species

Several species of mammals that belong to otherwise terrestrial groups have become facultative or obligate members of the marine ecosystem (Rice, 1998). The polar bear (*Ursus maritimus*; family Ursidae) and the arctic fox (*Vulpes lagopus*; family Canidae) range widely over the north polar pack ice. Among the 10 or so species of otters (family Mustelidae: subfamily Lutrinae), the sea otter (*Enhydra lutris*) of the North Pacific

and the marine otter (*Lutra felina*) of western South America are strictly marine, and local populations of at least six other species feed in coastal marine waters. Two species of bats (order Chiroptera) also catch fish in coastal waters; the greater bulldog bat (*Noctilio leporinus*; family Noctilionidae) of the neotropics and the fishing bat (*Myotis vivesi*; family Vespertilionidae) of the Gulf of California. Finally, the most unexpected marine mammal was a large ground sloth (*Thalassocnus natans*; order Xenarthra: family Megalonychidae) discovered in Pliocene deposits on the coast of Peru, where it evidently grazed on algae or sea grasses.

Clymene Dolphin

Stenella clymene

THOMAS A. JEFFERSON
Southwest Fisheries Science Center, La Jolla, California

Because the Clymene dolphin is one of the most recently recognized species of dolphins (Perrin *et al.*, 1981), very few papers have been published on this species (Perrin and Mead, 1994). Its restricted range, limited to the tropical and warm temperate waters of the Atlantic Ocean, has not been well studied cetologically. These two facts make the Clymene dolphin one of the least-known delphinids.

I. Characters and Taxonomic Relationships

The Clymene dolphin is a small, but rather stocky, dolphin with a moderately long beak, separated from the melon by a distinct crease (Fig. 1). The dorsal fin is tall and nearly trian-

Figure 1 *Clymene dolphins ride the bow wave of a research vessel offshore the Gulf of Mexico. Most of the species' distinctive characteristics are visible.*

gular to slightly falcate, and the flippers and flukes are typical of dolphins of the genera *Stenella* and *Delphinus*.

The COLOR pattern is tripartite, with a white belly, light gray flanks, and dark gray cape. The cape dips below the dorsal fin, somewhat lower than in the spinner dolphin. There is a dark gray line running down the length of the top of the beak, and often a dark, indistinct band between the white belly and gray sides. The most distinctive feature is a black "moustache" marking of variable extent on the top of the beak. With the exception of the moustache, most of the species' external characters are very similar to those of the spinner dolphin. This is one of the reasons why the Clymene dolphin was not fully recognized as a distinct species until 1981 (Perrin *et al.*, 1981).

These small dolphins probably do not reach much over 2.0 m in length, with males somewhat larger and heavier than females (Jefferson *et al.*, 1995; Jefferson, 1996). Adult-sized females have been between 171 and 190 cm, and males between 176 and 197 cm (Jefferson, 1996). The maximum weight known is about 80 kg, but they may get somewhat heavier than this.

The skull of this species is very similar to that of *Stenella longirostris* and *S. coeruleoalba* (especially the latter) (Fig. 2) It can be distinguished by its small size (<415 mm) combined with a short, broad rostrum.

Taxonomically, *S. clymene* has been considered to be most closely related to *S. longirostris* and *S. coeruleoalba* (Perrin *et al.*, 1981). Genetic studies by LeDuc *et al.* (1999) indicate that its cytochrome *b* sequence is actually closer to *S. coeruleoalba*.

II. Distribution and Ecology

The Clymene dolphin is found only in the Atlantic Ocean, in tropical to warm temperate waters. The range is not well documented, especially in South Atlantic and mid-Atlantic waters. Most sightings have been in deep, offshore waters.

There is very little known about the ecology of the species. It apparently feeds mostly on mesopelagic fishes and squids, including some species that are vertical migrators. Many dolphins bear bite marks and scars from cookie cutter sharks on their bodies.

III. Behavior and Life History

Schools of this species are often moderately large, although most appear to consist of less than a few hundred individuals (Perrin and Mead, 1994). Schools may be segregated by age and sex class, as evidenced by several mass stranded herds that were composed largely of individuals of one or the other sex (Jefferson *et al.*, 1995).

Clymene dolphins are active bow riders, often approaching ships from many kilometers away for a free ride. They are also often aerially active and they do spin (Fig. 3), although apparently not as frequently or as elaborately as the spinner dolphin.

There have been no studies of the life history of this species based on large samples of specimens. Most of what we know is based on scant information. Both males and females appear to reach sexual maturity by the length of 180 cm (Jefferson, 1996). Nothing is known of other life history parameters, but they are thought to be broadly similar to those of other members of the genus.

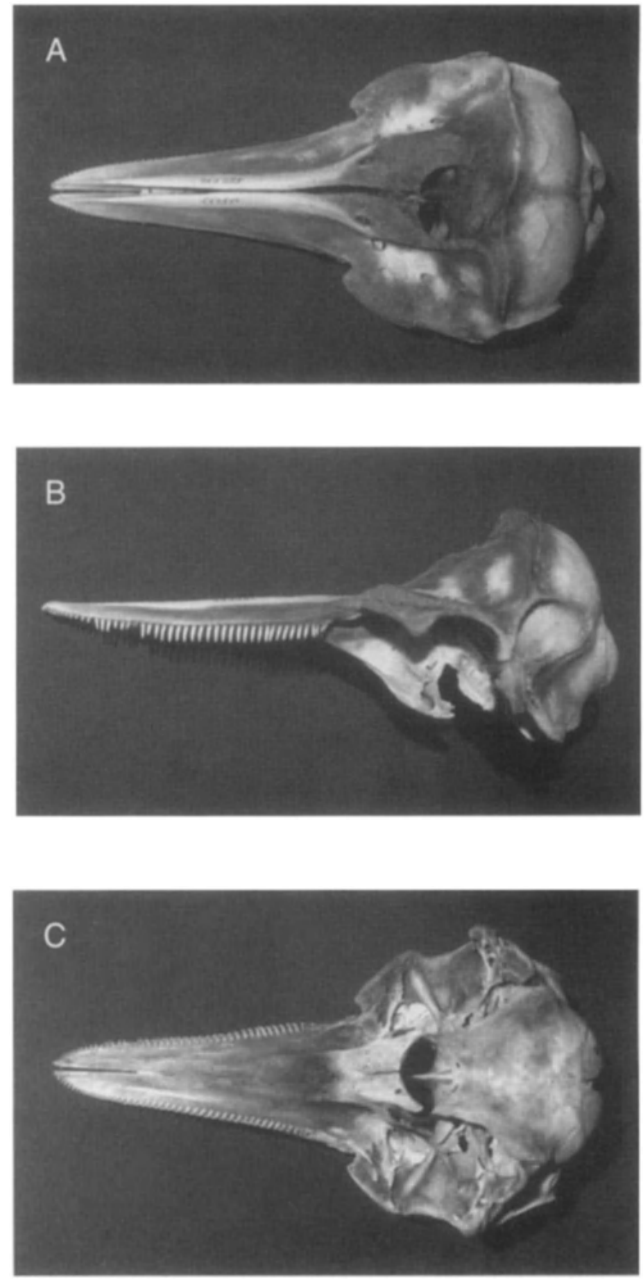

Figure 2 *Dorsal (A), lateral (B), and ventral (C) views of the skull of a Clymene dolphin from the Gulf of Mexico.*

IV. Interactions with Humans

No major conservation problems are known for this species, but it is likely that some undocumented problems exist. Some dolphins are known to be killed in directed fisheries in the Caribbean and incidentally in nets throughout most parts of the range (in particular, West Africa). There has been essentially no work on environmental contaminants in this species. Clymene dolphins have not been held captive, except for some animals that were held temporarily after stranding alive.

Coloration

WILLIAM F. PERRIN
Southwest Fisheries Science Center, La Jolla, California

Marine mammals are not as colorful as birds or fishes or reptiles, but many have striking and distinctive coloration patterns that are useful in their taxonomy, presumably have function and adaptive value, and can vary individually and with age, sex, geographic region, and even time of the year.

I. Terminology

A number of schemes have been proposed for naming the elements of color patterns in cetaceans; the usage here follows Perrin (1973, 1997) and Perrin *et al.* (1991). In delphinids and phocoenids (Fig. 1), the *bridle* is composed of the *blowhole stripe* running from the blowhole to the apex of melon and the *eye stripe* from the eye to the apex of melon. Both stripes may have complex internal structure. An *eye spot* may be visible, and there may also be a small *ear stripe* or *spot*. The *eye-to-anus stripe* runs from the eye to the anal/genital region and may have *accessory stripes*. The *flipper stripe* runs forward from the base of the flipper variously to the eye (e.g., in spinner dolphin, *Stenella longirostris*), corner of the mouth (e.g., pantropical spotted dolphin, *S. attenuata*), or forward along the rostrum to join the *lip mark* ventrolaterally (common dolphins, *Delphinus* spp.).

The overall color pattern in at least some delphinids can be analyzed in terms of interacting independent components (Fig. 2). A basic *cape* is covered with a *dorsal overlay* of varying extent and intensity and may not be visible except in fetal or anomalously pigmented specimens. A crisscross of the boundaries of these two elements in *Delphinus* spp. yields a complex four-part pattern of a dark-gray *dorsal field* (cape and overlay combined), buff or yellowish *thoracic patch* (cape alone), light-gray *flank patch* (overlay alone), and white *ventral field* (outside both cape and overlay). In some anomalous individuals, the overlay may be absent, yielding a simplified pattern of cape only [e.g., in *Delphinus delphis* (Perrin *et al.*, 1995) and *Stenella longirostris* (Perrin, 1973)]. Spotting appears to be yet another independent component that develops with maturation in some species.

In pinnipeds, coloration can be a property of different *pelages* or pelage elements, through a range from white to silver, gray or bluish gray, brown and black. The *lanugo* is a fetal pelage that develops and can be lost before birth, although in many species it is shed a few days or weeks after birth. Juveniles may undergo additional *molts* and changes of color. The coarse *guard hairs* can differ in color from the hairs of the *undercoat*. Many seals are simply uniformly colored or countershaded, but some have bold patterns, such as the harp seal (*Pagophilus groenlandicus*) and ribbon seal (*Histriophoca fasciata*), and others are spotted.

II. Development

Coloration typically changes between birth and adulthood. In some cases appearance changes radically, whereas in others the change is more in contrast and distinctness of pattern elements. Only a few examples are discussed here.

The spotted dolphins, *Stenella attenuata* and *S. frontalis*, are unspotted at birth (Fig. 3). Small dark spots appear in large juveniles in the gular region and spread over the ventral surface, enlarging as maturity approaches. Light spots appear on the back and spread in a similar fashion, although not in an even distribution over the back. In *S. attenuata* the dark ventral spots fuse and lighten to yield a light-gray, faintly dappled

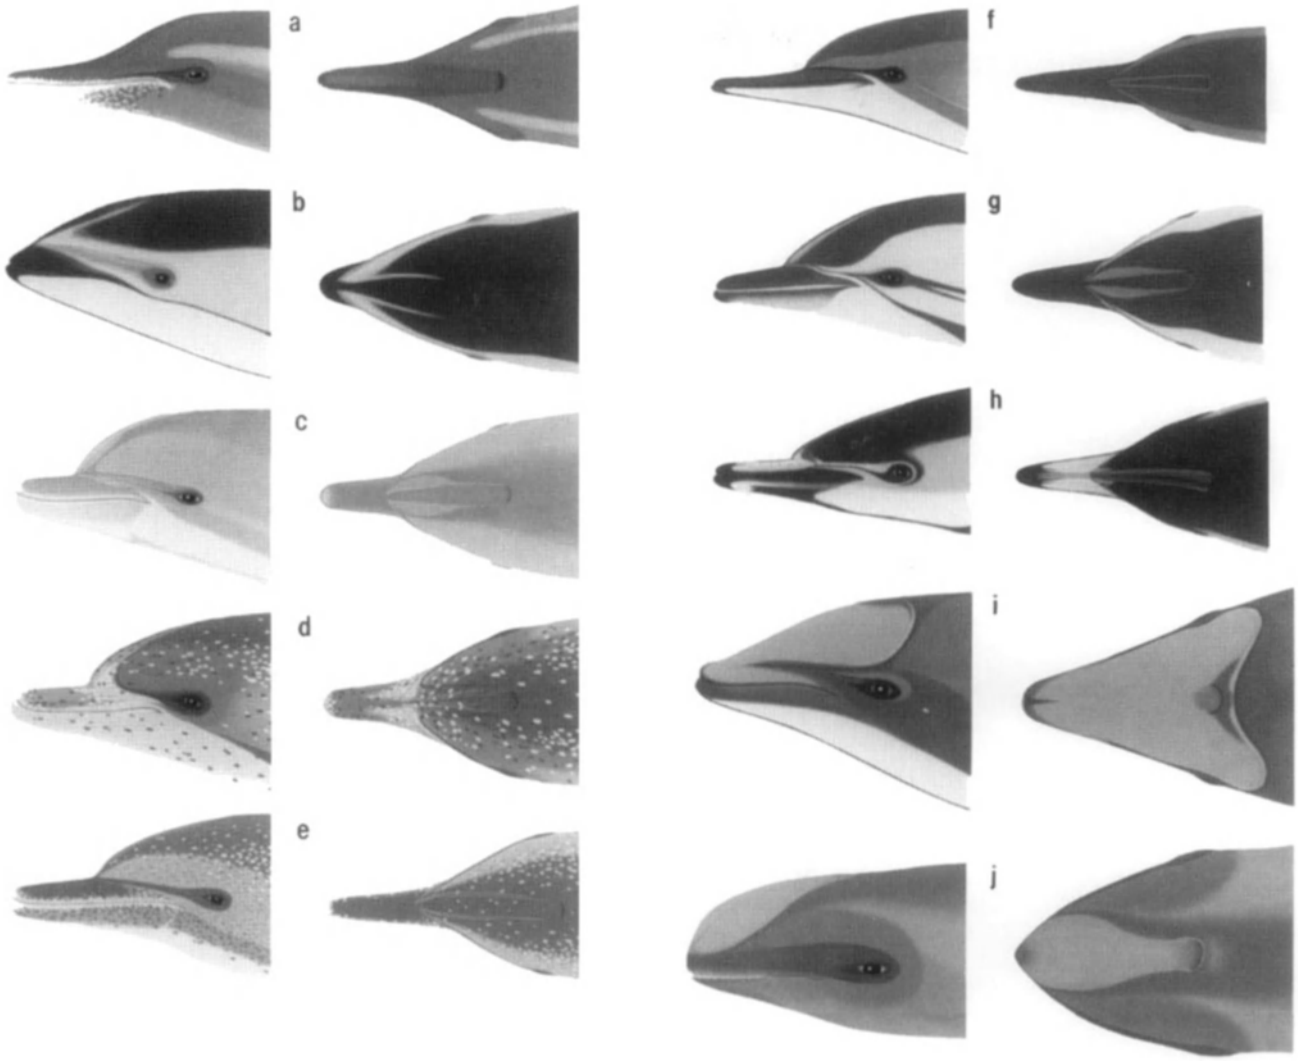

Figure 1 *Typical appearance of bridle in 10 delphinid species: (a)* Steno bredanensis, *(b)* Lagenorhynchus obliquidens, *(c)* Tursiops truncatus, *(d)* Stenella frontalis, *(e)* S. attenuata, *(f)* S. longirostris, *(g)* S. coeruleoalba, *(h)* Delphinus delphis, *(i)* Cephalorhynchus eutropia, *and (j)* Peponocephala electra. *From Perrin (1997).*

ventral surface. In *S. frontalis*, both ventral and dorsal spots persist into maturity.

The beluga, *Delphinapterus leucas*, is dark gray at birth but lightens as it grows; adults are white. A similar trend is seen in Asian populations of the Indopacific humpbacked dolphin *Sousa chinensis*. The reverse of this trend is seen in many other cetaceans, such as pilot whales and beaked whales; calves are lighter at birth and darken with age, although neonates of the bottlenose dolphin and the finless porpoise *Neophocaena phocaenoides* in some regions are darker than juveniles and adults.

The development of coloration tends to take opposite courses in different groups of pinnipeds (Bonner, 1990). Otariids are born dark and become lighter as juveniles, most darkening again as adults. However, most northern hemisphere phocids (the phocinines), including *Phoca largha*, *Pusa* spp., *Pagophilus groenlandicus*, *Histriophoca fasciata*, and *Halichoerus grypus*, are born with a white or yellowish lanugo (Fig. 4), which is shed at 2–5 weeks. This molt exposes either the adult pattern of spots or other marks or a juvenile countershaded coloration that later changes to the adult patterned state. The harbor seal, *Phoca vitulina*, and the hooded seal, *Cystophora cristata*, are unusual in that the lanugo is molted before birth (always in the hooded seal and usually in the harbor seal). The bearded seal, *Erignathus barbatus*, is born with a grayish-brown lanugo (with white muzzle and white blotches), and in the monk seals (*Monachus* spp.) and elephant seals (*Mirounga* spp.) the lanugo is black. In the southern phocids, the Weddell seal *Leptonychotes weddellii*, Ross seal *Ommatophoca rossii*, crabeater seal *Lobodon carcinophaga*, and leopard seal *Hydrurga leptonyx*, pups are born with pale-gray to brownish-gray coats; in the leopard seal the birth coat resembles the adult state in color and pattern. The walrus (*Odobenus rosmarus*) molts the lanugo *in utero* and has sparse whitish, yellowish, or silver-gray coat at birth. The lanugo, whether light

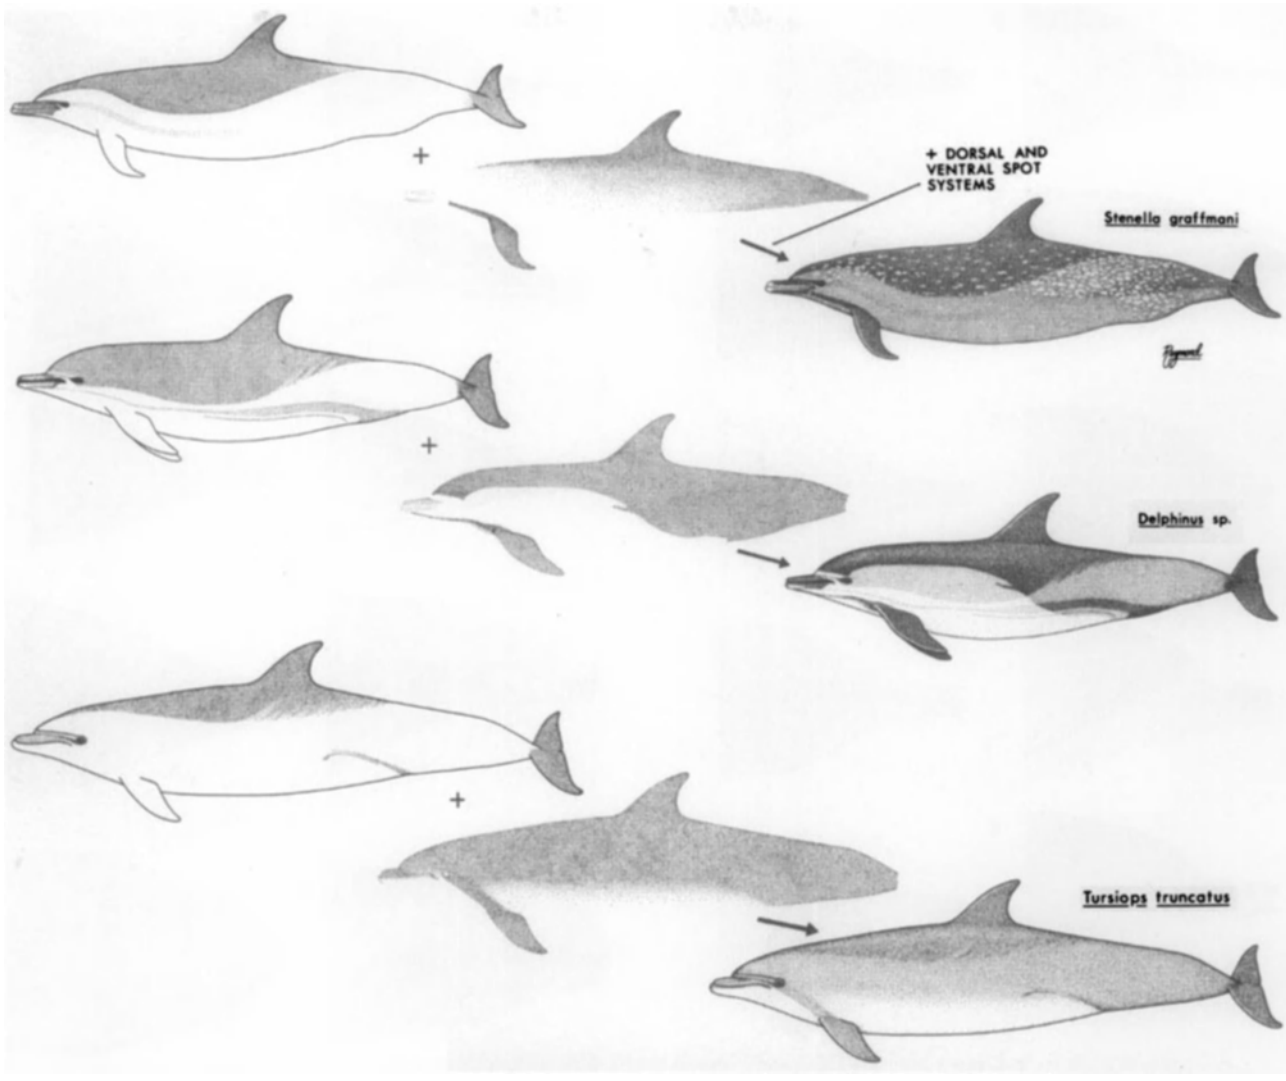

Figure 2 *Component analyses of color patterns of* Stenella attenuata, Delphinus delphis, *and* Tursiops truncatus *(from left to right): basic cape plus dorsal overlay yields a complex color pattern. From Perrin (1973).*

or dark, is usually thick and wooly. and it has been suggested that it functions in heat conservation until a BLUBBER layer accumulates. Another suggested function, at least for the white lanugo, is camouflage against predators on the ice. although the southern ice-breeding monachines do not have white coats at birth. It has been posited that intrauterine loss of the lanugo in the harbor seal is a secondary adaptation to breeding on land since its descent from an ice-breeding ancestor, implying a camouflage function. Why some birth coats are light and others dark is still a matter for speculation.

III. Sexual Dimorphism

In delphinid cetaceans, sexually dimorphic color pattern elements are typically associated with the genital region. For example. a black tear-drop-shaped patch surrounding the genital slit in Commerson's dolphin *Cephalorhynchus commersonii* has its apex directed posteriorly in adult males and anteriorly (sometimes with a posterior invagination around the genital slit) in females (Fig. 5). A lateral stripe extending from the eye to the genital region in Fraser's dolphin *Lagenodelphis hosei* is broader and darker in adult males than in females (Jefferson *et al.*, 1997). Adult male beaked whales (Ziphiidae) of many species tend to develop white areas on the head; in some species the entire head becomes white, whereas in others the white area may be confined to the front or top of the head or to the rostrum (Ridgway and Harrison, 1989).

Ventral coloration is dimorphic in the Mediterranean monk seal *Monachus monachus* from birth onward; as in some dolphins, the posterior boundary of a mark around the genital opening is arcuate in females and straight in males (Badosa and Grau, 1998). Adult males are also much darker than females.

In other phocids, the color pattern is usually more distinct and with darker elements in males than in females. e.g., in the

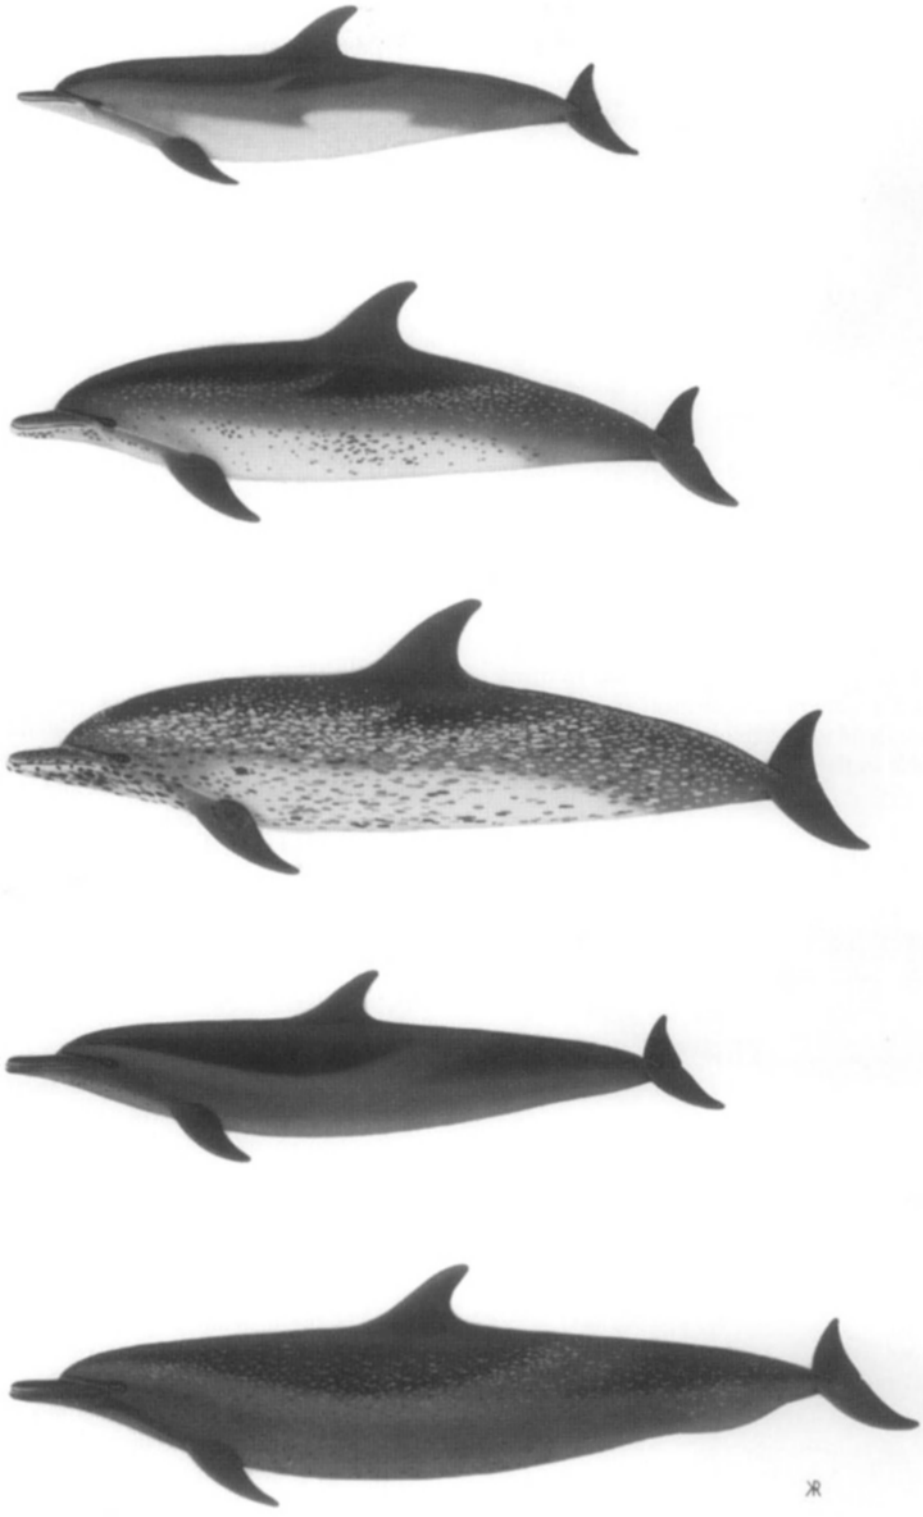

Figure 3 *Development of color pattern in two spotted dolphins:* Stenella frontalis *(top three) and* S. attenuata *(bottom two). From Perrin* et al. *(1987).*

Figure 4 *Recently born ringed seal pup, showing lanugo. From Ridgway and Harrison (1981).*

ribbon seal and harp seal. Some adult male gray seals are almost black, whereas females tend to be lighter colored. However, some species, e.g., the bearded seal and Weddell seal, are not noticeably dimorphic in coloration (Ridgway and Harrison, 1981). For walruses, the pattern seen in many phocids is reversed; old adult males tend to be lighter colored than females. The pattern is variable in the otariids; in some, e.g., the California sea lion *Zalophus californianus* and northern fur seal *Callorhinus ursinus*, the adult male is darker than the female, whereas in others, e.g., the Steller sea lion *Eumetopias jubatus*, there is no apparent dimorphism.

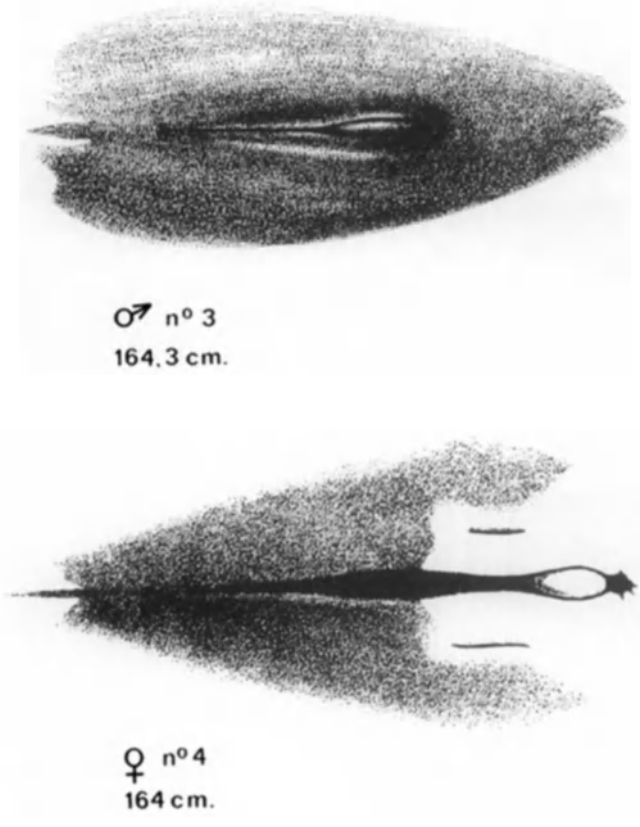

Figure 5 *Sexual dimorphism in the form of a genital patch in* Cephalorhynchus commersonii. *From Robineau (1984).*

IV. Geographic and Individual Variation

Color patterns vary among adults in marine mammal species, both individually and geographically. Biologists use individual variations in coloration and other natural marks as "tags" in studies of abundance, movements, and life history. "Tag and recapture" studies using natural marks can estimate population size; this has been applied to a number of cetacean species, including killer whales (*Orcinus orca*), minke whales (*Balaenoptera acutorostrata*), fin whales (*B. musculus*), blue whales (*B. physalus*), humpback whales (*Megaptera novaeangliae*), right whales (*Eubalaena* spp.), bowhead whales (*Balaena mysticetus*), bottlenose dolphins, and others (Hammond *et al.*, 1990). Long-range movements of migratory whales have been documented using natural marks, clarifying migratory cycles and stock structure and affiliations. Longitudinal studies of individuals and groups over generational time have been vital in arriving at estimates of such important life history parameters as age at first reproduction, calving interval, and survivorship, and these have been made possible by the use of natural marks to keep track of individuals (for the Atlantic spotted dolphin *Stenella frontalis* in the Caribbean, the killer whale in the Pacific Northwest, and a variety of other small cetaceans). Examples of coloration features that have been or could be used as natural marks include shape of the dorsal saddle and postocular spot in the killer whale (Fig. 6), details of the eye and blowhole stripes in dolphins and porpoises, color and patterning of the underside of the flukes in the humpback whale, and patterns of spots, blotches, and white areas on the body in right, gray (*Eschrichtius robustus*), bowhead, blue, and minke whales. Some naturally imposed marks, such as scars from infraspecific fighting and from bites by predators or cookie cutter sharks (*Isistius* sp.), have also proven useful, although factors such as fading and acquisition of new marks during a study must be taken into consideration. For some drably colored marine mammals, e.g., manatees (*Trichechus* spp.), scars (including those from collisions with boats and fishing gear) are the only marks available for use.

The use of natural marks in individually identifying pinnipeds from their patterns of spots and blotches has been complicated by the difficulty of photographing seals from a standard angle or in a standard posture. This problem has been approached by the development of computer-aided matching of images using a three-dimensional model to correct for orientation and posture (Hammond *et al.*, 1990).

As for other morphological characters, coloration tends to vary geographically most in those features that vary individually most within a population. For example, in spinner dolphins in the eastern Pacific, the degree to which the dorsal overlay obscures the underlying cape is highly variable; in some animals the cape is prominent whereas in others it is invisible (Perrin *et al.*, 1991). It is in this feature of the color pattern that spinner dolphins vary most from region to region around the world. Similarly, adult spotted dolphins of both species (*Stenella*

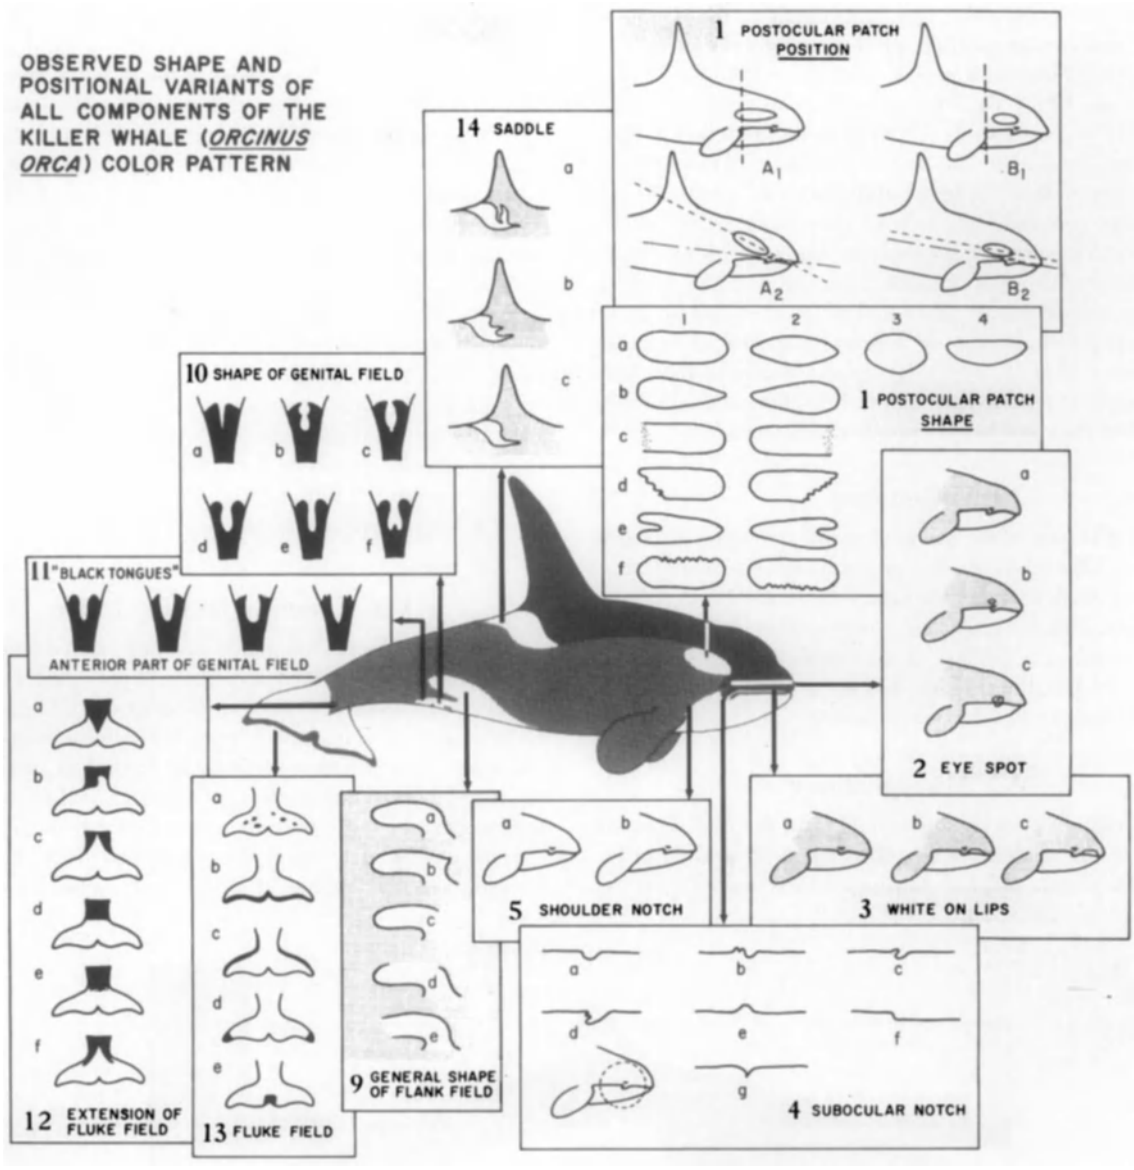

Figure 6 *Variation (individual and geographic) in components of the color pattern of* Orcinus orca. *From Evans* et al. *(1982).*

attenuata and *S. frontalis*) vary individually in the degree of spotting, and average spotting varies geographically as well; the offshore Gulf Stream form of *S. frontalis* is all but unspotted (Perrin *et al.*, 1987). The *truei* and *dalli* color morphs of Dall's porpoise (Fig. 7), originally described as different species, typify regional populations but include the range of coloration in a single population (Ridgway and Harrison, 1999). Baleen whales vary geographically in coloration of the baleen and in details of color pattern of the body and appendages, which also vary greatly within populations. Spotting is highly variable among individual harbor seals, and differences can be found between populations even on different islands in an archipelago (Hammond *et al.*, 1990). Humpback whales of the southern hemisphere tend to have more white pigmentation in their bodies than their northern hemisphere counterparts.

V. Genetics

Little is known of the genetic basis of coloration in marine mammals. Albinism is possibly an autosomal dominant trait as in humans. Analysis of populational data for the North Atlantic right whale, *Eubalaena glacialis*, suggests that the presence of white ventral skin patches is an autosomal recessive trait (Schaeff and Hamilton, 1999); it is not evident from data that the trait is subject to selection pressure.

VI. Microanatomy

Pigmentation in cetaceans is limited to the occurrence of melanin in the epidermis. The distribution of melanin in the skin of *Delphinus delphis* (Gwinn and Perrin, 1975) is described here as an example. The pigment is usually concentrated around the bases of the dermal papillae and extends in bands from their apices. Portions of the skin that appear white show very small amounts of diffuse pigment (particles unresolvable at 1250 × magnification) and small granules (less than 5 μm in diameter). The buff color characteristic of the thoracic patch is associated with an equal prominence of diffuse and small granules or higher density of diffuse pigment. The gray flank patch has some small granules but mostly large granules (>5 μm). The black regions of the back and flukes have the highest density of large granules. It may be hypothesized that the type of melanin that produces the buff color is of a composition that does not allow further polymerization but favors its combination with a protein instead of aggregation into granules. In gray and black areas of the color pattern, the aggregation of particles proceeds, and melanocytes containing them migrate toward the surface of the epidermis until diffuse pigment is largely replaced by granular pigment.

VII. Function and Evolution

An early analysis of coloration in cetaceans (Yablokov, 1963) proposed several functions: acquisition of prey, protection from predators, and communication with conspecifics. Cetacean patterns were divided into three types: (1) uniform or finely spotted, adapted to planktonic feeding or feeding in murky water or great depths where vision is not important; (2) strongly spotted, striped, or patterned, for intraspecific recognition; and (3) countershaded, as camouflage against predators in animals foraging near the surface. However, spots would seem also to

Figure 7 *Two color morphs of* Phocoenoides dalli: dalli *type (top) and* truei *type (bottom). From Jefferson (1988).*

be useful in camouflage, as the surface of the sea appears dappled when seen from below. Notably, spotted dolphins are strongly countershaded at birth and only begin to develop spots at about the age when they begin to forage on their own; in this case the likely function of the spots is camouflage against prey. The pattern of development is the reverse of that in many species of deer, which are spotted at birth and lose their spots as they become self-sufficient; here the function is camouflage against predators. The stripes and marks on the typical delphinid head (eye stripe, blowhole stripe, flipper stripe, eye spot, and lip mark) may also serve as camouflage against prey, obscuring the eye and mouth as in many terrestrial mammals and other tetrapods, including reptiles, amphibians, birds, and fishes. Many cetaceans have prominent white color pattern elements or patches, often bordered with dark pigmentation; these may function in species recognition or serve to signal the positions of school mates in low-light conditions. Similar functions have been suggested for the bold color patterns seen in some phocid pinnipeds, together with possible uses in signaling gender and age. The patterns may also serve in disruptive coloration for camouflage against predator or prey.

The fin whale is unique among marine mammals in being asymmetrically patterned. The left anterior third of the body and the baleen on the left side are dark, but the lower jaw and the anterior baleen on the right side are white. The white area has been proposed to function to maintain countershading when the whale rolls on its side during feeding or to startle prey during prey herding.

A simple countershaded pattern has been proposed to be the most primitive and generalized for the delphinid cetaceans (Mitchell, 1975) because it is a pattern shared by many taxa of marine organisms inhabiting near-surface waters and used for concealment through counterlighting. The crisscross pattern of *Delphinus* spp. is perhaps the most derived (as the most complex), with a possible function of obscuring the presence of a small calf swimming side by side with the mother.

The color pattern can evolve through paedomorphosis, the retention of fetal or juvenile characteristics into adulthood. The dark "hoods" on the heads of some dolphins and small-toothed whales may have evolved this way. The system of stripes on the head (eye stripe and blowhole stripe) in delphinid and phocoenid cetaceans develops from a single mark across the back of the head behind the blowhole in small fetuses (Perrin, 1997). A progressive forward invagination of the mark on each side of the head creates the two stripes, which are initially broad and then narrow to varying degrees. The stripes vary among species in width and definition, but in some species, e.g., *Cephalorhynchus* spp. and some of the globicephalinine species such as *Peponocephala electra*, a fetal condition is retained and the "blowhole stripe" effectively covers the entire top of the head (Fig. 1). It is interesting to note that the *Cephalorhynchus* species are also paedomorphic in their osteology, convergent on the phocoenids in body and skull size and shape.

Paedomorphosis may account for geographic variation in the expression of color pattern elements in some species. For example, the cape is visible in the fetus of the killer whale but is usually not expressed in the postnatal animal. However, the cape is distinctly visible in all whales in an Antarctic population. Similarly, the adult of the Kerguelen Islands form of Commerson's dolphin *Cephalorhynchus commersonii* retains a grayish portion of the color pattern seen only in calves in the South American population (Robineau, 1986).

VIII. Coloration as a Taxonomic Character

Color pattern features are useful in taxonomy. In some cases, what were thought to be color variants of a single species have proved to be distinct species [e.g., the common dolphins *Delphinus delphis* and *D. capensis* (Heyning and Perrin, 1994) and the minke whales *Balaenoptera acutorostrata* and *B. bonaerensis* (Best, 1985)]. However, in other cases, species defined on the basis of color pattern differences have been subsequently lumped [e.g., the striped dolphin, *Stenella coeruleoalba*, and its nominal synonyms (Fraser and Noble, 1970) and the *dalli* and *truei* forms of Dall's porpoise, *Phocoenoides dalli* (Ridgway and Harrison, 1999)], demonstrating that the same caution must be used in employing color pattern characters as in the use of any other morphological characters. The contributions of ontogenetic, individual, and geographic variation must be delineated before species-level differences and higher-level taxonomic relationships emerge.

One use of coloration in higher-level taxonomy has been in the cladistic analysis of relationships among the delphininoid cetaceans (Fig. 8); the delphinids and the phocoenids are sister taxa in sharing the derived *bridle*, or system of head stripes, consistent with phylogenetic relationships in the group based on other morphological characters (Heyning, 1989).

IX. Ephemeral and Anomalous Variation

Real and apparent changes in coloration can be ephemeral or environmentally induced. For example, some dolphins (and old walruses) are at some times pink and other times white. The Amazon river dolphin *Inia geoffrensis* is also known as "*bufeo colorado*" because of its pink color when seen in its natural habitat; in captivity in a temperate-latitude aquarium it is white. Some adult individuals of the Indo-Pacific humpback dolphin, *Sousa chinensis*, in the waters of Hong Kong have been observed to be bright pink whereas some other tropical dolphins sometimes exhibit pink bellies. This fact is even incorporated in the scientific name of one dolphin, the dwarf spinner dolphin of Southeast Asia, *Stenella longirostris roseiventris* (Perrin *et al.*,

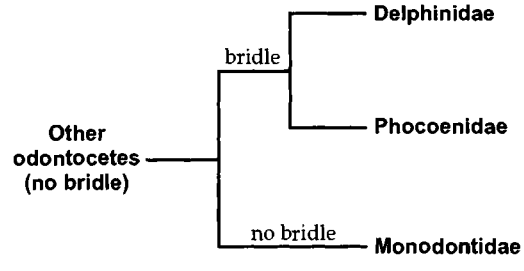

Figure 8 *Cladistic relationships among the living families of delphinoid cetaceans based on the presence or absence of the bridle. From Perrin (1997).*

1999). The pink color is due to dilation of subcutaneous blood vessels, presumably for purposes of thermoregulation; dolphins everywhere must dispose of excess heat generated by metabolism, which is a greater problem in warm tropical water. Even the Arctic walrus, *Odobenus rosmarus*, must "dump" heat, and palely pigmented old males may appear "rosy" during relatively warm weather. In cetaceans, the pink coloration is visible only in animals or parts of animals that are normally white (lacking melanin), although light-gray dolphins, such as immature individuals of *Sousa chinensis*, may sometimes appear purplish because of the subcutaneous suffusion with blood. When a "pink" walrus enters the water, the skin becomes ischemic (deprived of blood) and the animal appears white.

Other pinnipeds change color when wet; e.g., the brown California sea lion becomes almost black. Seasonally molting pinnipeds change color, becoming drabber as the molt approaches. Reddish pelage in harbor seals can be the result of deposition of iron oxide precipitates on the hair shaft. Even conditions such as water color, cloud cover, and angle of sun can cause cetaceans to apparently change color in the water. The striped dolphin, also known as the blue-and-white dolphin, can appear brown and white in turbid water or under overcast skies. A sojourn in high latitudes can lead to an accumulation of a coat of yellowish diatoms in the blue whale *Balaenoptera musculus*, leading to one of its other common names, "sulfur-bottom." In one minke whale taken in the Antarctic, the areas normally white were pinkish and the baleen, blubber, and connective tissue were orange; the cause of the "carotenoid" coloration was not apparent (Kato, 1979) but may have been metabolic. Cetaceans in captivity in shallow tanks can become darker when exposed to the sun. The intensity of coloration has been reported to vary seasonally in common dolphins in the Black Sea. In some cetacean species, apparent stripes or spots can be scars. Adult male beaked whales inflict long parallel rakes on each other with their teeth (the behavior also occurs in species in which the teeth erupt in females). Most cetaceans that frequent tropical waters bear oval or stellate scars from the bites of cookie cutter sharks; these can be so numerous as to give the animal an overall spotted appearance.

Anomalous conditions such as albinism, melanism, and piebald coloration have been recorded for many cetacean and pinniped species. In one anomalous color pattern variety that has been seen in the short-beaked common dolphin in widely separated parts of the world, the dorsal overlay is missing, eliminating the typical crisscross pattern (Perrin *et al.*, 1995).

Coloration in cetaceans changes with death. Subtle elements of color pattern disappear quickly in a dead stranded animal as the skin dries, and a dolphin with a complex color pattern can turn solid black when long dead or frozen (careful thawing in water can sometimes bring back some of the pattern). The outer layers of the skin can be abraded away during stranding, which has resulted in more than one report of a stranded "white whale". The accounts of coloration in some original species descriptions of cetaceans were based on long-dead specimens and thus are defective (e.g., Heaviside's dolphin, *Cephalorhynchus heavisidii*, is not uniformly black as originally described, but boldly patterned). Much remains to be learned about the color pattern of the living animal for many species.

Common Dolphins

Delphinus delphis, D. capensis, and *D. tropicalis*

William F. Perrin
Southwest Fisheries Science Center, La Jolla California.

The short-beaked common dolphin (*Delphinus delphis*) is the most numerous dolphin in offshore warm-temperate waters in the Atlantic and Pacific, often coming from a distance to join a boat and ride the bow wave. The very closely related long-beaked common dolphin (*D. capensis*) is seen less often in most regions and is difficult to distinguish from its congener at sea. The very-long-beaked endemic Indian Ocean common dolphin (*D. tropicalis*) is poorly known and of uncertain taxonomic status.

I. Characters and Taxonomic Relationships

All the common dolphins are slender and have a long beak sharply demarcated from the melon (Fig. 1). The dorsal fin is high and moderately falcate, although in some areas it may be erectly triangular. The three species are distinguished from other dolphins by a unique crisscross color pattern formed by interaction of the dorsal overlay and cape, resulting in distortions of the usual delphinine lateral and ventral fields. The lower margin of the dorsal overlay passes high anteriorly and dips to cross the ventral margin of the low-riding cape, yielding a four-part pattern of dark gray to black uppermost portion or spinal field (cape under dorsal overlay), buff to pale yellow anterior portion or thoracic patch (undiluted cape), light to medium gray posterior portion or flank patch (undiluted dorsal overlay/lateral field), and white abdominal field. A dark flipper-to-anus stripe may parallel the lower margin of the cape and extend to the genital region. A dark flipper stripe runs forward to join the lip patch on the underside of the beak. In the short-beaked species, the color pattern is more crisp, the thoracic patch is more yellowish, the subcape stripe tends to be anteriorly narrow and faint, and the flipper stripe tends to be narrow and pass low below the corner of the gape. In the long-beaked species, the pattern is more muted, the spinal field may be grayish, the thoracic patch tends to be pale buff, the flipper-to-anus stripe tends to be broad anteriorly and may be pronounced and contiguous with the flipper stripe, and the flipper stripe tends to wander toward the corner of the gape before passing ventrally to join the lip patch mark. The Indian Ocean common dolphin is similar to the long-beaked species in coloration. In the short-beaked species, the dorsal fin and flippers may be all white or have white centers. These relative features may not be evident in juveniles.

Full species status for the three forms has not been widely recognized until recently (Evans, 1994; Heyning and Perrin, 1994; Rice, 1998), and data on size and weight for the three species have been commingled in the literature for some parts of the world. Data exist for well-documented series of adults of two species from California waters. In the short-beaked species, males were 172–201 cm long (n = 28) and females were 164–193 cm (n = 37) *vs* 202–235 cm (n = 15) and 193–224 cm (n = 10), respectively, for the long-beaked form. The short-beaked species ranged to about 100 kg and the long-beaked species to about 135 kg. However, this pattern of differential size may not hold globally; a geographic form of the short-beaked species in the eastern tropical Pacific ranges in length to 235 cm, as large as the long-beaked species in California waters.

The SKULLS of *Delphinus* spp. are different from those of all the other delphinines (*Stenella* spp., *Tursiops* spp., *Sousa* spp., and *Lagenodelphis hosei*) in the combination of long narrow rostrum and deep palatal grooves. They are similar to the skulls of *Stenella longirostris, S. clymene, S. coeruleoalba,* and *L. hosei* in having a strongly dorsoventrally flattened rostrum with distally splayed teeth, about 40–60 teeth in each row, relatively small temporal fossae, and sigmoid mandibular rami. The two sympatric species differ in proportional length of the rostrum in adults: the ratio of rostral length to zygomatic width in *D. delphis* is 1.21–1.47 and in *D. capensis* is 1.52–1.77 (Heyning and Perrin, 1994). Upper/lower tooth counts in California were 42–54/41–53 (n = 49/47) and 47–60/47–57 (n = 53/51), respectively. Vertebral counts were 74–80 (n = 80) in *D. delphis* and 77–80 (n = 25) in *D. capensis*. The osteology of *D. tropicalis* has not been well described, but the rostral/zygomatic ratio of the holotype specimen is 2.06 and the tooth counts 65–65/57–58, both well beyond the upper range of *D. capensis* for California. Six *Delphinus* skulls from the Arabian Peninsula ranged continuously from 1.72 to 1.94 in rostral/zygomatic ratio. Three (with the lowest ratios) had been identified as *D. capensis* and the others as *D. tropicalis*; the range overlaps that of *D. capensis* in California (Smeenk *et al.*, 1996). It has been suggested that *D. tropicalis* may be a very long-beaked form at the end of a cline of *D. capensis* extending into the Indian Ocean rather than a separate third species of *Delphinus* (Heyning and Perrin, 1994; Smeenk *et al.*, 1996; Rice, 1998).

The common dolphins are members of the delphinid subfamily Delphininae *sensu stricto* (LeDuc *et al.*, 1999). In a cladistic phylogenetic analysis based on cytochrome *b* mtDNA, they share a strongly supported polytomic clade with *Stenella coeruleoalba* and *S. clymene* (sister taxa), *S. frontalis,* and *Tursiops aduncus. D. tropicalis* is basal in the *Delphinus* clade, with California *D. delphis,* Black Sea *D. delphis,* and *D. capensis* in a subsidiary three-part polytomy, making *D. delphis* seemingly paraphyletic. However, apparent paraphyly among terminal taxa can result from lineage sorting in newly evolved species (LeDuc and Perrin, 1999); reciprocal monophyly has not yet had a chance to evolve in such cases. As noted earlier, *Delphinus* shares several skull features with *S. longirostris,*

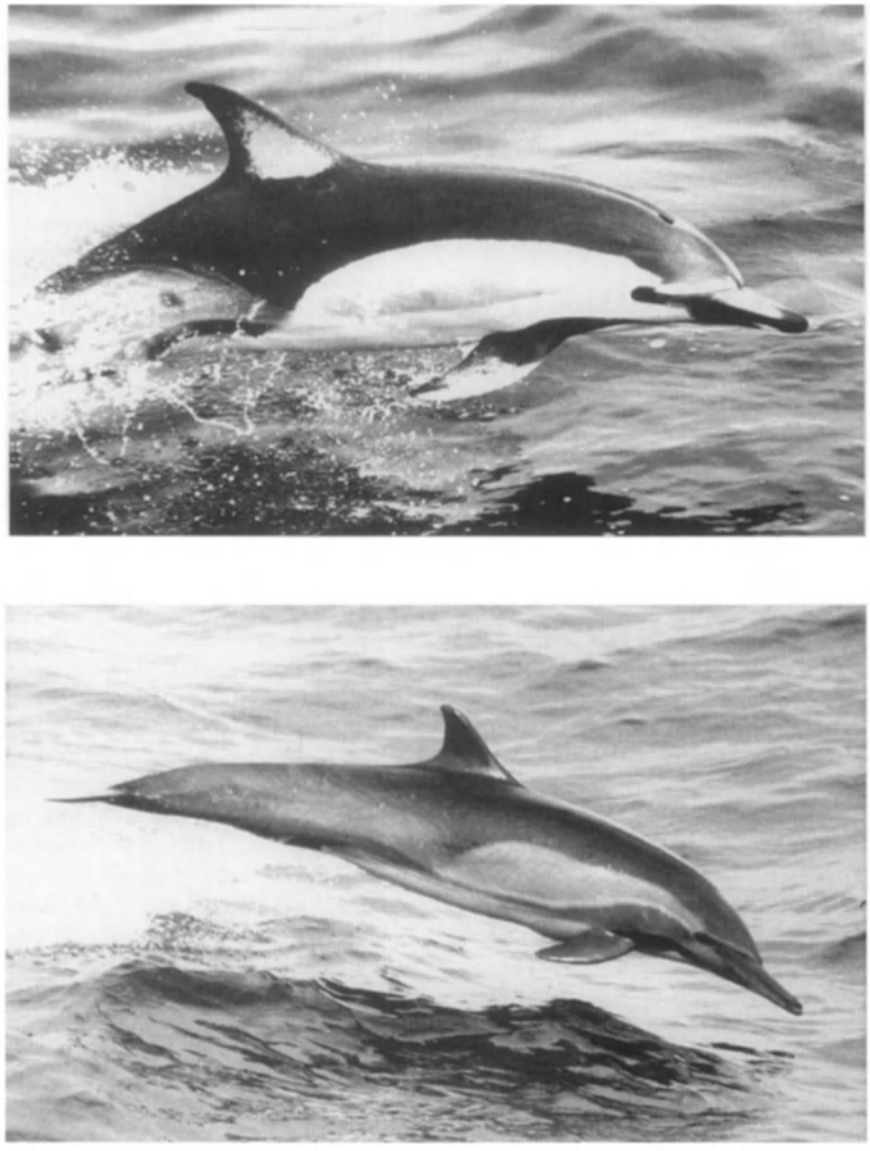

Figure 1 *Short-beaked (top) and long-beaked (bottom) common dolphins,* Delphinus delphis *and* D. capensis, *respectively. From Heyning and Perrin (1994).*

S. coeruleoalba, S. clymene, and *L. hosei,* but that grouping is not supported by the molecular results to date.

II. Distribution and Ecology

Common dolphins occur in warm-temperate and tropical waters worldwide from about 40–60°N to about 50°S (Jefferson *et al.*, 1993), but because the three species were considered to be forms of one until recently, many DISTRIBUTION records and much documentation of range have not been identified to species (Rice, 1998). Based on records with diagnostic characters (Fig. 2; Heyning and Perrin, 1994), *D. delphis* occurs from southern Norway to West Africa in the eastern Atlantic (including the Mediterranean and Black Seas), from Newfoundland to Florida in the western Atlantic, from southern Canada to Chile along the coast and pelagically in the eastern Pacific; in the central North Pacific (but not in Hawaii); from central Japan to Taiwan and around New Caledonia, New Zealand, and Tasmania in the western pacific; and is possibly absent from the South Atlantic and Indian Oceans. *D. capensis* occurs disjunctly in warm-temperate and tropical coastal waters in West Africa, from Venezuela to Argentina in the western Atlantic, from southern California to central Mexico, and in Peru in the eastern Pacific, around Korea, southern Japan and Taiwan in the western Pacific, and in waters of Madagascar, South Africa, and possibly Oman in the Indian Ocean. The identification of the Oman specimens is in some doubt (Smeenk *et al.*, 1996). *D. tropicalis* is known only from the northern Indian Ocean and Southeast Asia.

D. delphis and *D. capensis* are narrowly sympatric in some nearshore waters; schools of the two species may be seen in the

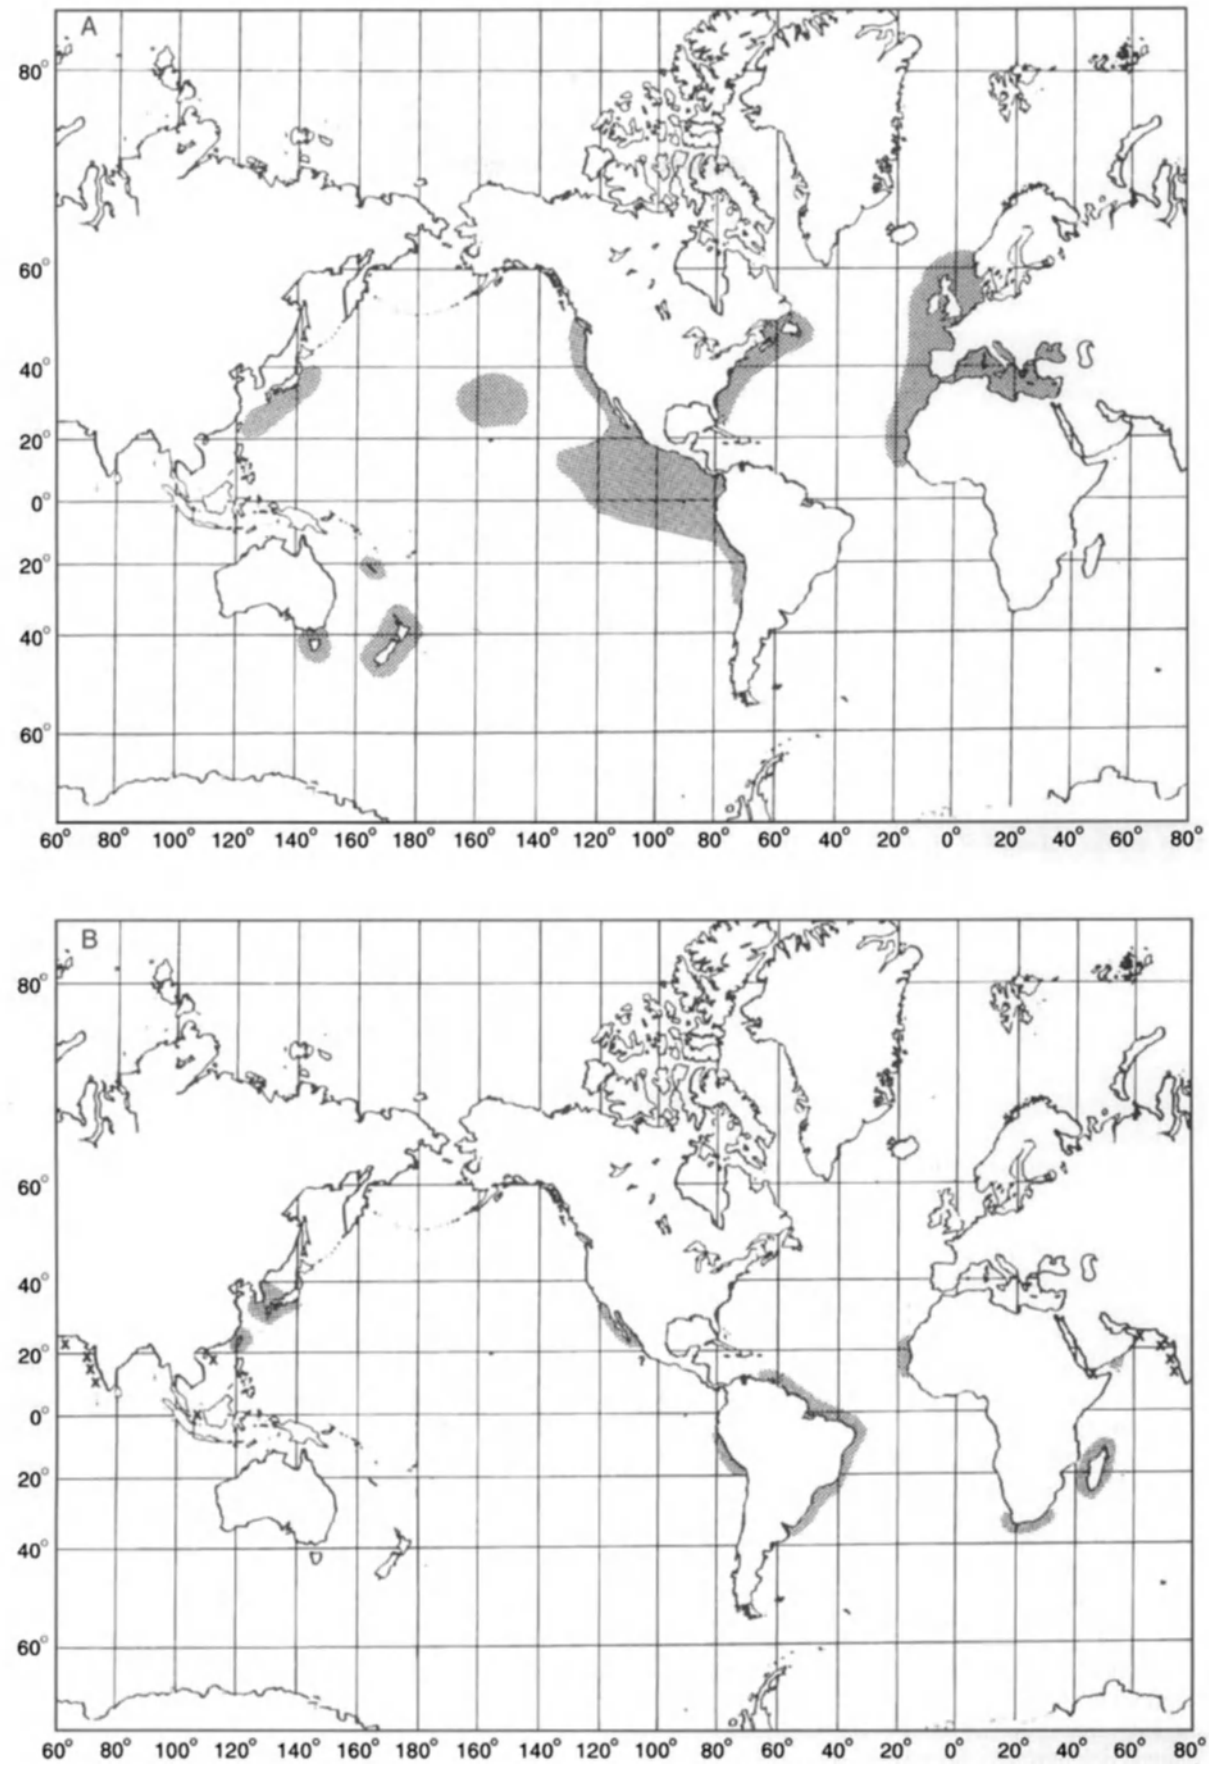

Figure 2 *Approximate known distributions of (A) short-beaked common dolphin* Delphinus delphis *and (B) long-beaked common dolphin* D. capensis. *Records of nominal species* D. tropicalis *represented by Xs. From Heyning and Perrin (1994).*

same general area on the same day. However, *D. capensis* seems to prefer shallower and warmer water and generally occurs closer to the coast. In the eastern North Pacific, substantial seasonal and interannual changes in abundance of *D. delphis* suggest migrations that vary with oceanographic conditions; the movements may be north–south and/or inshore–offshore (Forney and Barlow, 1998). In the tropical eastern Pacific, *D. delphis* occupies primarily upwelling-modified habitats with less tropical characteristics than surrounding water masses (Reilly and Fiedler, 1990); separate northern, central, and southern stocks associated with different upwelling areas are recognized in the management of incidental mortality in tuna fisheries (Perrin *et al.*, 1985).

As would be expected for a species occupying a wide range of habitats, common dolphins feed on a variety of prey, including small mesopelagic fishes and squids found in the deep scattering layer and epipelagic schooling species such as small scombroids, clupeoids, and market squids (Evans, 1994; Ohizumi *et al.*, 1998). Foraging dives to 200 m have been recorded. Diet varies with season as well as with region (Evans, 1994). FEEDING habits of the three species have not been compared.

III. Behavior and Life History

Schools of hundreds or thousands are thought to be composed of smaller subunits of about 20–30 perhaps closely related individuals (Evans, 1994). Differences between schools in cranial measurements and color pattern suggest that schools have temporal integrity at some level. There may be segregation in schools by age and sex. Association with schools of pilot whales (*Globicephala* spp.) and other dolphins (*Lagenorhynchus* spp.) have been observed, as has "bow riding" on mysticete whales, possibly the origin of bow riding on vessels. Common typical aerial behavior includes "pitch poling," in which the dolphin leaps high vertically and falls lengthwise back into the water to create a large splash. In some areas in the eastern tropical Pacific, schools of *D. delphis* "carry" yellowfin tuna and are chased and captured by tuna fishermen using purse seines.

Gestation in *D. delphis* in the Black Sea is 10–11 months (Perrin and Reilly, 1984), with length at birth at 80–90 cm. The calving interval varies from about 1 (Black Sea) to about 3 years (eastern Pacific). Weaning occurs at 5–6 months in the Black Sea, but possibly later in other areas. Estimates of age at sexual maturation vary with region from 3 years (Black Sea) to 7–12 years (eastern Pacific) for males and 2–4 and 6–7 years, respectively, for females. Part of the range of variation may be a density-dependent effect due to exploitation. Maximum estimated age is 22 years (Black Sea).

IV. Interactions with Humans

Short-beaked common dolphins die in large numbers in tuna purse seines in the eastern tropical Pacific (Evans, 1994) and, with long-beaked and Indian Ocean common dolphins, in gill net fisheries around the world (Perrin *et al.*, 1994); the impact of these kills on the populations is for the most part unknown.

Common dolphins have been kept successfully in captivity for up to 8 years in eastern European oceanaria and reproduced successfully in captive facilities in the United States, New Zealand, and Russia (Evans, 1994). *D. capensis* has hybridized with *T. truncatus* in captivity, producing viable offspring of unknown fertility (T. Goff, unpublished data).

Communication

KATHLEEN M. DUDZINSKI
Dolphin Communication Project, Oxnard, California

JEANETTE A. THOMAS
Western Illinois University, Moline

ETIENNE DOUAZE
Greenleaf Walk, Singapore

Social behavior is organized into patterns of coordinated activities among individuals of a species. This coordination is achieved through the exchange of information about conspecifics, other species, and the environment. Communication is

the glue that holds animal societies together. To understand communication in a given species, it is important to view the mode of the signal (*i.e.*, visual, audible, tactile, gustatory, or olfactory), medium in which the signal is transmitted (air and/or water), mechanisms of signal production (anatomical and/or physiological), and functions of signal (*e.g.*, aggression/submission, mate attraction, parental care, territorial defense).

This article is a brief overview of communication in marine mammals. Even with more than 40 years of focused studies on the social lives of marine mammals, relatively little is understood about the majority of species within marine mammal groups—cetaceans, pinnipeds, sirenians, mustelids (sea otters, *Enhydra lutris*) and ursids (polar bears, *Ursus maritimus*). Behavioral characteristics and social relationships are adapted to each species' unique ecology. Marine mammals are either amphibious or totally aquatic. Each life mode imposes different restraints on signal exchange and communication. A paucity of studies on communication exists for many marine mammals, especially polar bears, sea otters, dugongs (*Dugong dugon*), and manatees (*Trichechus* spp.). The majority of research on communication has been conducted on pinnipeds (such as Weddell seals, *Leptonychotes weddellii*; and California sea lions, *Zalophus californianus*) and cetaceans (particularly bottlenose dolphins, *Tursiops* spp.; killer whales, *Orcinus orca*; and humpback whales, *Megaptera novaeangliae*). Thus, our discussion highlights and compares species predominantly represented in the literature.

I. Definition

A clear definition of communication is needed to facilitate consistency among studies and to avoid ambiguities in methods. Bradbury and Vehrencamp (1998) provided this definition: "communication involves the provision of information (via a signal) by a sender to a receiver, and subsequent use of this information by the receiver in deciding how to respond." Determining how communication contributes to the maintenance and coordination of behavior among individuals of a group is pivotal to understanding social behavior.

The signal is the vehicle by which the sender and receiver exchange information or communicate. Both the sender and the receiver rely on the accurate interpretation of signals to meet common group challenges such as reproduction, predator defense, foraging, and parental care. Communication promotes group cohesiveness (Vauclair, 1996). Signals are mechanisms or "tools" specialized over time to be informative, salient to interactions among individuals, and adapted for optimum transmission in their environment(s). Active communication signals provide intentional information to a conspecific that benefits the sender. However, communication can also be passive and information transfer unintentional. For example, a killer whale is alerted to the presence of a sea lion jumping in the water by a splashing sound. This inadvertent noise by the sea lion cues the killer whale to the presence of a tasty morsel and members of a killer whale pod coordinate a hunt through various acoustic and visual signals. The acoustic cue does not benefit the sender at all and there was no intentional communication from the prey to the predator. Predators are adapted especially to detect and exploit passive cues, whereas prey are adapted to minimize the sending of passive cues. In active communication, an efficient signal from the sender matches the most adaptive response by the receiver. For example, sound exchange among killer whales probably enhanced group foraging on the aforementioned sea lion. It is beneficial to both the sending and the receiving killer whales to communicate effectively.

Signals can be subtle, such as a unique color pattern or a slight change in body orientation, or signals can be more dramatic, as exemplified by a 193-dB trill made by a male Weddell seal patrolling its underwater territory or a lob-tailing dolphin warning an intruder. Detailed examination of signaling behavior in an individual or group provides the genesis for understanding information exchanged and interpreting the biological basis for the intent and meaning of a signal and the resulting response.

Signals are adapted for optimal transmission in an environment, to convey appropriate information for a given context, and often are accentuated by other behaviors. Recipients use diverse sensory abilities to decipher the meaning of a signal. A sender's signal can be modified based on location, spatial relationship with the receiver, past experience, age, sex, reproductive status, environmental factors, presence of other conspecifics, and other referents. Likewise, the interpretation of signals can depend on similar factors about the receiver. Therefore, the meaning a signal conveys has a contextual basis. For example, the same signal given by a sender in one context could result in a different meaning to the receiver in another context, i.e., a jaw pop from a dolphin might be used to warn an intruder in one situation or reprimand a youngster in another circumstance. The message is the information the sender encodes in the signal, whereas the meaning is the significance attached to the signal by the receiver and the potential effects on the receiver's subsequent actions (Bradbury and Vehrencamp, 1998).

Sensory channels or modes in mammals include chemical (*i.e.*, taste and olfaction), mechanical (*i.e.*, tactile and acoustic), photic (visual), and electromagnetic (Herman, 1980; Reynolds and Rommel, 1999). These modes are used only if both the sender and the receiver are capable of accessing the pathway, detecting the signal, and interpreting the message. While most terrestrial mammals evolved signals in each of these sensory channels (Hauser, 1997), marine mammals have not, primarily because of limitations of the aquatic environment. In marine mammals, communication is achieved primarily by acoustic, tactile, visual, and gustatory sensing (Reynolds and Rommel, 1999). Marine mammals, and fully aquatic groups in particular, place less reliance on olfaction. Messages often have cross-modal components that are partly conveyed in one mode and refined in another mode. For example, a threat vocalization often is accompanied by a visually distinct threatening body posture.

II. Communication in Air and Water

Transmission of signals in water varies depending on water temperature, salinity, clarity, depth, ice cover, ambient noise, local topography, vegetation, and surface and bottom reflections (Anderson, 1969; Herman, 1980). In general, sound in

water travels 4.5 times faster and with less attenuation than in air, whereas the distance light penetrates is affected more by particulate matter suspended in the water column and depth. Thus, in water, sound provides a more affective method of communication over long distances, whereas visual, postural, or tactile signals are for short-range communication. In contrast, communication in air can include olfaction and long-distance visual displays. In air, sound attenuates more rapidly, is masked by wind and ambient noise, and is used only over shorter ranges for communication.

Because mysticetes and odontocetes are totally marine, signal exchange in air is limited to only a few aerial displays, such as breaches, lob tails, leaps, and spins. Olfaction is useless and the predominant signal modes are acoustic and tactile.

Because pinnipeds are amphibious, their sensory systems evolved as a compromise between the need to signal both in air and in water. While hauled out, many pinnipeds produce social sounds with an open mouth. These sounds often are concurrent with bared teeth or head-up postures that convey additional information. In contrast, social interactions under water occur with the mouth closed and often are associated with sounds, swimming postures, or a change in swim speeds or direction that accentuates the message. In contrast to water, where scent marks would diffuse quickly, land provides a "permanent" site for scent marking; thus olfaction likely plays a more important role in communication in pinniped colonies on land.

The communication environment of amphibious sea otters is most similar to their terrestrial mustelid cousins and pinnipeds. Sounds are most likely used in airborne communication, but there are no published records of underwater sounds in sea otters. The churning intertidal zone in which sea otters forage is not a good environment for acoustic signaling.

Although totally aquatic, sirenians, unlike cetaceans, do not dive deeply or echolocate. They do communicate at the water surface, using tactile and visual exchanges, but aerial displays, such as leaps, have not been observed and are likely not used. Manatees and dugongs use visual communication at short ranges, but rely heavily on audition at ranges beyond their vision. The dugong has a relatively elaborate sound repertoire that apparently is more complex than that of manatees.

Polar bears have similar sensory abilities to other ursids. Polar bears spend the majority of their time on land, only rarely entering the water to swim or forage. Although there are no published accounts of underwater sounds from polar bears, it is doubtful these predators have a large repertoire underwater. As in other marine mammals, olfaction and vision are of limited use in water for polar bears. Communication is primarily through airborne visual and olfactory signals. Communication among bears is limited to a short mating period, aggression between territorial males, and mother/cub interactions.

III. Context of Signal

A behavior characterizing a specific message for adults could have an entirely different meaning when exhibited by a juvenile. A good example is the "S" posture reported for many cetaceans (*e.g.*, Herman, 1980; Norris *et al.*, 1994). This posture has the head "up," anterior ventral surface (*i.e.*, chest) "down," peduncle "up," and flukes "down." This posture was observed in old and young Atlantic spotted (*Stenella frontalis*) and bottlenose (*Tursiops truncatus*) dolphins (Fig. 1). During play, juveniles perform a modified "S" with oblique angles of approach and much rubbing contact. During adult aggression, the posturing dolphin, usually a male, performs the "S" maneuver toward conspecifics accompanied by direct approaches, a bubble cloud, jaw clap, and often hits. Another context of the "S" posture is that of males during courtship indicating a willingness to copulate. It is possible that some behaviors (e.g., jaw claps, hits) are not specific to particular expressions of aggression (or play, etc.) unless modified by or coupled with a specific posture or approach.

Play often is characterized by mock fighting behaviors that are modified with subtle cues reminding conspecifics that the intent of ongoing activities is not truly aggressive. Play occurs in young during the formation of long-term social attachments and while young learn the meaning and proper use of the signals within their social structure. Because pinniped pups do not manipulate objects with their fore flippers, are usually kept separate from other pups by their mothers, and develop rapidly (in comparison to cetaceans), evidence of play is limited. Occasionally, Weddell seal pups chew on or manipulate a chunk of ice with their fore flippers in a playful manner. Under water, these pups spend a great deal of time learning to adjust their buoyancy. Initially, their fat bodies float at the surface, the pups struggle to go deeper by dramatic undulations of their hind flippers, and as soon as flipper motion stops the pup bobs back to the surface like a floating cork. The pups repeat the diving/pop-up sequence many times before they perfect the seemingly effortless swimming motion of older seals.

A signal can have different meanings to a male and female of the same species. For example, the repeated thumping sound, head-up posture, and display of the large proboscis in a male northern elephant seal (*Mirounga angustirostris*) warn an intruding male to stay away from a harem master's territory and attract females as potential mates. At the same time, this display warns nearby pups to move or be trampled.

IV. Chemical Communication

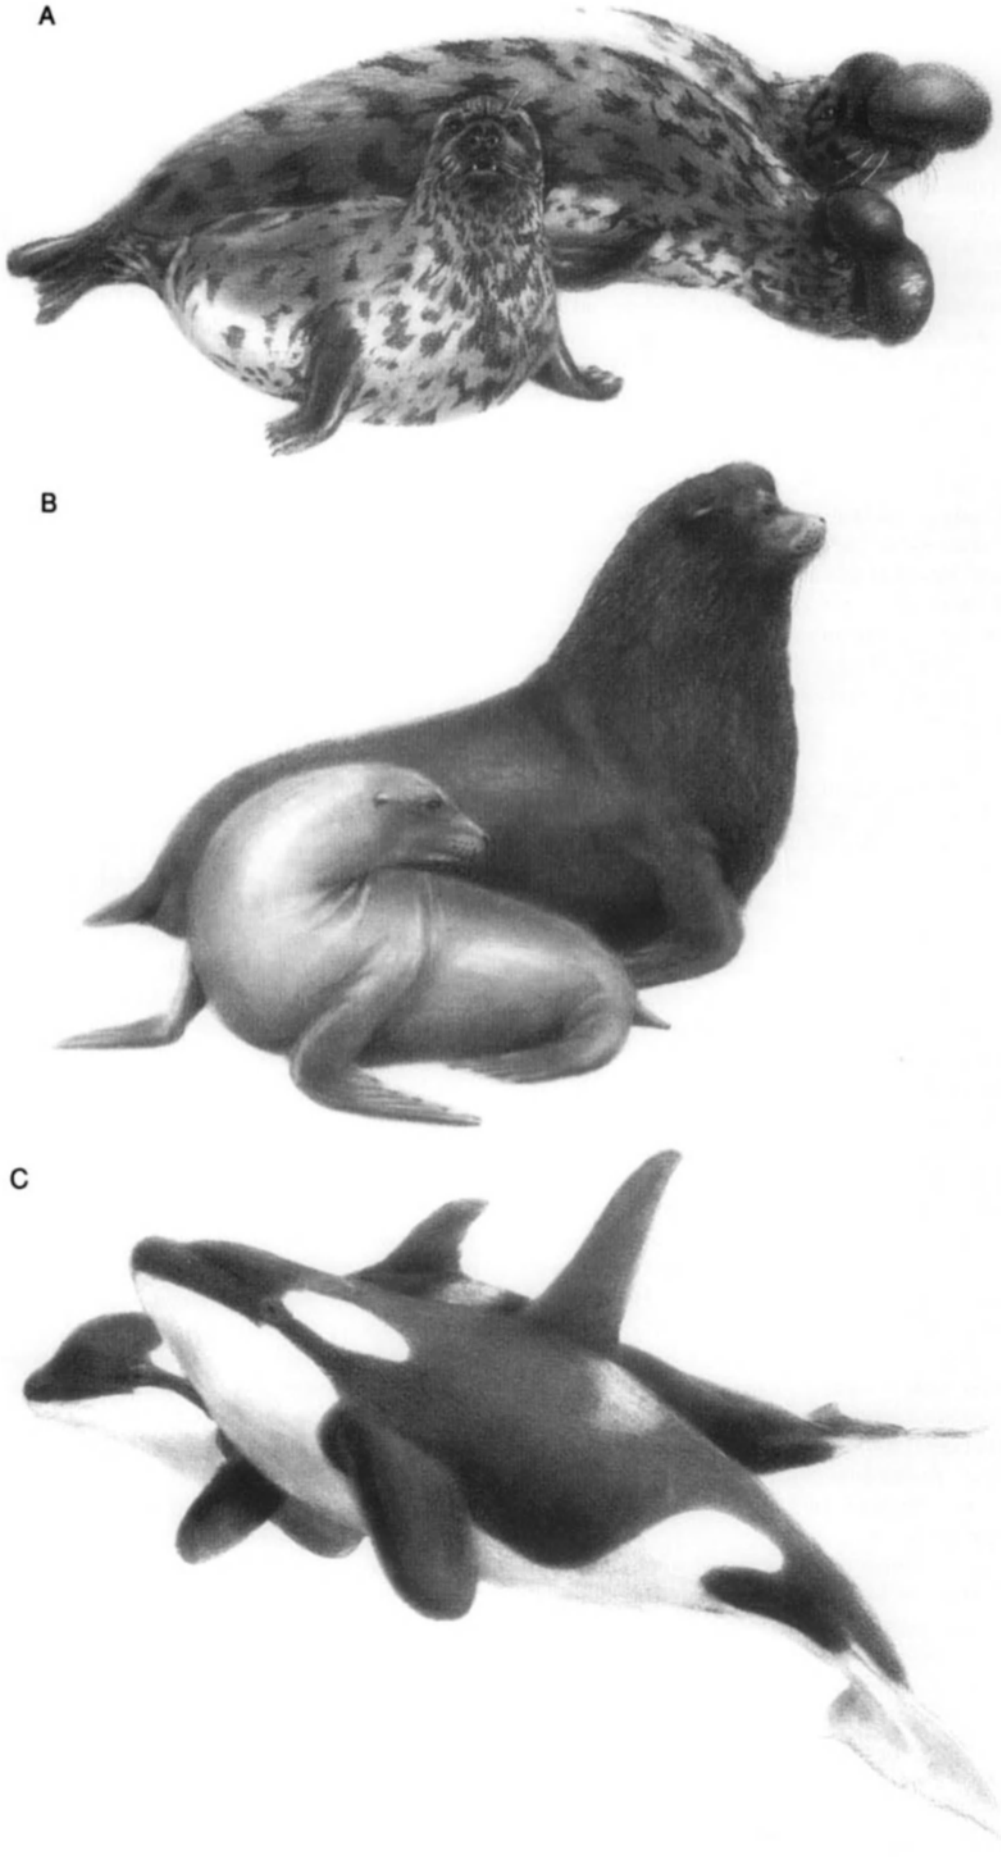
Chemoreception is common among terrestrial mammals, but little is understood about how marine mammals sense chemical signals in the water (Reynolds and Rommel, 1999). The olfactory sense and anatomy are ill-suited for communication in water, and this sensation declines with greater adaptation to an aquatic lifestyle (Reynolds and Rommel, 1999). Jansen and Jansen (in Anderson, 1969) found that adult odontocetes lack olfactory nerves, bulbs, and tracts; the same are reduced greatly in adult mysticetes. The possibility that scents are pheromonal in nature and function has not been examined in marine mammals, although anecdotal accounts exist. Yablokov (1961) suggested that belugas (*Delphinapterus leucas*) release a "pheromone" when alarmed. Belugas react to blood in the water by either quickly escaping or becoming unusually excited. Trails of both feces and urine deposited by schools of dolphins could contain sexual pheromones. At times, spinner dolphins (*Stenella longirostris*) appear to swim deliberately through dispersing excrements deposited by schoolmates (Norris *et al.*, 1994).

Most studied marine mammals have the ability to taste, although with somewhat different receptive qualities than terrestrial mammals (Reynolds and Rommel, 1999). Taste buds have been documented behaviorally and physiologically for both cetaceans and sirenians (*e.g.*, Herman, 1980; Schusterman *et al.*, 1986; Reynolds and Rommel, 1999). Friedl *et al.* (1990) experimentally tested the taste sensitivities of bottlenose dolphins (*T. truncatus*) and found they can discriminate sour, sweet, bitter, and salty solutions. They were least sensitive to different salt concentrations, which seems adaptive given they live in a marine environment.

The olfactory anatomy of pinnipeds is variably reduced, more for phocids or odobenids than for otariids (Reynolds and Rommel, 1999). Pinnipeds employ scents to exchange or gain information about colony members. For example, male northern fur seals (*Callorhinus ursinus*) sniff the hindquarters of females to assess their estrous state (Reynolds and Rommel, 1999). The largest glands of pinnipeds are around the vibrissae and could play a role in mother/pup recognition. Mothers and pups maintain a great deal of nose-to-nose contact and use odor cues for recognition in air. Little work has been conducted on pinniped taste sensations. Friedl *et al.* (1990) examined taste abilities in California sea lions (*Zalophus californianus*), and Kuznetsov (1990) demonstrated gustatory abilities in Steller sea lions (*Eumetopias jubatus*). Both studies found similar taste abilities with some sensitivity to acidic, basic, and salty solutions, but not to sweet.

Sirenians have a rudimentary olfactory system (Reynolds and Rommel, 1999) and likely rely, to a limited degree, on chemicals for signal exchange among conspecifics. However, because aquatic plants are known to have different smells, manatees and dugongs could use this sense in foraging. No information is available on taste abilities in sirenians.

Unlike other mustelids, known for their musky smell, the sea otter has no scent glands. This is likely a result of the aquatic environment in which scent marking would have limited usefulness. Kenyon (1975) reported that sea otters in water commonly surface and sniff the air, and male sea otters smell the genital area of an estrous female during precopulatory behavior. It is assumed that sea otters and polar bears have taste abilities similar to their terrestrial counterparts, although the exact extent of this sense is unknown for these species.



Polar bears have a keen sense of smell, especially useful in foraging. While little is known about how olfaction is used for communication among polar bears, patterns are likely similar to those observed in other ursids and used by males to find potential mates (Ovsyanikov, 1996; Stirling, 1999). No studies are available on taste abilities of polar bears.

V. Visual Communication

Behavioral displays are well documented for many marine mammals with visual detection and acuity levels being good both above and under water for all species studied (Reynolds and Rommel, 1999). Under water, VISION is limited by light levels, the concentration and type of organic matter, and depth (for a thorough discussion of light in the ocean and visual adaptations by marine mammal species for visual detection and acuity above and below the water, see Reynolds and Rommel, 1999). Visual cues can be simple displays, such as body postures or coloration patterns, or they can be elaborate sequences of behaviors that indicate a context, species, age, sex, or reproductive condition. Several pinnipeds incorporate body coloration or postures into visual displays. For example, a territorial Weddell seal patrols the water underneath a crack in the fast ice, using loud trill sounds accompanied by an S-shaped posture that thrusts the chest forward and the hind flippers downward. Movements and postures often are highlighted in species with conspicuous color patterns. In clear water, visual signals provide cetaceans and other marine mammals a close-range alternative to acoustic signaling; however, displays could inadvertently alert predators or prey.

SEXUAL DIMORPHISM is a distinct visual cue and prevalent in many marine mammals. Females tend to be larger in mysticetes, whereas most odontocete males are larger. In mysticetes, size differences are likely due to the half-year fast that females endure each breeding/calving season. In odontocetes, the size discrepancy between genders is likely related to social signals: either direct competition among conspecifics or as an indication of fitness to potential mates. In many pinnipeds and the polar bear, males are two to three times larger than the females. Sea otter males are slightly larger than females, while there is no indication that adult male and female manatees differ in size. Secondary sexual characters often represent a passive visual display that could function to serve in mate selection (for an overview, see Thomas and Kastelein, 1990). Examples include the postanal keel in male spinner dolphins, tusk in male narwhals (*Monodon monoceros*), large dorsal fin in male killer whales, a bulbous, pronounced nose and larger chest in male elephant seals, and white fur heads in male sea otters (Fig. 2).

The variety of patterns and shades of black and white colors on cetacean bodies have been discussed elsewhere (see Thomas and Kastelein, 1990); however, use of COLORATION differences as communication signals is rarely addressed. Color

A
B
C

patterns can signal intention, species, individual identification, age, and reproductive status. Recurrent types of body marks and color patterns in marine mammals include spots, streaks, longitudinal stripes, saddle patches, capes, blazes, chevrons, and eye patches. Generally, color patterns in cetaceans take three forms: uniform, countershaded, and disruptive (Fig. 3). Uniform and countershaded color patterns likely result from predator pressures to be inconspicuous, with little communicative value. At close range, disruptive markings likely facilitate intraspecific signaling and thus schooling and other coordinated behavior. Dusky dolphins (*Lagenorhynchus obscurus*) likely use their longitudinal striping and white flank patches to corral fish during coordinated feeding bouts, but may also employ these same markings to communicate with conspecifics about the ongoing activity (in Thomas and Kastelein, 1990). Vivid eye patches in killer whales might intimidate prey. Atlantic spotted dolphins possess a similar increase in spot pigmentation with age. Belugas exhibit different colors between juveniles (gray) and adults (white).

In pinnipeds, otarids and walrus have no color markings used in communication. Walrus do change color from gray to brownish red as they warm up while hauled out. In contrast, phocids have a variety of color patterns, including stripes, streaks, spots, rings, and bands (Fig. 4). The ribbon seal (*Histriophoca fasciata*) and the harp seal (*Pagophilus groenlandicus*) have bold black and white or piebald markings that are distinguishable from a distance. Color patterns can be used in camouflage, as well as in signaling. Harp seals pups possess a pure white coat for blending into the arctic ice, whereas juveniles show black spots. The number and prominence of spots increase as harp seals age. Although observational and experimental evidence is lacking to support a communicative value for developmental changes in pigmentation or patterning in marine mammals, the possibility that color pattern differences coupled with age and behavioral differences might convey information to conspecifics cannot be discounted.

To enhance the communicative function, color patterns and morphology often are modified by postures or behaviors. Postures signal intent and demeanor of a sender and provide insight to the meaning concluded by a recipient. Terrestrial social mammals communicate much information through subtle and overt kinesic and nonlinguistic expressions, including changes in facial expressions, irregularities in respiration, and overall carriage of the body. Evolution has streamlined the cetacean body for swimming, but limited communication via facial or overt kinesic expressions. Still, subtle shifts in posture or slight body movements could be communicative between individuals or groups. For example, a slight shift in placement of a pectoral fin might signify a change in swimming direction or other shift in position among dolphins in a school. Similarly, aggression and threats in dolphins appear to be expressed through a direct vertical or horizontal approach that often is coupled with jaw claps, head shakes, body hits or slams, and emission of a bubble cloud. Submissive behavior is associated with an oblique angle of approach, mutual rubbing, or tactile contact. Often the ventral or lateral sides of the body are displayed to conspecifics.

Similarly, some pinnipeds enhance morphological characters with behaviors. The inflated red nasal sac of the hooded seal (*Crystophora cristata*) and the proboscis of the male elephant seal are used to defend territories from competing males and to attract females. Thus, the nasal sac has evolved as a signal demonstrating male fitness and intent.

VI. Tactual Communication

Visual displays are useful for close-range communication among marine mammals and, because of close proximity, visual displays readily become tactile signals. Extensive touching and rubbing occur in both captive and free-ranging animals during play, sexual, maternal, and social contexts using the nose or rostrum, flippers, pectoral fins, dorsal fin, flukes, abdomen, and the entire body. Tactile contacts often are observed during aggressive interactions, but are characterized by more overt actions, such as biting, raking, ramming, and butting. Obviously, tactile contact is limited to short distances for signal exchange. Tactile signals can be modified to increase the information content—who, where, and how animals touch, as well as the intensity of a touch, factor into the signal content.

A. Tactile Anatomy

Adult odontocetes do not have vibrissae. Some newborn odontocetes have hairs on the rostrum that could have a sensory function, but information is not available. Similarly, some adult mysticetes, bowhead (*Balaena mysticetus*) and right whales (*Eubalaena* spp.), for example, have a few hairs on their rostrum that could serve a tactile function. Cetaceans have well-developed skin sensitivity (Reynolds and Rommel, 1999). Ridgway used galvonic responses to test tactile sensitivity in different body regions of bottlenose dolphins and found the most sensitive areas were the insertion of the pectoral fin, gape of the month, tip of the rostrum, and abdomen.

Pinnipeds, sirenians, sea otters, and polar bears possess vibrissae, which function as a mechanical sensor for touch or pressure (Fig. 5). Pinnipeds and sea otters have mystachial and supercilliary vibrissae; the number varies by species. Vibrissae are heavily innervated and pinnipeds are capable of waving them forward to inspect an object. Pinniped vibrissae detect slight pressure changes similar in magnitude to the lateral line system of fish.

The manatee is unique among marine mammals in its ability to use its vibrissae or bristles in a prehensile manner. Manatees have bilobed, prehensile lips that are highly vascularized to support the numerous mystachial bristles. These bristles are likely

Figure 2 *Examples of passive visual displays in marine mammals. (A) The inflatable red nose and nasal sac of hooded seal adult males, (B) the sexual dimorphism in sea lions and fur seals, and (C) the sexual dimorphism in killer whale dorsal fins. Sketches by Jennifer Schmid-Webster.*

modified vibrissae and used in tactile exploration of the environment, vegetation, or conspecifics (Reynolds and Rommel, 1999). Manatees rub on each other, as well as inanimate objects, and females with calves maintain much body contact. The dugong has the most developed sensory hairs of any marine mammal; they are present over the entire dugong body surface, being most dense on the muzzle (Reynolds and Rommel, 1999).

Sea otters, like other carnivores, have mystachial (eight rows, 62 each side), superciliary (four each side), and nasal (three each side) vibrissae. Kenyon (1975) reported that mystachial vibrissae play the most important role in tactile sensing while hauled out or during underwater foraging. Mystachial vibrissae can be voluntarily moved forward to investigate objects and could be used for tactile signal exchange. Sea otters have unique front paws: heavily padded, coarse-textured, webbed digits with retractable claws. The exaggerated structure of these paws might aid in tactile sensing of prey, in grooming, or in conspecific communication (Fig. 5).

As with other ursids, polar bear mothers probably groom their cubs and remain in close physical contact, especially in the maternal den. Polar bears have large paws with bare pads that function as snowshoes to disperse their weight evenly to

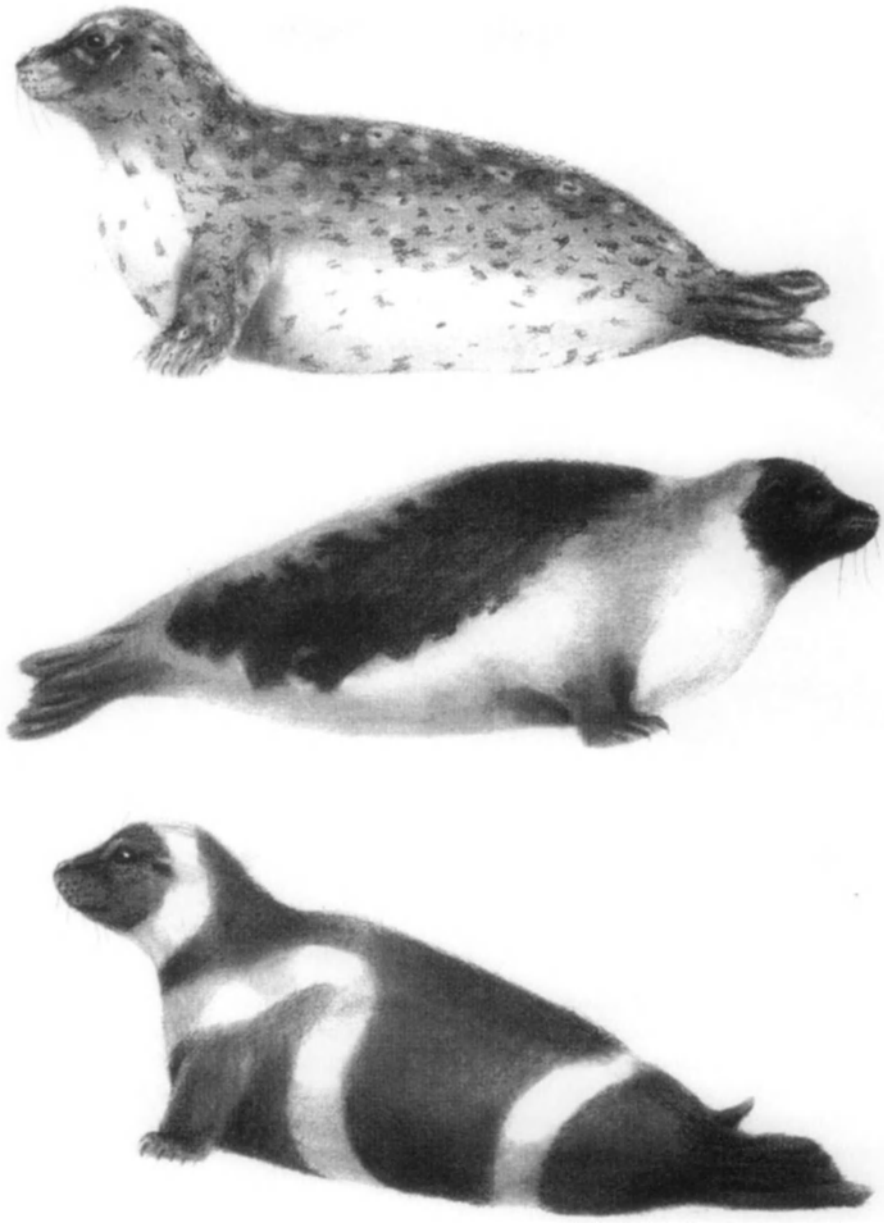

Figure 4 *Examples of color patterns in three seals: (top) harbor, (middle) harp, and (bottom) ribbon. Sketches by Jennifer Schmid-Webster.*

avoid breaking through thin ice. These large feet help with propulsion, and footpads are covered with small, soft papillae that increase friction between the foot and ice. Bare body regions are most likely to have a communication function, i.e., the muzzle, nose, ears, footpads, and insides of the thighs. Still, whether these anatomical traits function in tactile signal exchange is unknown.

B. Responsiveness to Touch

An inclination for tactile responsiveness has been noted in wild and captive studies of all cetaceans. Among mysticetes, the "friendly" gray whales (*Eschrichtius robustus*) of San Ignacio Lagoon are noted for approaching and rubbing under small boats and tolerance for petting by tourists. In the wild, both Atlantic spotted and bottlenose dolphins rub body parts into the sand or along rocky edges. Belugas rub molting skin off their bodies at a few distinct pebbly beaches and under the ice surface in the Arctic. All odontocetes in captivity seek and are receptive to gentle body contact. Mild tactile stimulation (*i.e.*, rubbing of gums, flippers, or dorsal fin) serves as an effective re-enforcer in training situations using bottlenose dolphins or the Amazon River dolphin (*Inia geoffrensis*). Trainers suggest that tactile stimulation is reinforcing and perhaps rubbing by another dolphin might also be rewarding.

Figure 5 *Composite drawing depicting specific characters useful to tactition in pinnipeds, fissipeds, and sirenians. Vibrissae differ in the extent of beading per unit between phocids and otariids. Sirenian bilobed lips, vibrissae, and a portion of their flipper are shown (center). The walrus tusk and vibrissae are presented in the lower right. The sea otter paw vibrissae and fur are shown at the lower left. Sketches by Jennifer Schmid-Webster.*

Pinnipeds vary in the degree of gregarious behavior and thus tolerance for tactile stimulation by conspecifics. Leopard seals (*Hydrurga leptonyx*) are solitary predators and rarely seen in close proximity. In contrast, Weddell seals congregate in breeding colonies, but each mother/pup pair maintains an individual space. The more polygynous pinnipeds, such as walrus (*Odobenus rosmarus*) and California sea lions, often crowd onto beaches, piling on top of each other, with little regard for personal space. Regardless of adult spacing, mothers and pups maintain close tactile communication. Young pinniped pups often crawl over their mothers and sleep touching their mother. There is, however, no maternal grooming of the young in pinnipeds.

In Crystal River, Florida, some manatees seek physical contact with divers, whereas others avoid divers. Florida manatees sometimes "body surf" on currents generated below dams when floodgates are partially opened. This surfing can last for up to an hour with manatees repeatedly riding the currents in parallel formation. Often, nuzzling and vocalizations accompany manatee body surfing (Reynolds and Odell, 1991). When not eating (nearly 8 hr per day), manatees curiously investigate objects, socialize by mouthing and rubbing against each other, and play together (Reynolds and Odell, 1991). Thus, touch is likely an important information component in manatee life.

Mustelids [sea and marine otters (*Lutra felina*)] possess thick layers of fur for warmth and protection and thus grooming is part of their social structure, as with many social terrestrial mammals. Unlike other marine mammals, sea otters groom their pups by licking their fur. They are the only marine mammal to have the ability to hold and manipulate their young for grooming. Mother sea otters spend a great deal of time grooming their pup and remove feces by licking the fur in the pup's anal region. Sea otter grooming behavior is probably at least partially hygienic in function; however, in other mammal species (e.g., primates, canids), grooming behavior signals affection, appeasement, or reconciliation.

More data are required to better understand how polar bears use touch in signal exchange. As in other ursids, mother polar bears likely have close tactile contact with their young for nursing and grooming in the den. Adult males are seen in intense fights grasping each other with "bear holds," nose-to-nose open mouth threats, growls, and biting.

C. Sexual Contacts

Head or body rubbing, pectoral fin rubs, and other touching contribute to simple affiliation, greetings, or represent courtship activities. Head rubbing was reported in a number of mysticete and odontocete species including, but not limited to, southern right whales (*Eubalaena australis*), gray whales, humpback whales, killer whales, bottlenose dolphins, Atlantic spotted dolphins, and pilot whales (*Globicephala* spp.). Lengthy

and frequent contact with pectoral fins, flukes, dorsal fin, or body during social, play, or precopulatory behavior is common among cetaceans (Fig. 6; Pryor, 1990).

In mysticetes, such as the right whales, sexual activity occurs in groups of one or more females and several males. As many as three males surround a single female and two of them push her into position, enabling the third male to align himself for mating. Researchers believe this is an example of cooperation among males, but this hypothesis has not been substantiated. This behavior certainly requires good communication among the whales.

Copulation often is preceded by gentle mouthing at the genital area for many delphinids. In mature dolphins, precopulatory play becomes progressively more violent, with participants DIVING forcefully after each other and at other times ramming melons with such force that loud reverberations result. This behavior apparently signals sexual stimulation and receptivity because it almost always ends in copulation. Most dolphins also seek self-stimulation: captive dolphins expose various body parts to tactile stimulation, including opening the mouth under a water hose or rubbing against a brush, wall, or the tank floor for long periods of time. Both male and female dolphins masturbate by rubbing their genitals against objects in a tank, even when available mates are present (Herman, 1980). In a study that played back sounds from an oil-drilling platform, the dominant male beluga responded by rubbing his genitals against the vibrating transducer. In harem-forming seals and sea lions, several strategies are employed during mating, with varying degrees of signal exchange. Subadult males often attempt *not* to communicate to harem masters while sneaking to mate with females. Females, however, may choose not to mate with the potentially less desirable subadult male by signaling to the harem master vocally, behaviorally, or posturally.

Some pinnipeds mate on land (e.g., elephant seal and California sea lion) whereas others mate in the water (e.g., Weddell and leopard seals, walrus). Mating in the two media requires different signal exchange. In all pinniped species, mating is accomplished by the male mounting the female from the rear and clasping her abdomen with his fore flippers.

Figure 6 *Two subadult Atlantic spotted dolphins engaged in precopulatory petting exchanges. The female is above the male and is rubbing the male's melon with her left pectoral fin. Photograph by K. M. Dudzinski.*

Once a sea otter male has found an estrous female, the two actively roll and splash about together at the surface. They nuzzle and fondle each other with forepaws (Kenyon, 1975). This behavior lasts for up to 1 hr. During this time, they make their way to a suitable haul-out site, which acts as the center of their courtship activity, but mating occurs in water. Sea otter females often exhibit bloody noses that attest to this species' rather aggressive mating habits. Mating can last up to 14 min with the male mounting her back, biting and grabbing her nose, and grasping her abdomen. It is possible that some of these actions could function as signals to induce estrous in the female.

D. Affiliative Contacts

Affiliative contact is assumed to strengthen bonds between individuals with high association indices but also could indicate to competitors that individuals exchanging contact have a strong bond, at least for the time being. Affiliative contact is observed most commonly between mother/calf dyads for all marine mammal species.

Nose touching or nuzzling often is observed between mothers and offspring in sea otters, pinnipeds, and sirenians. However, nuzzling is not only exchanged between mothers and offspring, but between older individuals during social exchanges.

In pinnipeds, the degree of affiliative contact varies with the social system. For example, the male monogamous crabeater seal (*Lobodon carcinophaga*) maintains a season-long bond with a female, remaining paired on their own ice floe until mating. Gregarious walrus and elephant seals pile on top of each other while hauled out. Weddell seal mothers and pups maintain discrete pairs while hauled out, often chasing away intruders. Hawaiian monk seals haul out similarly in well-spaced mother/pup pairs, but the mothers tolerate an occasional wandering pup and sometimes even nurse it.

Sea otter mothers maintain close tactile contact with their pups. Mothers float on their backs and support their pup on their abdomen for nursing or for the pup to rest. If disturbed, the mother grasps the pup with her front paws and swims away or dives with the pup. Wild sea otters form resting, floating groups called rafts. Sea otters rest in close proximity, often bumping into each other as they sleep. In California, these rafts are formed in kelp beds, with the sea otters rolling in the kelp to serve as an anchor. In Alaska, there is no kelp so sea otters group together in calm water areas. The rafting behavior likely provides "safety in numbers" for resting sea otters who could become prey of killer whales. Rafting behavior could also help animals remain close to shore in rough seas. Surely there is communication among raft members to coordinate the group resting behavior.

Sirenians maintain close tactile contact between mother and calf. Manatee calves swim parallel and directly behind the mother's flipper. It is possible that mother/calf communication is most effective in this formation or that there is some hydrodynamic advantage for the calf. Neonate dugongs swim in near contact to their mothers and occasionally reach out with a flipper to touch mother, possibly for reassurance of her presence or to maintain their bond (Reynolds and Rommel, 1999).

Because mammary glands are pectoral in sirenians, mothers embrace calves close to them. Manatees grasp conspecifics in a hug-like embrace (at times, captive manatees "hug" their trainers). So far as is known, all sirenians are polyestrous. A single female manatee has been seen pursued by males on widely separate dates. In manatees, the mating herd can remain together for up to 1 month, with males vying for the closest position to the female. Dugong mating has several phases. The "follow phase" with groups of animals moving into a tight cluster around an estrous female; the "fighting phase" consisting of violent activity, including splashing, tail thrashing, rolls, and body lunges; and the "mounting phase" in which one male mounts the female from beneath with several others clinging to them. It is not clear if more than one male mates at that time. Dugong mating is much more violent than in manatees.

Polar bears are solitary except for a single female and her young. During the breeding season, females are polyandrous with males competing for access to a female. Touch in polar bears is likely important during interactions, but little is reported for more than play-fights or aggressive contacts. A nose-to-nose greeting is sometimes offered as a begging signal by one bear that approaches another with a food source.

E. Aggressive Contact

Exchanges of aggressive behavior (*i.e.*, fights) occur among cetaceans over objects, space, proximity to conspecifics, food, or mates. Mysticetes show obvious wounds from intraspecific aggression. Behaviors such as breaching and lob tailing often are used during aggressive exchanges or to indicate irritation or anger; however, in other situations, these actions could possess a noncommunicative function (e.g., parasite removal). Similarly, many odontocete species show intraspecific rake marks from the teeth of their peers. Male long-beaked common dolphins (*Delphinus capensis*) are extensively scarred on trunks and fins during the mating season and males have more teeth missing than females. Risso's dolphins (*Grampus griseus*) represent the extreme case with their adult coloration being light gray or white from the multitude of rake marks inflicted by competitive cohorts. Fighting dolphins slash and bite with their teeth, slash and ram with their jaws, and strike with their flukes and rostra. Encounters sometimes result in injuries and permanent scars.

Large males are considered the most aggressive and direct behaviors at peers and immature males most frequently, although females are not immune to aggressive attacks from males. In the wild, vertically organized swimming arrangements are seen among groups of pantropical spotted dolphins (*Stenella attenuata*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), and bottlenose dolphins. This regime could be a dominance arrangement expressed as highest priority given to top dolphins who have the quickest access to the surface. For sperm whales (*Physeter macrocephalus*), male–male competitions, in apparent dominance contests, include extensive tooth-raking that sometimes escalates into violent head ramming and locking of the jaws by two animals while twisting and biting.

Mother cetaceans punish their young with less violent, yet still effective methods. Calves or juveniles can be held against the sea or tank floor, bitten, or even held out of the water by mothers or other adults—behavior that is likely disciplinary given the participants and context.

Male Stellar sea lions (*Eumetopias jubatus*), elephant seals, walrus, and Weddell seals all bear scars and often sport bloody chests that result from aggressive encounters with other males during the height of the mating season. Male elephant seals compete and exchange aggressive bellows, blows, bites, and lunges when competing for access to females. Unfortunately, Hawaiian monk seal (*Monachus schauinslandi*) females sometimes die from aggressive mating attempts by a male, even a group of males. Presently, the adult sex ratio is skewed toward more males than females in several Hawaiian atolls.

In contrast, manatees are slow moving and seemingly docile, not known for interanimal aggression.

A sea otter in a dangerous situation reverts to typical mustelid aggressive behavior, including biting and aggressive sounds.

Among polar bears, hissing and snorting signify aggression, and an attacking bear will charge forward with head down, ears back, and teeth bared. Aggressive contacts can include growling, hitting, and biting. A 3:1 adult male to female breeding ratio produces intense competition for mating rights (Stirling, 1999). Broken canine teeth and other scars often result from these battles.

F. Touching without Contact

1. Echolocation Because dolphin skin is exceptionally sensitive to touch, some researchers suggest that sound might be used as an acoustic probe or means of physical contact among individuals. Human divers report the sensation of being echolocated on by dolphin as "feeling like a zipper was opened along their chest or as a dotted line going along their chest." Atlantic spotted dolphins in the Bahamas and spinner dolphins in Hawaii have been observed to produce a "genital buzz"; this behavior includes one dolphin inspecting the genital region of a second while producing a pulsed buzzing sound (Fig. 7). No physical contact between dolphins is observed concurrent with genital buzzing—"touch" occurs via sound.

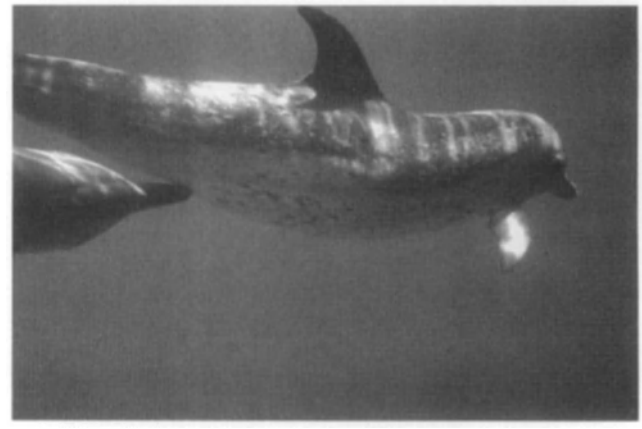

Figure 7 *A genital buzz from a juvenile female Atlantic spotted dolphin to a second juvenile female of the same species. The context of this action was play. Photograph by K. M. Dudzinski.*

2. Bow Riding Bow riding is a behavior in members of the cetacean family Delphinidae. Groups of dolphins often approach vessels of various sizes to surf or swim inside the wake produced by the bow as it moves through the water. These bow-riding bouts can last for a few minutes or hours. Good communication among individuals is required for such intricate swimming. Dolphins are seen vying for the position closest to the bow. Perhaps shifts in dolphin movements by the group are sensed by pressure changes in the spaces among individuals. It is possible that dolphins detect subtle movements in the water column that signal a change in direction to the group. This ability also would be useful to dolphins traveling in turbid environments where subtle posture shifts could not be detected visually.

VII. Auditory Communication

Marine mammals use both vocal and nonvocal sounds for acoustic communication because sound travels faster in water than in air and acoustics are a more reliable means of information exchange among individuals separated by meters to kilometers.

A. Nonvocal Communication

1. Cetacea Nonvocal communication can include noise from various body parts projected into the air, striking the water surface as well as the percussive sounds of jaw claps, teeth nashing, or bubble emissions. Breaches, leaps, tail slapping, and chin slapping produce sounds under water that likely carry a communicative message. Humpback, right, and gray whales and Pacific white-sided, Hawaiian spinner, and bottlenose dolphins are known to leap vigorously into the air, called breaching. A breach produces airborne and underwater sounds upon reentry that carry for several kilometers. Breaching could be a spacing mechanism or help whales remain in acoustic contact. Breaching often indicates general excitement or arousal deriving from any of several causes, including sexual stimulation, location of food, or a response to injury or irritation. Calves and their mothers also breach on occasion and sometimes in unison. Clearly, there can be many immediate causes of breaching (*e.g.*, parasite removal), and further study is needed to clarify and understand the multiple contexts in which breaching occurs. Dusky dolphins are well known for the three leap types they produce in association with three stages of cooperative feeding: head-first reentry leaps, noisy leaps, and social, acrobatic leaps. The latter two create sounds that function to signal peers or, as for the noisy leaps, could act as a sound "barrier" to disorient prey and keep them tightly schooled. Upon water reentry after a spin, a breach, a back slap, or a head or tail slap, spinner dolphins generate omnidirectional noise that propagates over short to intermediate distances. Spinner dolphins' aerial behavior seems designed to produce noise, as many leaps are common at night, when visual contact is limited, or in daytime occur in fully alert, but dispersed schools. Visual signals during leaps likely convey position information to schoolmates and could facilitate aerial inspection for feeding sites or for detecting environmental features. In many cetaceans, ventral chevrons or white underflukes are displayed above water during leaps or breaches. These color patterns vary among individuals, and leaps certainly draw attention to the whale's identity.

Most observers agree that tail slaps convey threat or accompany frustration in addition to establishing contact. Tail slapping, which produces extensive, low-frequency underwater and aerial sound, often occurs dozens of times in succession. It is likely that tail slaps among mysticetes and odontocetes have an agonistic component. Pectoral fin slapping is observed predominantly in humpback whales, although other baleen whales exhibit this behavior. The exact communicative nature of pectoral fin slapping is not clear, although again it may signal irritation, maintain individual spacing, or invite play or socializing.

The percussive sound of a jaw clap with the accompanying posture of an approaching animal is often considered a threat or warning signal. Altogether, the social functions of nonvocal auditory signals seem mainly limited to affiliation, recruitment, and expressions of excitement, annoyance, or aggression.

2. Pinnipedia Pinnipeds do not use nonvocal communication as much as cetaceans, *i.e.*, fewer tail or flipper slaps or breaches. The most common example of nonvocal communication in pinnipeds is teeth chattering, which provides both an acoustic and a visual aggressive sign. Weddell seals, for example, teeth chatter both under water and on land to seals intruding their space. Weddell, ringed, (*Pusa hispida*), and Baikal (*P. sibirica*) seals repeatedly slap their sides with fore flippers while hauled out. This sound seems to warn intruders and is quite loud, especially from a wet seal. Many pinnipeds also produce a loud snort or hiss as they exhale, especially after a long dive. This exhalation could have communication significance because it is more forceful under some situations.

3. Sirenia Manatees are known to slap the water surface with their tail as a form of communication. Manatees sometimes play "follow-the-leader" (Reynolds and Odell, 1991), in which animals swim single file and perform behaviors synchronized with the lead animal. This behavior requires close communication, perhaps using many sensory channels. Still, more observations are required to better understand nonvocal signal exchange among sirenians.

4. Mustelidae Little is known about nonvocal auditory communication in sea otters.

5. Ursidae Little is known about nonvocal auditory communication in polar bears.

B. Sound Communication

1. Mysticete Cetaceans Generally, baleen whale sounds are very different from those of odontocetes, with a wide range of types and quantity of phonation across mysticete species. Social functions proposed for mysticete sounds include long-range contacts, assembly calls, sexual advertisement, greeting, spacing, threat, and individual identification; however, only rarely has a specific sound been associated with a given behavioral event. It is probable that sounds produced by mysticetes serve to synchronize biological or behavioral activities in listeners that promote subsequent feeding or breeding. More data are required to describe sound communication more completely in baleen whales. Known and examined baleen whale

sounds seem to fall into three basic categories: low-frequency moans, short thumps or knocks, and chirps and whistles.

A. MYSTICETE LOW-FREQUENCY MOANS Low-frequency moans range from 1 to 30 sec, with fundamental frequencies between 20 and 200 Hz. These sounds can be either pure tones, as in the second-long 20-Hz sounds of fin whales (*Balaenoptera physalus*), or more complex tones with a strong harmonic structure. Theoretically, these low-frequency, long-wavelength sounds are ideal for long-range communication. A 20-Hz moan from a fin whale has a wavelength of almost 75 m, which means that it passes unimpeded over most obstacles, only bouncing off something large, like a seamount with a diameter greater than 75 m. These sounds could travel hundreds, even thousands, of kilometers to reach conspecifics for signal exchange. Payne predicted that theoretically the low-frequency, high-amplitude signals of mysticetes could travel from pole to pole if it were not for interfering oceanic bottom topography.

Low-frequency sounds (20 Hz) of blue whales (*Balaenoptera musculus*) are recorded across ocean basins at distances of several hundred kilometers. Blue whales are the largest creatures to inhabit the earth; they traverse large expanses in relatively short time. It is no wonder then that the social structure of these animals reflects a scale that we are only beginning to comprehend.

B. MYSTICETE SHORT THUMPS OR KNOCKS Short thumps or knocks are under 200 Hz, but <1 sec long, and are currently known to be produced by right, bowhead, gray, fin, and common minke whales (*Balaenoptera acutorostrata*). In the 1970s, Clark recorded and studied southern right whale sounds in relation to behavior and found that their sounds were not random but were related to social context and activity. Blow and body sounds (e.g., flipper slaps) were documented as well as vocal emissions. Resting whales were least soniferous, whereas mildly social groups produced the most varied suite of sounds, including high, hybrid, and pulsive calls, body and flipper slaps, and forceful blows. Clark's work showed that "up calls" functioned as a request for contact between whales: lone swimming whales often produced up calls that were returned by other whales in the vicinity prior to joining (Clark, 1983, Figure 8).

C. MYSTICETE CHIRPS AND WHISTLES Mysticete chirps and whistles are always >1 kHz, but change frequency rapidly and are less than 0.10 sec in duration. These pure tones involve harmonics and seem to be produced by most baleen whales.

Cynthia D'Vincent, Fred Sharpe, and colleagues documented underwater sounds from humpbacks on the Alaskan feeding grounds. During the summer feeding season, humpbacks often forage in a coordinated manner. Several individuals emit bubbles around fish schools and surface in a ring, with each whale always in the same position. Concurrent with these feeding bouts are several sounds that are individually distinct (Fig. 9). Any coordinated, even cooperative, behavior requires communication among individuals. If specific roles are played within a certain activity, then individuals need a method of recognizing each other. Humpback feeding sounds exhibit characters distinct to each individual and thus probably help coordinate their respective positions or roles at each stage of feeding.

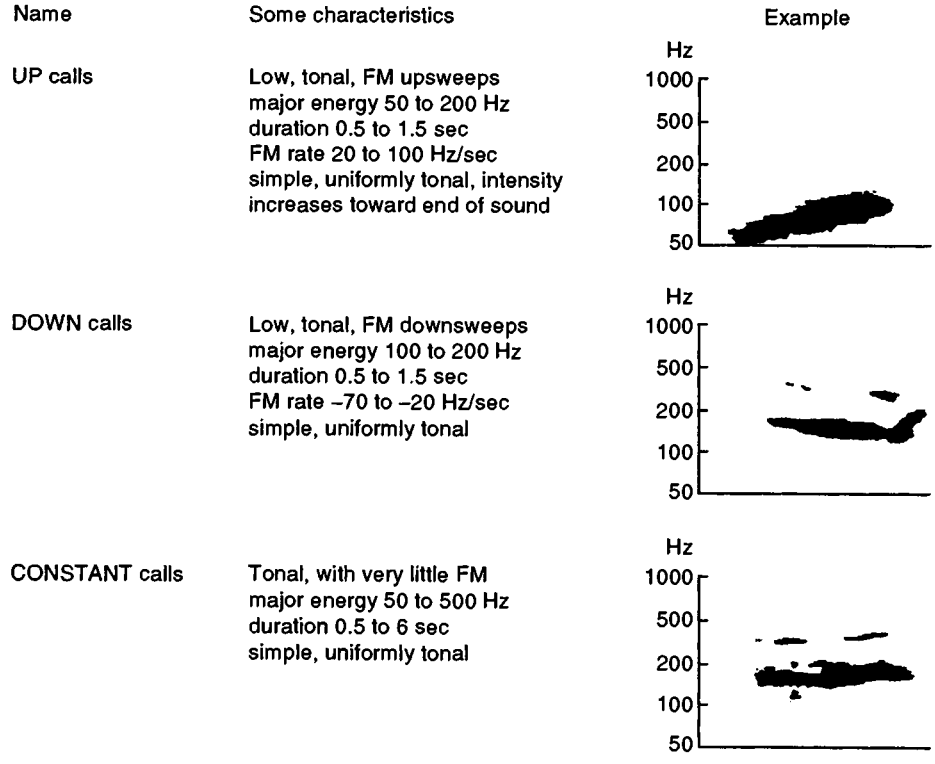

Figure 8 *Example of southern right whale "up calls" and two other calls for comparison. Adapted from Clark (1983).*

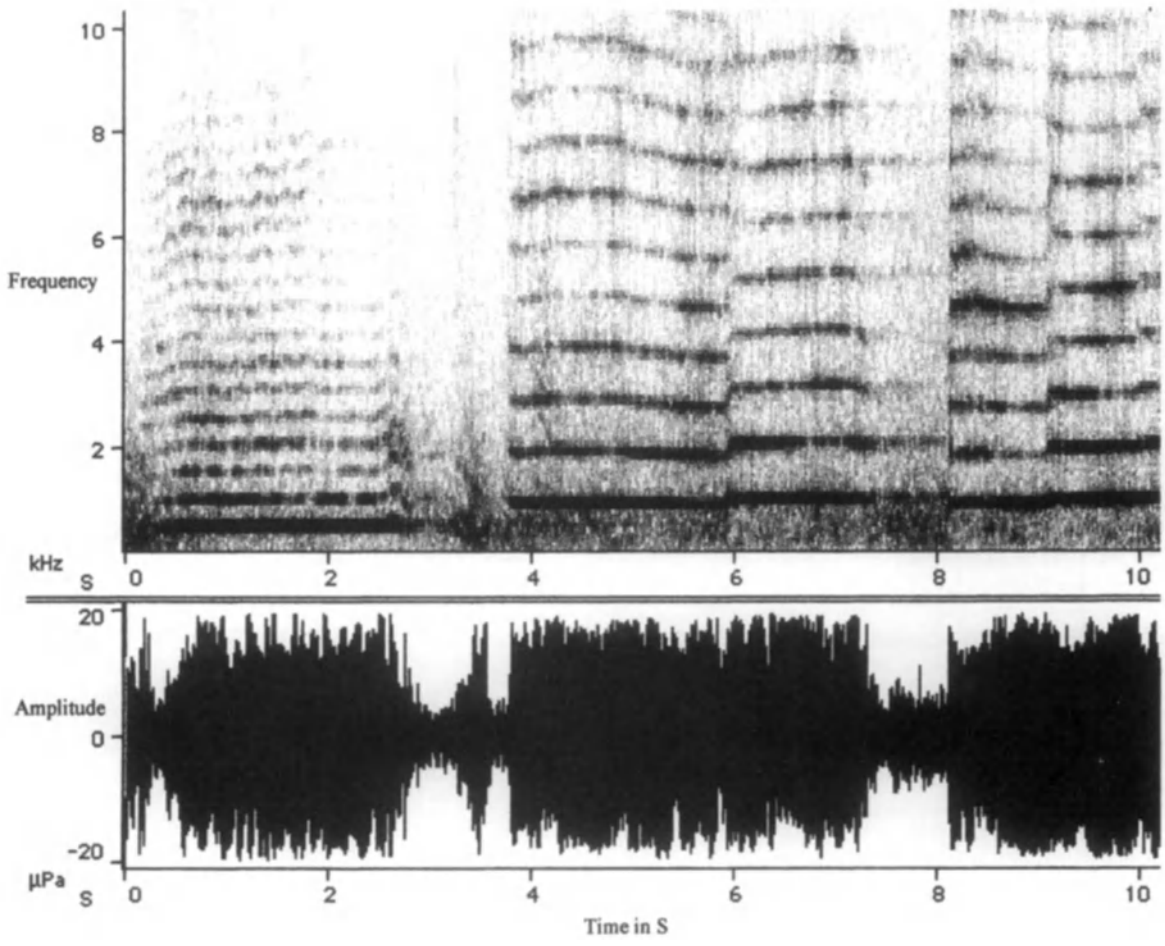

Figure 9 *Example of individually identifiable humpback whale feeding calls. Y axis is frequency in kHz on sonogram and amplitude on waveform. X axis is time in seconds. Sound example and figure courtesy of F. Sharpe.*

Sounds that are variable through time and do not exhibit a continuous or consistent pattern have been lumped as "social sounds." In 1986, Greg Silber determined that social sounds from humpback whales were produced from groups of three or more individuals and were usually linked with intraspecific competition among males. Silber suggested that social sounds in this context reflected agitation or acoustic threats. Still, detailed information on specific functions of social sounds is lacking.

D. MYSTICETE SONG Humpback whale songs are probably the most recognized and well known of mysticete vocalizations. Only males sing while solitary and all sing the same song during each breeding season. While males do not sing outside of the breeding season, the song remains relatively constant from the end of one breeding season to the start of the next. The song could advertise each male's fitness as a mate and control male spacing when advertising to females. For whatever the specific purpose, humpback songs represent an evolved signal used by males to communicate information about their internal (e.g., reproductive condition or fitness) and external (e.g., location, proximity) state to conspecifics, likely both females and other males.

Humpback whales also produce social sounds that are correlated with group size and surface activity on the breeding grounds. Larger groups with much surface activity produce more sounds than smaller groups. Researchers observed that singers cease their song to join noisy social groups. It is possible that songs represent a strategy of lone males in finding a mate, whereas social sounds indicate more direct competition between males for a female.

2. Odontocete Cetaceans Odontocete sounds can be divided broadly into two signal types: pulsed and narrow-band tonal sounds. Some pulsed sounds (clicks) are implicated in echolocation and can be of broad spectral composition as in the bottlenose dolphin or of narrow-band composition as in the narwhal. Other burst pulsed sounds, described in the literature as barks, squawks, squeaks, blats, and moans, have social functions (Fig. 10). Narrow-band tonal sounds are continuous signals called whistles. Limitations in audio equipment had suggested that whistles, frequency-modulated (**FM**) pure tones, were limited to the human mid- to upper sonic range of frequency (5–15 kHz) and of 0.5–2.0 sec in duration (Fig. 11).

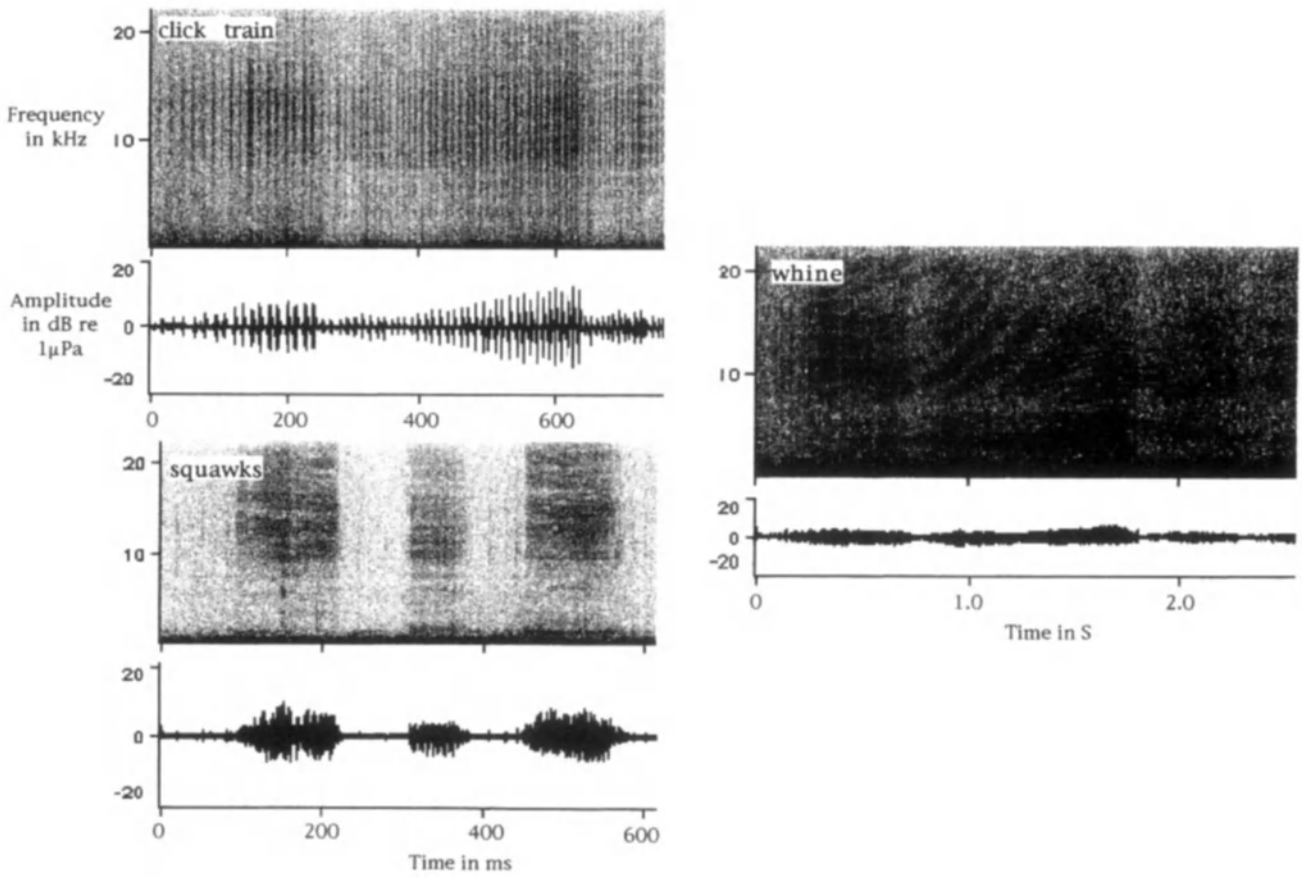

Figure 10 *Examples of dolphin click trains, squawk sounds, and a whine. All are pulsed or amplitude modulated in structure and vary primarily in repetition rate. Click trains function for investigation of objects or peers, whereas the latter two examples communicate social information and potentially referential details to conspecifics. Sounds courtesy of K. M. Dudzinski.*

Improvements in technology yielding a more complete bandwidth recording of dolphin sounds indicate that dolphins produce FM pure tones across a broad frequency range, from 5 to at least 85 kHz. Other FM tonal sounds include screams and chirps.

Research on sound communication in bottlenose dolphins and other delphinids has centered on whistle sounds for pragmatic reasons. The sonic range of whistles is recorded and analyzed easily. Also, whistles are produced by the most common captive species, the bottlenose dolphin, and appear to have no function other than communication. Because the number of nonwhistling species, such as the harbor porpoise (*Phocoena phocoena*) and Commerson's dolphin (*Cephalorhynchus commersonii*), is relatively large, it is premature to regard whistles as the principal means for sound communication among odontocetes.

A. ODONTOCETE PULSED SOUNDS All recorded toothed cetaceans produce pulsed sounds. These sounds can be used for echolocation or communication (Herman, 1980; Au, 1993). They can be divided into two subclasses: pulse trains and burst-pulse sounds. Pulse trains, also called click trains, are sequences of acoustic pulses repeated over time. Individual pulses are about 50 μsec, with varying peak frequencies of 5–150kHz. The repetition rate of pulses within a click train can vary from 1–2 to several hundreds per second. Click trains are thought to function mainly for echolocation.

Burst-pulse sounds can be defined as high repetition rate pulse trains where the interpulse interval is <5 msec which are similar in shape to echolocation pulses, but with about a 6- to 10-dB lower amplitude. Because of the high repetition rate in burst pulses, these sounds are no longer perceived as discrete sequences of sounds by the human ear but are heard as a continuous sound. Their peak frequencies vary with species from 20 kHz in killer whales to above 100 kHz in Commerson's dolphins.

Burst-pulse sounds are proposed as functioning primarily for communication. The directional characteristics of many of the pulsed sounds, the relative ease with which they can be localized, their variability, and possibly the power with which they can be produced enhance their potential value as communication signals. Indeed, in situations described as alarm, fright, or distress, broad-band high-intensity squeaks have been heard from bottlenose dolphins and harbor porpoises. River dolphins, killer whales, and Commerson's dolphins, as well as Physeteridae and Phocoenidae, which do not whistle, most likely communicate via pulsed sounds.

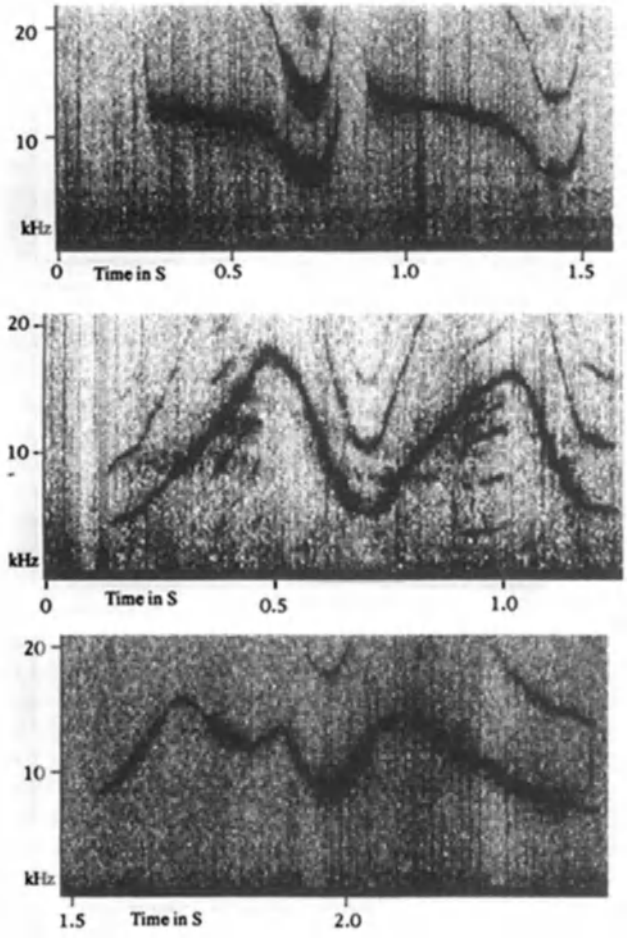

Figure 11 *Examples of narrow-band tonal sounds (i.e., frequency-modulated or whistles) from Atlantic spotted dolphins recorded in the Bahamas. Y axis is frequency in kHz and X axis is time in seconds. Sounds courtesy of K. M. Dudzinski.*

It is possible that the timing of clicks contains social significance. The timing of sperm whale clicks (codas) is thought to communicate the identity of the phonating whale and perhaps other social information.

Another possibility for information exchange via pulsed sounds would be through passive communication, i.e., "eavesdropping." Depending on their position relative to another clicking dolphin, one individual might listen to the emissions and echoes of others rather than actively transmitting signals. Xitco and Roitblat (1996) showed that a bottlenose dolphin trained to listen to echolocation clicks of an actively echolocating dolphin also could discriminate targets. This provides evidence that dolphins are capable of detecting and interpreting the echoes of another's sonar. Definitive evidence is still lacking for free-ranging odontocetes. Their results raise the interesting question about the proper "etiquette" of echolocation and how the task of clicking is organized within a group of cetaceans.

B. ODONTOCETE NARROW-BAND TONAL SOUNDS Narrow-band tonal sounds, *i.e.*, whistles, are produced over a range of 5–20 kHz, are frequency modulated, and can last from milliseconds to a few seconds. These sounds sometimes have a rich harmonic content that extends into the ultrasonic range of frequencies up to 70–80 kHz for some dolphin species. Whistles vary greatly in contour from simple up-or-down sweeps to frequency-modulated warbles to U loops and inverted U loops. Whistles often grade from one type to another. Whistles are thought to function only for communication, but are not produced by all odontocetes. In at least two odontocete species, false killer whales (*Pseudorca crassidens*) and belugas, animals shift whistle frequency ranges upward to avoid low-frequency ambient noise.

Why some odontocete species whistle and others do not is a very intriguing question. If the whistle appears only under certain ecological or social conditions, these should be found through careful comparisons of whistlers and nonwhistlers. Although a low degree of gregariousness is a feature characterizing some nonwhistling species, this idea is not consistent with findings concerning Hector's dolphins (*Cephalorhynchus hectori*) and killer whales, which live in groups of up to 10 members that occasionally congregate in large numbers but still do not produce whistles.

Of relatively low frequency, whistles travel longer distances in water than pulsed sounds. Although less directional than pulsed sounds, whistles probably are localized easily by cetaceans. Bottlenose dolphins and probably other whistling species can produce whistles and clicks simultaneously. Given these attributes, whistles provide a potential vehicle for maintaining acoustic communication and coordination during food search by echolocation. Also, whistles possess little overlap with the major portion of the echolocation frequency spectrum, minimizing potential masking effects. If whistles have species, regional, or individual specificity, this would at least allow for the identification of schoolmates or familiar associates or aid in the assembly of dispersed animals and in the coordination, spacing, and movements of individuals in rapidly swimming, communally foraging herds.

Assigning particular sounds to specific individual dolphins in the wild presently is difficult, if not impossible. A wealth of data has been gathered on dolphin vocal behavior as related to general behavioral activity. Hawaiian spinner dolphins, bottlenose dolphins, beluga whales, and pilot whales produce a variety of sounds that vary in type and rate with behavioral activities. For these species, the highest rate and variety of sounds (*e.g.*, whistles, screams, barks) were recorded during social activities. In contrast, when resting, acoustic behavior was almost nonexistent. These results seem intuitively correct, i.e., signal exchange would be higher when dolphins were engaged in more interactive behaviors with conspecifics.

While data on sound rates and occurrences are valuable, it is not an examination of communication by the strictest definition. Studies of animal communication require the ability to identify individuals and the signals used. It is especially important to identify the emitter and receiver when examining the intricacies of subtle interactions among social animals. Until recently, cetacean researchers were not able to identify individual soniferous dolphins within free-ranging groups.

Many different situations can elicit whistling. Whistling could appear as a simple phono-reaction in response to hearing

another animal's whistle. Mimicry of whistles or of artificial sounds has been documented in bottlenose dolphins and belugas, revealing the plasticity of the sound production system. Studies by Peter Tyack and Louis Herman proved dolphins to be skilled mimics of tank-mate whistles and artificial frequency tones. A correlation between whistling and feeding was noted among wild and captive delphinids. For example, pods of false killer whales produce more whistles while feeding than during traveling. Dolphins accidentally captured in tuna seine nets whistle intensely. Captive bottlenose dolphins newly introduced into a tank or temporarily separated from a familiar tank mate whistle nearly continuously.

There have been several attempts to inventory the whistle repertoire of wild and captive delphinids. This is often difficult because the whistle contours are so variable. The size of a repertoire, including both whistles and pulsed sounds, is probably limited to fewer than 40 discrete types. However, it is possible that whistles are graded rather than discrete signals. In a graded system, several basic types of signals transition to one another through a series of intermediate forms. Still, strong evidence is lacking for many odontocetes. Although sophisticated devices can faithfully describe the frequency versus time function (contour) of a whistle sound, it is left to human judgment to decide when one contour is significantly different from another. Standardized analysis of whistles by taking 20 measurements along the contour of each whistle was conducted by Brenda McCowan and Diana Riess, and Vincent Janik reviewed four methods for analyzing whistles contours with respect to the categorization of patterns into separate classes. Human observation is routinely used to classify whistle contours because human observers were more likely than computers to identify signatures used while an animal was isolated. Discrepancies in methodologies led Janik to stress the importance of external validation of categories when categorizing behavior patterns, including animal sounds.

In 1965, the Caldwells presented the idea of signature whistles from observations indicating that each dolphin in a captive group tended to produce whistles that were individually distinctive, stereotyped in certain acoustic features, and therefore called "signature" whistles. In the late 1980s and early 1990s, Tyack and colleagues proposed the hypothesis that dolphins use "signature whistles" to refer to each other and themselves (Leatherwood and Reeves, 1990).

3. *Pinnipedia* Pinnipeds typically produce frequency-modulated and pulsed sounds. Except for male walruses, pinnipeds do not whistle. The number of vocalizations produced by pinnipeds is correlated with their mating system and whether mating occurs underwater or on land. In general, otarids are much more vocal on land, often obtaining high densities in highly soniferous colonies. Phocids tend to be more vocal underwater, especially in the true seals that mate underwater, *e.g.*, polar pinnipeds.

Polar pinnipeds are much more vocal underwater than temperate or tropical pinnipeds. Early polar explorers reported hearing "eerie, ghost-like sounds from underneath the water." Because of polar bear predation, Arctic pinnipeds, are essentially silent while hauled out. In contrast, Antarctic pinnipeds are vocal when they haul out. Comparing the vocal repertoire size and MATING SYSTEM of three species of Antarctic phocids, we find distinctive differences. The Weddell seal congregates in colonies up to 100 mothers with pups, whereas males establish underwater territories beneath the fast ice that are vigorously patrolled and defended with an elaborate repertoire of 34 sounds. Mating in Weddell seals is polygamous; males mate with as many females as will enter their territory. Presumably, the 2-month period that males defend their underwater territory assists females, hauled out on the ice above, in mate selection. The polygynous, but solitary, leopard seal has an intermediate number of underwater vocalizations, apparently used to establish short-term underwater territories in the pack ice and attract females to mate. The crabeater seal is seasonally monogamous: a male hauls out on an ice floe with a female, guards her and her pup against attacks from predators, and then conveniently is available for mating when the pup weans. It is unlikely that this male is the pup's father, and the pair bond is well established for the season. This pinniped has a single monotonous call.

In all pinnipeds, mothers and pups exchange vocalizations that are important in pup recognition and reuniting the mother with her pup after she returns from a foraging bout. Recognition of one's pup is especially important in some otarids mothers that go to sea to forage for up to 7 days before returning to nurse their pup. In many pinnipeds, the vocal repertoire of the mother and pup is unique and distinct from their sounds during other social activities. This repertoire occurs mostly while hauled out, but is also used by mothers coaxing their pups into the water or to haul out.

The majority of documented pinniped sounds are within the range of human hearing. Only one study on a captive leopard seal has examined ultrasonic frequencies, and underwater sounds were found up to 164 kHz. More research is needed in this area. Some species are nearly silent, whereas others have large repertoires that vary by season, sex, age, and whether the animal is in the air or water. Pinniped calls have been described as grunts, rasps, rattles, growls, creaky doors, warbles, trills, chirps, chugs, clicks, and whistles. Clicks are produced, but experimental attempts to demonstrate echolocation have not been successful. These studies, however, were on California sea lions and harbor seals (*Phoca vitulina*) and some researchers suggest that ECHOLOCATION, if present in pinnipeds, would more likely occur in the polar pinnipeds who live in ice-covered waters and total darkness during the polar winters.

Phocid calls are primarily between 100 Hz and 15 kHz, with peak spectra <5 kHz. Typical source levels of underwater sounds are 130 dB re 1 μPa, but are as high as 193 dB re 1 μPa in a territorial Weddell seal (Fig. 12). Elephant seals are reported to produce infrasonic to seismic vibrations while vocalizing in air. One of the most elaborate repertoire of sounds is from the Weddell seal, who has a separate repertoire of sounds for communicating while hauled out from its sounds for underwater contexts. At one colony in the Antarctic, the Weddell seal had 34 types of underwater sounds (Thomas and Kuechle, 1982), including trills, chugs, chirps, guttural glugs, clicks, and mews. Eleven types of trills are used exclusively by males for territorial advertisement and defense and could be used in a

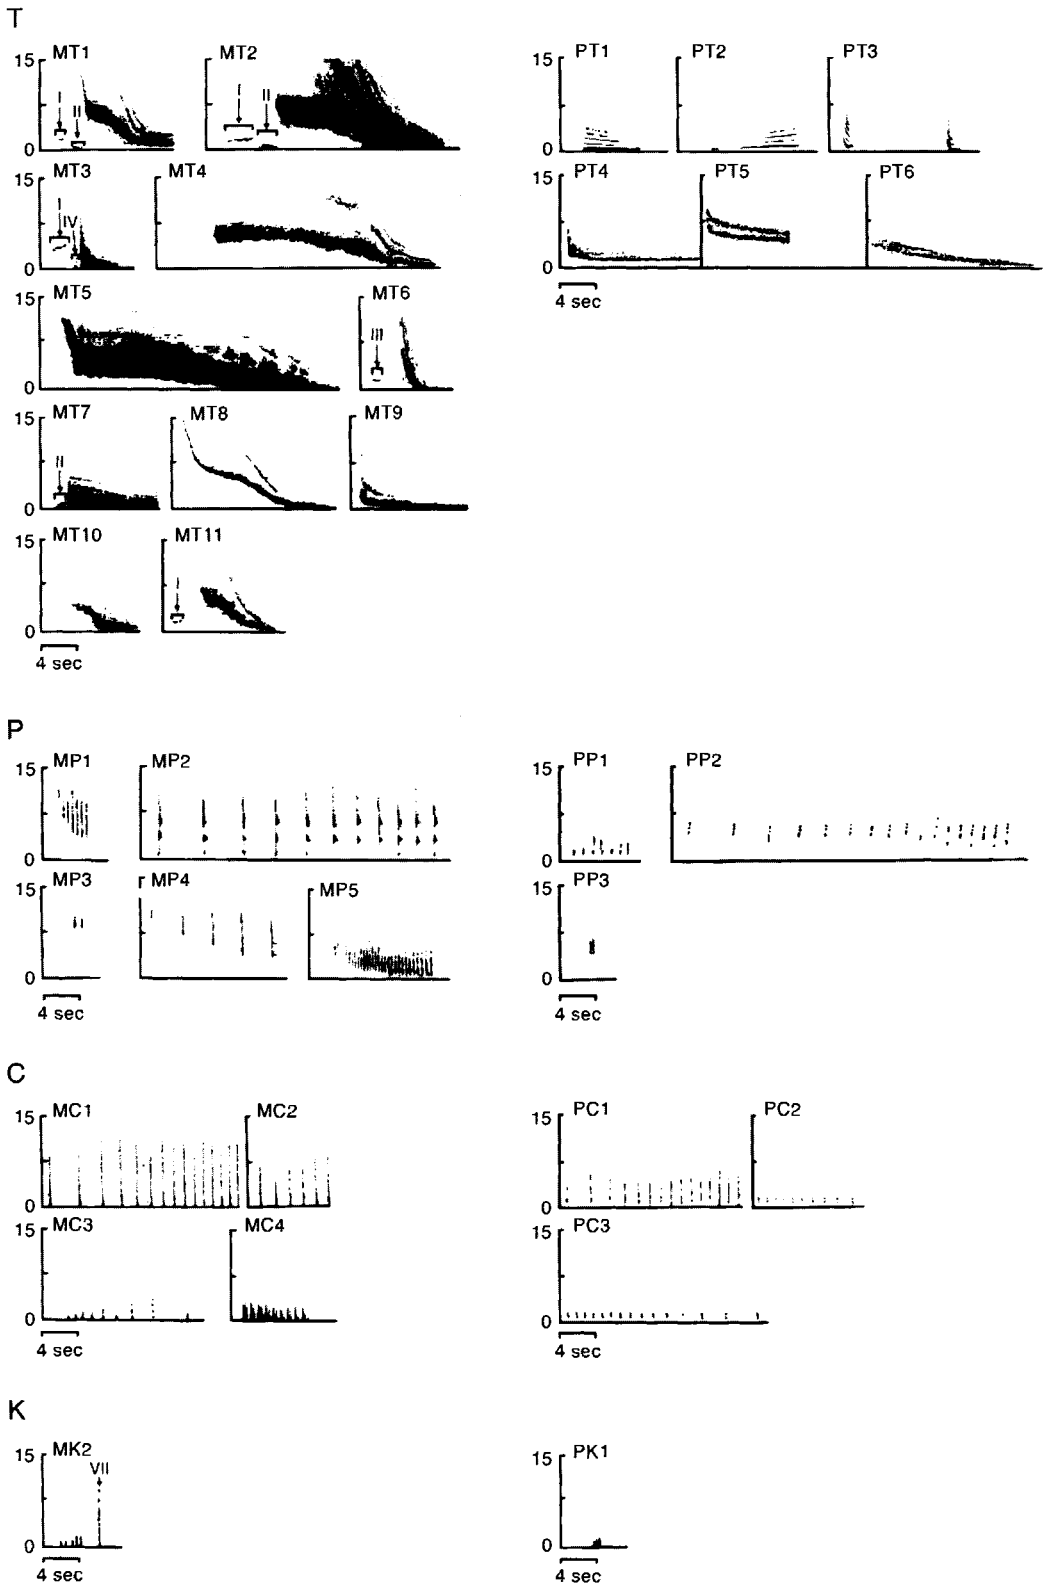

Figure 12 *Geographic variations in some underwater sounds from Weddell seals at McMurdo Sound and Palmer Peninsula, Antarctica. Sonograms have upper frequency scale 15 kHz, time designated by scale bar. Each sound has a location, call, and type designation, e.g., MT1 is trill type 1 from McMurdo Sound and PC1 is chirp type 1 from Palmer Peninsula. T = trill, C = chug, P = chirp, K = knock. Missing sonograms under a location indicate no corresponding call type at that location. Sounds courtesy of J. A. Thomas.*

graded context to convey the degree of warning, *i.e.*, shortest, quietest trills are just a reminder, but long, loud trills are an emphatic warning to an intruder. This species also uses prefixes and suffixes with main call types, seeming to warn or emphasize a message. The trills are as long as 75 sec (Fig. 12). The repertoire on the opposite side of the Antarctic shows geographic variations, including some unique usage of "mirror-image" calls, *i.e.*, an upsweep followed by the mirror-image, downsweep. Male pups as young as 2 months try to perfect the long, loud trills, using comical, voice-cracking sweeps reminiscent of adolescent adults. The leopard seal, the largest pinniped predator, produces a surprisingly musical repertoire of sounds, but primarily during mating. This seal also exhibits geographic variations (Fig. 13) in sounds around the Antarctic.

Otariid airborne sounds range from 1 to 4 kHz, with harmonics up to 6 kHz. Barks in water are slightly louder than in air and both center around 1.5 kHz. Individual California sea lion sounds have unique variations suggesting signal components for identity. Odobenid sounds are low in frequency, 500 Hz, with a peak of 2 kHz. Underwater, walruses have a unique bell-like sound, but also produce clicks and whistles. Recent studies indicate that territorial male walruses have their own distinctive sound patterns.

4. Sirenia Sounds of sirenians are low in amplitude and probably only propagate short distances. From field observations of mother/calf manatee pairs, it appears that vocalizations play a key role in keeping the mother and calf together. Some researchers even describe this vocal exchange as dueting, where the mother and calf exchange chirps (see Reynolds and Odell, 1991). Another example of communication in manatees again included a mother/calf pair on opposite sides of a flood control gate. For nearly 3 hr, the mother placed her head in the narrow opening and vocalized to the calf until the gate opened enough for the calf to swim through. Although most evidence is anecdotal, sirenians (at least manatees) seem to use sounds to communicate with conspecifics.

Dugongs are highly social, occurring in groups up to several hundred animals. Sound and vision probably play the most important roles in communication. Vocalizations of dugongs are low frequency, ranging from 1 to 8 kHz and seem to be especially important in maintaining the mother/calf bond. Studies in the clear waters of Shark Bay suggest that dugong males establish territories to attract estrous females. Reynolds and Odell (1991) suggested that low-frequency vocalizations play a role in mate attraction in dugongs.

Manatee and dugong sounds are described as chirps, whistles, squeals, barks, trills, squeaks, and frog-like calls. West Indian manatee sounds range from 0.6 to 5.0 kHz, whereas Amazonian manatees have higher sounds near 10 kHz, with distress calls having harmonic structure up to 35 kHz (Reynolds and Rommel, 1999). Dugongs produce calls between 0.5 and 18 kHz with maximum energy between 1 and 8 kHz (Reynolds and Rommel, 1999).

5. Mustelidae In sea otters, social interactions, pup care, and mating occur at the water surface; still, little is known about sea otter vocal behavior. No underwater sounds have been reported for sea otters. The intertidal zone is a noisy, churning environment that would not be a good environment for exchange of sounds and would make recording difficult. In addition, sea otters forage singly and probably do not need to communicate while foraging. Kenyon (1975) provided the only detailed summary of sea otter sounds and these were based on sounds heard in air. He described their sounds as (1) baby cry—a sharp, high-pitched "waah-waah" sound used by pups in distress situations or when wanting to attract mothers attention; (2) scream—given by adults in distress or when a female has lost her young (it is an "ear-splitting" version of the pup cry detectable 0.5 miles away in the wild); (3) whistle or whine ("whee-whee")—a high-pitched sound resembling a human

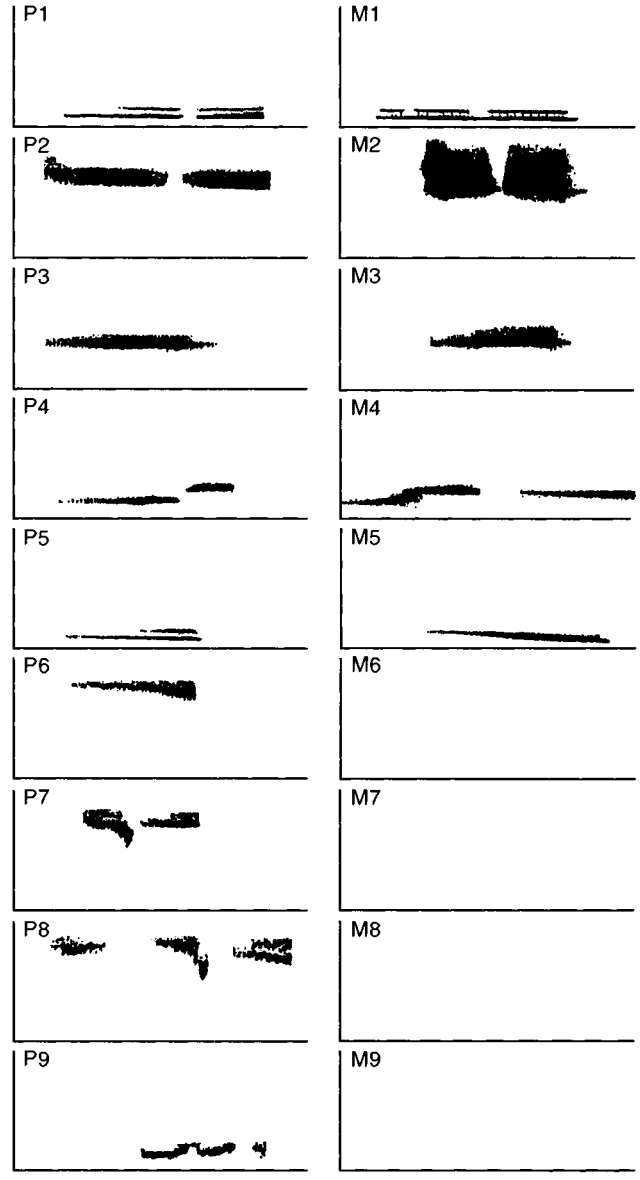

Figure 13 *Geographic variations in underwater sounds from leopard seals. Sonograms have an upper frequency scale of 5 kHz and time frame is 10 sec. P1–P9 are from Palmer Peninsula. M1–M5 are from McMurdo Sound, Antarctica. M6–M9 represent no corresponding sound types with those at Palmer Peninsula. Sounds courtesy of J. A. Thomas.*

whistle (denotes frustration or mild distress, given by captive sea otters when feeding is delayed, detectable 200 m away in the wild); (4) coo ("ku-ku-ku")—produced by females before and after mating or while eating a "particularly pleasing food," detectable only 34 m away; (5) snarl or growl—originating deep in the throat produced by a newly captured sea otter, audible only a few meters away; (6) hiss—short, explosive cat-like hiss used in startle situations; (7) grunt—soft groaning sound produced while eating; (8) bark—a staccato bark trailing off into a whistle, indicative of frustration produced by a young male; and (9) cough, sneeze, and yawn as in other mammals.

6. Ursidae Polar bears have a variety of sounds used in different contexts. Growls serve as a warning to others bears and defense of a food source. Hissing, snorting, loud roars, and groans or grunts are aggressive sounds. Chuffing was documented as a response to stress, whereas mother bears will produce soft cuff sounds or low growls when scolding cubs (Ovsyanikov, 1996).

VIII. Acoustic Signal Exchange: Language or Not?

In the 1950s and 1960s, Lilly tried unsuccessfully to find behavioral correlates with sounds emitted by the captive bottlenose dolphin and then concentrated on research about vocal mimicry in dolphins. While Lilly's early work was groundbreaking in its approach to observing and studying the communication of another species, his later work and conclusions are considered controversial at best. He believed and wrote that dolphins could mimic human sounds and inferred that dolphins had their own natural language and were amazingly intelligent beings worthy of our worship. More recently, Sigurdson showed it to be extremely difficult to train bottlenose dolphins to acoustically mimic even the simplest sounds for communication with humans.

There is little evidence that dolphins possess a language of sounds, as humans. However, laboratory experiments showed that bottlenose dolphins can understand the meaning of sounds organized with simple syntactic rules to represent objects, actions, and modifiers. Using match-to-sample methodology, Herman *et al.* (1984) trained bottlenose dolphins to respond to coded instructions. For example, the trainer could present three cues for "*fetch* the *surfboard* to the *person*." One dolphin was taught using acoustic cues, while a different individual learned a vocabulary of gestures by the trainer. Herman *et al.* showed that dolphins could understand three dozen words: nouns and actions; generalize known words into concepts, regardless of color, size, and shape; decode five- to six-word sentences, such as "pipe bottom hoop surface place in"; understand novel sentences; and interpret both gestures and acoustic signals according to a word-order grammar.

In short, Herman *et al.* showed that dolphins understand the syntax and word order of trained commands. However, Herman has yet to explore the capacity of dolphins for logical reasoning, problem solving, or the ability to answer acoustic commands with their own sounds. Nonetheless, the capacity for sound mimicry, condition-ability of vocalizations, advanced rule-learning capabilities, and other demonstrated intellectual traits suggest that dolphins, like some of the greater apes, could be capable of learning an artificial language in a laboratory setting.

Along a similar track, Schusterman trained California sea lions to conduct many of the same "language-like" tasks based on hand cues from a trainer. California sea lions adapted quickly and accurately to the tasks. Interestingly, Pepperberg trained an African gray parrot to answer questions in mimicked human speech. The quality of mimicry and apparent understanding of this bird is truly remarkable, thus questioning the use of "language-like abilities" as an indication of superior cognition by dolphins or sea lions.

Whether marine mammals use syntax, grammar, or language in the wild remains to be documented. However, whales, dolphins, seals, sea lions, sea otters, and manatees do use several different signals to exchange information among conspecifics about activities and relationships. Signals include visual displays and cues, sound emissions, postures, and natural markings to indicate age, sex, and individual identification.

IX. Conclusions

Animals live in an ever-changing world. Reactions and responses to environmental and social variables must be flexible and adaptive for survival and reproduction. Examination of signaling behavior and subsequent receiver responses provides a window into nonhuman minds, as well as to the social complexity of other species. It can be assumed that evolutionary processes are at work on signals to keep them informative and useful to individuals. Ecological factors, coupled with social relationships and interactions, provide the principal force in the evolution of communication systems (Hauser, 1997). Foraging, mating, and parental strategies are examples of components that influence signaling behavior. In marine mammals, coastal or oceanic species living in relatively clear water may be more likely to use visual signals (e.g., postures, coloration patterns) than species inhabiting riverine or turbid environments. Similarly, amphibious species require a suite of signals useful both in air and underwater. Differential communication is also evidenced in the foraging methods of several delphinid species. Communal foragers have more complex signals compared with more solitary hunters. Frequent interactions with conspecifics necessitate a higher rate of information exchange than for solitary species. Observing and examining the social and ecological differences among individuals and groups will help elucidate the mechanisms underlying the use and evolution of different signals to exchange information among individuals, i.e., communicate.

Competition with Fisheries

ÉVA E. PLAGÁNYI AND DOUGLAS S. BUTTERWORTH
University of Cape Town, South Africa

From an ecological perspective, competition is a situation where the simultaneous presence of the two competitors is mutually disadvantageous. This article focuses on biological interactions and, specifically, the direct competition for food and fishery resources between marine mammals and fisheries, in contrast to operational interactions in which marine mammals damage or become entangled in fishing gear with negative consequences for both the fishery and the animals. These two forms of conflict are sometimes difficult to separate because, for example, animals may damage fishing gear in the process of removing fish therefrom. A third oft-cited marine mammal–fishery interaction concerns facilitation of the spread of PARASITES to commercial fish species, but this is not of direct relevance to the current topic.

Competitive interactions between marine mammal populations and fisheries can be either "direct" or "indirect." In the former case the two groups share a common prey species, whereas in the latter case, for example, a marine mammal may prey on a species that is also an important component in the diet of a commerical fish species.

Perceived conflicts between marine mammals and humans in pursuit of common sources of food have come increasingly to the fore in recent years. Escalating pressures on shared resources are expected in the future because of both increasing marine mammal populations and an increasing human population. Reductions in direct takes in response to recognition that several populations of marine mammals were heavily overexploited in the 19th and earlier part of the 20th century, as well as a widespread change in people's perceptions of whether marine mammals should still be regarded as resources available for harvest, have meant that several marine mammal populations are currently on the increase, sometimes by as much as 5–10% per annum. From the human population perspective, the Food and Agriculture Organization of the United Nations (FAO) has estimated that 950 million people worldwide currently rely on fish and shellfish for more than one-third of their animal protein. Based on the past trend in annual harvests from marine capture fisheries, FAO have predicted that, by as soon as the year 2010, supply may be unable to meet the global demand.

Commerical fisheries and marine mammals frequently target the same fish species so that, faced with shortages in marine food production in the future, it is likely that the possible impacts of growing marine mammal populations on the sustainable harvest of commercial fisheries will be vigorously questioned. Concerns about the consequences for fisheries of an increasing marine mammal population have already been expressed in southern Africa, for example, where in 1990, Cape fur seals (*Arctocephalus pusillus pusillus*) were estimated to consume some two million tons of food a year. Considering that this amount was about the same as the annual human catch of fish in the region and that the fur seal population was anticipated to increase further, the reasons for concerns and potential for conflict are obvious. A second example concerns the Pacific Ocean, where marine mammals are estimated to consume about 150 million tons of food per annum, which is some three times the current annual fish harvest by humans.

This article first presents a brief summary of some specific examples that address the question of whether marine mammal populations have negatively impacted the potential yields from fisheries through competition. Examples of perceived competitive interactions are included because, in most cases, the evidence is inconclusive. Second, some examples pertinent to the reverse—whether fisheries negatively impact marine mammals—are summarized.

I. Detrimental Effects of Marine Mammals on Fisheries

A. Pinnipeds (Seals, Sea Lions, and Walruses)

In the early 1990s, catastrophic collapses occurred in the cod (*Gadus morhua*) fisheries on the east coast of Canada. Al-

though several hypotheses have been posited to explain this, the most likely cause was overfishing. Harp seal (*Pagophilus groenlandicus*) populations off Newfoundland and Labrador have been increasing at an estimated rate of 5% per annum since the mid-1980s and are known to consume a substantial tonnage of juvenile cod. The socioeconomic implications of the collapse of the cod fishery were huge, with some 40,000 fishermen rendered out of work, and there is an obvious temptation to argue a causal relationship between the failure of these cod populations to recover as rapidly as expected after their protection and the increase in harp seal abundance. Although the results of at least one ecosystem modeling study support the hypothesis that the recovery of these cod populations is being retarded to some extent by the increased biomass of harp seals, ecosystem models generally have poor predictive reliability, largely because of data limitations.

Demonstrating that either a fishery or a marine mammal will be affected adversely as a result of an increase in the removals by one party of a limited resource is not simple. Inferences based on assumptions of a linear relationship between predator and prey abundance are often incorrect because of the complex nonlinear interactions in an ecosystem. For example, off the west coast of South Africa, seals consume almost as much hake as is taken by the commercial fishery (Fig. 1). However, the commercially valuable hake consists of two species, a shallow-water (*Merluccius capensis*) and a deep-water species (*M. paradoxus*), with the larger of the shallow-water species eating the smaller individuals of the deep-water species. The results of multispecies models suggest that the net effect of a seal cull would be less hake overall because fewer seals would mean more shallow-water hake, and hence more predation on small deep-water hake. This study by Andre Punt and colleagues highlights the complexity of predation, food–fish, and fishery interactions and hence the difficulties of demonstrating conclusively that marine mammals are in direct competition with humans for food fish, as may superficially appear to be the case.

B. Whales

Numerous multispecies modeling studies have been employed to investigate the direct and indirect effects of minke whales (*Balaenoptera acutorostrata*) on cod, herring (*Clupea harengus*), and capelin (*Mallotus villosus*) fisheries in the Greater Barents Sea. Minke whales are abundant in this region and prey on all three species, prompting the question of whether fishermen could expect greater catches if the populations of these marine mammals were reduced. The indications of these studies are that there is competition between whales and fishers in this region and that the fisheries are likely to respond linearly to changes in whale abundance. They estimate that each minke whale reduces the potential annual catches of both cod and herring by some 5 tons. Similarly, studies off Iceland suggest that the piscivorous minke, humpback (*Megaptera novaeagliae*), and fin whales (*B. physalus*) may be having a considerable impact on the region's cod stock. The cod fishery is of key importance to the Icelandic economy, and the rebuilding of the cod population and catches are recognized as an important economic consideration. It is therefore not surprising that arguments have been put forward that there is a need to reduce whale populations to permit commercial fisheries to increase.

Whereas marine mammals are thought to exert relatively minor influences on systems such as the North Sea and Baltic Sea, they have been identified as potentially serious competitors off, for example, the northeastern United States, a region that includes important fishery areas such as the Gulf of Maine and Georges Bank. The latter region exemplifies the conflicts

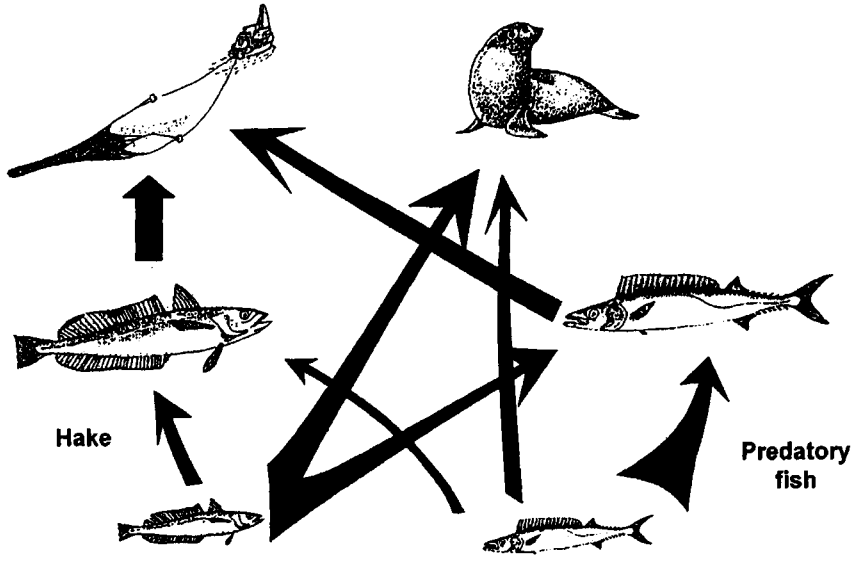

Figure 1 *Schematic showing the complexities of predation, food–fish, and fishery interactions as summarized in a minimal realistic model of Cape fur seals and Cape hake interactions off South Africa. Reproduced from Punt (1994), with permission.*

that can arise between fishery management plans tasked with rebuilding prey populations and prescriptions, by the U.S. Marine Mammal Protection Act in this case, to facilitate an increase in the abundance of marine mammal predators.

C. Small Cetaceans

In many areas of the world, coastal fishermen consider dolphins as serious competitors, although retaliation by the fishermen usually has only minor effects on the populations or on their perceived damage to fisheries. Short-beaked common dolphins (*Delphinus delphis*) in the Mediterranean have often been perceived as a threat to the purse seine and trawl fisheries operating in these waters and, as a result, have been deliberately caught in direct retaliation. Declines in this population have been attributed to both direct and incidental catches by these fisheries.

The largest hunt designed to reduce the perceived level of competition with fisheries took place in the Black Sea from 1870. In the mid-1900s, tens of thousands of dolphins and porpoises were killed every year as a result of fishing industry claims of competition. Other examples of cetacean kills due to perceived competition include the bombing of belugas (*Delphinapterus leucas*) from the air by the Quebec government in the 1920s and 1930s, the commissioning by the Icelandic government in 1956 of a United States naval vessel to kill killer whales (*Orcinus orca*), and the use of explosives and firearms by Alaskan fishers in the mid-1980s to eliminate local killer whales.

D. Sea Otters

Sea otters prey on a variety of marine invertebrates such as urchins and abalone. Off southern California, southern sea otters (*Enhydra lutris nereis*) have been labeled by some as responsible for the decline of the abalone fishery, but there is little direct evidence to support this notion. The commercial abalone fishery in California was closed in late 1997, and factors such as commercial fishing, poaching, disease, and changing environmental conditions are all thought to have contributed to the decline of this commercially valuable shellfish. Although the southern sea otter population is not increasing, perceptions of the level of competition between otters and commercial abalone fishers have increased because of the recent southward movements of otters, which has increased the overlap between otter fishing grounds and abalone fishing areas.

II. Detrimental Effects of Fisheries on Marine Mammal Populations

A. Pinnipeds

The western Alaska population of Steller sea lions (*Eumetopias jubatus*) has shown a continuous decline since the 1970s and was listed in 1997 as an endangered species under the U.S. Endangered Species Act. Several groups have argued that this decline is due in part to the large fishery harvest of walleye pollock (*Theragra chalcogramme*), which is both a key source of food for sea lions and currently the most important U.S. commercial fishery. Measures to reduce the perceived competition between sea lions and fisheries for groundfish stocks include the establishment of "buffer" (no-trawl) areas to include important locations where the sea lions breed, feed, and rest, as well as specifying a pollock harvest which is distributed more evenly over the remaining areas and spread throughout the year. However, the results of modeling studies indicate that the observed sea lion population decline cannot be explained solely through trophic interactions, and rather is more likely linked to shifts in environmental conditions, which lead to changes in the favored complex of species. Moreover, studies such as that by Andrew Trites and colleagues highlight the difficulties of predicting the direction and magnitude of a change in an ecosystem arising from a reduction in predation or fishing pressure. They posit that, paradoxically, Steller sea lion and northern fur seal (*Callorhinus ursinus*) populations might realize greater benefits if adult pollock and large flatfish were fished more heavily. This competitive release effect may result because, for example, pollock are cannibalistic and hence decreased adult pollock abundance as a result of heavier fishing may result in increased numbers of juvenile pollock available to marine mammals.

B. Whales

Competition effects are difficult to quantify, but it has been proposed by Whitehead and Carscadden (1985) that the collapse of the eastern Canadian capelin fishery in the 1970s had a negative effect on fin whales. They suggested that a shortage of capelin might have allowed humpback whales to outcompete fin whales because the latter rely principally on capelin as a prey source. If competitive predation between a marine mammal and a fishery occurs, this implies that the marine mammal population is limited by food availability and hence it should be possible to demonstrate a response of some vital population parameters to a change in food availability. Recent probable population increases of several krill-eating marine mammals, such as Antarctic minke whales (*Balaenoptera bonaerensis*), crabeater seals (*Lobodon carcinophaga*), and fur seals (*Arctocephalus gazella*), have been attributed by some investigators to a likely large increase in the availability of KRILL (*Euphausia superba*) in Antarctic waters. Following the substantial reduction through overexploitation of large whale populations during the early 20th century, some 150 million tons of "surplus" krill is argued to have become available annually to other predators. This "krill surplus" theory enunciated by Laws has yet to be universally accepted, and scientists are addressing questions such as whether the mean age at maturity of minke whales and crabeater seals has dropped in recent years as a response that might result from an increase in food availability.

Modeling studies by Andrew Trites and colleagues suggest that marine mammal populations can be reduced quickly through reductions in prey abundance, but show a generally slow recovery when abundant food becomes available.

C. Small Cetaceans

Dolphin populations that have localized coastal distributions, such as the Indo-Pacific humpbacked dolphins (*Sousa chinensis*) off KwaZulu-Natal, South Africa, may be vulnerable to commercial fishery expansions because of increased competition with fishermen for limited food resources.

D. Sea Otters

Recent declines in northern sea otter (*Enhydra lutris kenyoni*) populations in Alaska have been linked indirectly to competition with fisheries. As outlined earlier, fishing is argued to be one of the factors contributing to the decline of pinniped populations (harbor seals *Phoca vitulina* and Steller sea lions) in some of the Aleutian Islands. Killer whales preferentially feed on pinnipeds in this region, but as a result of the decline in pinnipeds, they have switched to sea otters as prey. The work of Estes and others argues that reduced populations of fish prey that provide high caloric and nutritive value to pinnipeds may impact not only directly on pinniped populations, but also indirectly on killer whale and sea otter populations.

E. Sirenians (Dugongs and Manatees)

Although direct kills and incidental capture in fishery gear are problems, these mammals feed mostly on vascular aquatic plants so that there is no direct competition with humans for a shared food resource.

III. Assessing the Competitive Effects

Whereas commercial fishermen in many parts of the world perceive marine mammals as serious competitors for a scarce resource, other organizations argue that marine mammals are being used simply as scapegoats for failed fisheries management policies. Scientific evidence is therefore increasingly being sought to settle these disputes, but it is becoming increasingly appreciated that the scientific methodologies required to address them are complex, time-consuming, and beset with difficulties.

Initial attempts to quantify the impact of consumption by marine mammals on fish catches used a simple approach. They took account of the fact that, particularly for pinnipeds, the sizes of fish eaten tend to be smaller than are taken by commercial fisheries. Thus 1 ton of a commercially desired fish species eaten by seals does not translate into exactly 1 ton less in the allowable catch for fishers. This is because although a fish eaten by a seal would have grown larger by the time it became vulnerable to fishing, it might also have died before reaching that size as a result of other sources of natural mortality.

It is now acknowledged that such computations, which essentially treated marine mammals as the equivalent of another fishing fleet, are likely to be inadequate because of oversimplification. Three complicating factors need to be addressed in performing more realistic computations, while still accepting that both data and computing power limitations necessarily restrict the degree of complexity that is viable to incorporate in multispecies models. The first concerns how many of the large number of interacting species in any ecosystem need to be considered. Second, do age-structure effects need to be taken into account? This can become important when, for example, one species that predates on the small juveniles of a second finds itself the prey of the larger adults of that same species. Thus, whiting *Merlangius merlangus* feeds extensively on the youngest (0+ and 1+) age classes of the commercially valuable cod, in turn a major predator on the smaller individuals of whiting. Finally, the customary modeling assumption that species interactions occur homogeneously over space may well be sufficiently flawed to invalidate results. Moreover, the distribution of seal breeding and resting sites does not necessarily reflect their feeding distributions. Modern animal tagging technology has demonstrated, for example, that grey seals (*Halichoerus grypus*) and southern elephant seals (*Mirounga leonina*) may travel hundreds of kilometers to a preferred feeding site.

More recent attempts to quantify marine mammal–fishery interactions have taken account of at least one of these complicating factors, although studies have yet to reach the stage where all three are considered simultaneously. However, with the development of generalized multispecies modeling tools such as Ecosim and Ecospace by Carl Walters and colleagues, groundwork is being laid to provide a more reliable basis for scientific evaluation of these competitive effects.

IV. Considering the Influence of Fish Harvesting on the Ecosystem

The adoption of the Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR) was a watershed in international fishing agreements in that it was the first to acknowledge the importance of maintaining the ecological relationships among harvested, dependent, and related populations of marine resources. Krill is the primary food source of a number of marine mammal species, and concern has been expressed that the rapidly expanding Antarctic krill fishery might negatively impact or retard the recovery of previously overexploited populations, such as the large baleen whales of the Southern Hemisphere. In response to this CCAMLR mandate, modeling procedures have been developed to assess the impact of Antarctic KRILL harvesting on krill predator populations and to explore means of incorporating the needs of these predators into the models that are used in recommending annual krill catch levels. For example, Antarctic fur seals from Bird Island, South Georgia, are another example of a previously overexploited population that is now growing rapidly such that its needs for krill as a food source may in due course conflict with the objectives of krill harvesters. These competition effects have thus far been addressed by Robin Thomson and colleagues who calculate, within a modeling procedure, the level of krill fishing intensity that would reduce krill availability, and hence the population of a predator to a particular level. In general, initiatives such as these pursued under CCAMLR recognize the need to balance the needs of predators with the socioeconomic pressures underlying fishery harvests and represent a realistic step forward in resolving some of the management quandaries resulting from competition for limited marine resources.

V. Food Web Competition

Andrew Trites and colleagues assessed the competition between fisheries and marine mammals for prey and primary production in the Pacific Ocean. Although the 84 species of marine mammals inhabiting the Pacific consume about three times

as much food as humans harvest, most of the species consumed are not of current commercial interest. The greatest overlaps occur with pinnipeds (60%) and dolphins and porpoises (50%). The least overlap is with baleen whales and beaked whales. The observed dietary overlap between the prey items of marine mammals and fisheries is less than expected because specialized feeding habits mean, for example, that some of the targeted prey either are not desired for human consumption or are not currently viable for commercial harvest. Trites and others argue that while direct competition between fisheries and marine mammals for prey appears limited, indirect competition for primary production may be cause for concern. Such so-called food web competition may occur if there is overlap between the trophic flows supporting the two groups (see Fig. 2). Evidence in support of food web competition between marine mammals and fisheries is provided by a negative correlation between estimates of primary production required to support fisheries catches and to support the number of marine mammals estimated in the different FAO areas of the Pacific Ocean.

VI. Summary

Despite a persistent notion worldwide that there is a mass for mass equivalence in the prey of marine mammals and the yields available to fishers, the balance of the evidence collected thus far indicates that this is not the case. Furthermore, the complexity of ecosystems could well be such that the response to a marine mammal cull could, for example, be highly diffused through the food web, involving many other species. In some cases, competition effects are reduced because, for example, one of the putative competitors in fact reduces the abundance of a predatory fish species, in turn affecting the abundance of the target prey species. It is worth noting that although marine mammals are the most obvious scapegoat of fishers because of their visibility, there is typically greater competitive overlap of the feeding "niches" of fish predators with those of fishermen.

Because of the difficulties of providing definitive scientific advice on such questions, scientists often equivocate. It is currently virtually impossible to wholly substantiate claims that predation by marine mammals is adversely impacting a fishery or vice versa. In the absence of definitive answers, fisheries managers are increasingly applying the "precautionary principle," which requires that "where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation," but this has been argued both ways in this context: either that marine mammal culls should not take place in the absence of clear evidence that they will benefit fisheries or alternatively that marine mammals should be culled in the absence of clear evidence that their consumption of fish will not possibly damage fisheries.

As more and better information on marine mammal DIETS becomes increasingly available, one of the key uncertainties in resolving questions as to the degree of competitive overlap be-

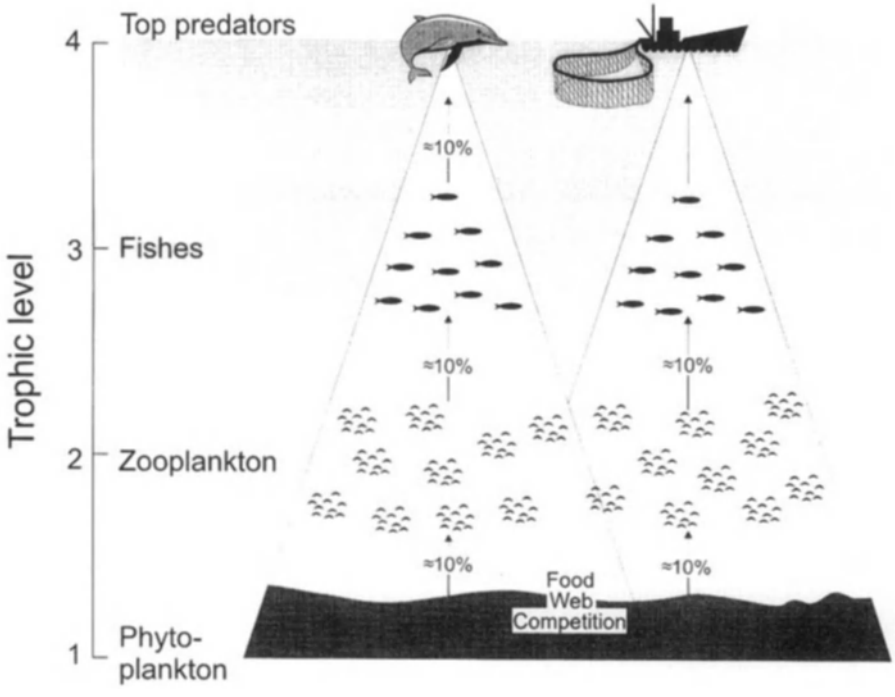

Figure 2 *Schematic example of indirect competition for food by marine mammals and fisheries. The representation shows how top predators, such as marine mammals, may be affected by fisheries because of limits on the primary productivity available to support the two groups. Thus even though the mammals' prey and species taken by fisheries may not overlap, so-called food web competition occurs at the base of the food pyramids. Reproduced from Trites* et al. *(1997), with permission.*

tween marine mammals and fisheries relates to limited understanding at present of the feeding strategies of marine mammals. There is a need to quantify not only spatial and temporal variability in diet, but also the conditions under which predators switch to alternative prey species as the abundances of the various species change. It is also important to bear in mind that some marine mammals that are highly specialized feeders (or, conversely, highly specialized fishers) are most vulnerable to competition effects because they cannot easily change their diet in response to overfishing of a vital food source.

Conservation Biology

BARBARA L. TAYLOR
Southwest Fisheries Science Center, La Jolla, California

To many, "save the whales" is nearly synonymous with "conservation of nature." Whales have become flagship species for wildlife conservation because many of us have lived through the near EXTINCTION of many species of whales at the hands of our fellow humans. It is amazing that humans were able to come so close to exterminating many marine mammals from the huge oceans that cover our planet. What makes marine mammals so vulnerable? Or the flip side of that same coin, why must we go to special lengths to conserve marine mammals?

I. Causes of Vulnerability

The field of conservation biology has arisen to meet the special needs of conserving biodiversity. Prior to the 1980s natural resource management was focused primarily on managing species that were of economic or recreational importance and hence the emphasis then on "fish and game." The tools used to manage these generally more abundant species were not always appropriate for the more rare species that were increasingly facing extinction. Conservation biology has not only developed many important tools to assess risk and prescribe the needed conservation actions, but in the process has developed a new management philosophy. Because many marine mammals were nearly extirpated, many of the tools and management models were developed in this field.

A. Understanding Risk through the History of Exploitation

When species come close to extinction, scientists analyze what risks the species face in order to take management actions to reduce those risks. Marine mammals share a number of these risk factors that make them particularly vulnerable to human impact. Before considering the biological components of marine mammal vulnerability, it is important to note that their exploitation has an economic basis: marine mammals are and have been a very profitable natural resource to exploit. Although marine mammals have always been valued for their meat by native peoples such as the Eskimo, it was the ability to use modern weaponry and transport the goods to distant markets that set the scene for the first wave of decimation of marine mammals. The attributes that make marine mammals vulnerable are easily explained in the context of their exploitation through history.

The first species to be lost were those that were especially vulnerable because they were naturally rare and had limited distributions. Steller's sea cow (*Hydrodamalis gigas*), for example, lasted only a few years after being discovered in the Aleutians. However, even relatively abundant species could be rapidly overexploited if they congregated in easily accessible

areas. The more these species congregated, the more vulnerable they were. Thus, most land-breeding species of pinnipeds were quickly driven to near extinction. Although records of the extent of the decimation of populations are poor, we know that some populations, such as northern elephant seals (*Mirounga angustirostris*) and sea otters (*Enhydra lutris*) in California, were reduced to very low size because at some point they were thought to be extinct.

What made the great whales vulnerable? Right whales (*Eubalaena* spp.) are slow moving and congregate in predictable areas to feed. Bowhead whales (*Balaena mysticetes*) are similarly slow moving and were also found in areas in sufficient density and predictability to be rapidly overharvested. Among bowhead whales the populations that fared the best occupied the least accessible habitat: heavy ice pack that served as a refuge from ships. Pacific gray whales (*Eschrichtius robustus*) were easily exploited because they concentrated in breeding lagoons and migrated in a dense, easily accessible coastal corridor to get from their Alaskan feeding grounds to their Mexican breeding grounds. Sperm whales (*Physeter macrocephalus*) were valued for their oil, which was said to have lit the lamps of the Western world. Again, sperm whales swam slowly enough that row boats deployed from sailing ships could be used to hunt them. Also, the blows of the whales could be spotted for miles from the tall crows nests of ships. They were also found in concentrations in predictable areas, although they were taken opportunistically from most of the world's oceans. Sperm whale products were sufficiently valuable that thousands of ships hunted them even when the average trip lengthened from one to several years as populations declined. The Yankee whaling era did eventually end because petroleum products became less expensive than whale products.

Technological advances allowed whale products to be sufficiently profitable in the 1920s: fast catcher boats, lethal explosive harpoons, and factory ships that allowed rapid processing anywhere in the world. Now the large fast-moving baleen whales, like blue whales (*Balaenoptera musculus*), could be exploited for their vast quantities of meat and BLUBBER. The past overexploitation of other whale species led to the formation of the International Whaling Commission to attempt to manage the harvest. The failure of this organization is legendary (Gambell, 1999) as species after species was successively severely overharvested. In the decade of the highest catch (1956–1965), official numbers killed were 631,980, and this is known to be an underestimate because the Soviets were guilty of vast underreporting in this era.

Technology had now reached the point that even species that lived in remote areas and sometimes in relatively low densities could be located and harvested with remarkable efficiency. For example, sperm whales were hunted by a fleet of catcher boats that ranged in front of the mother factory ship spaced apart roughly equally. These catcher boats methodically searched the sea and converged once they found their prey. World War II antisubmarine sonar technology was used to follow whales under water so as to be poised for the kill when the whales surfaced to breathe. The average time to kill all whales of legal length in the group (which often numbered about 20) was only 1 hr. Perhaps more amazing was that individual whales, which were at least 30 feet long, were completely butchered aboard the factory ship and sent below to be made into various products in only 20 min! Blue whales in the Antarctic were reduced from an estimated 350,000 to approximately 460 (Gambell, 1999), and the vast majority of this whaling (predominantly by the British fleet) occurred over a period of only 10 years (1930–1940).

B. The Biology of Vulnerability

Why were these species so vulnerable to rapid overexploitation? The risk factor that all marine mammals share that makes them vulnerable to such rapid overexploitation is that they reproduce relatively slowly. Most fish mature in a few years and can produce thousands of eggs. Their life history strategy allows for many individuals to be consumed as prey. Marine mammals, to the contrary, are the predators. They have not evolved to withstand high rates of predation. At most, marine mammals produce one offspring per year. Most pinnipeds and some porpoises can mature in 3 to 4 years, have offspring annually, and only live up to about 20 years old. Some pinnipeds have been documented to grow at rates of up to 12% per year (Wade, 1998). Thus, 6–10% per year could be harvested and allow the population to persist. Of course, commercial sealers of the last century were harvesting at rates much greater than 12%/year and thus drove populations to commercial or actual extinction.

Most cetaceans have a much lower population growth rate. Perhaps the slowest growing species is the predator of predators: the killer whale. Killer whales (*Orcinus orca*) not only mature late at about age 12, but they invest large amounts of parental care into their offspring and thus have calves on average only once every 5 years. Recent research estimated that a population that was harvested for purposes of public display in the 1970s is only just now recovering to the numbers found then. This population was growing at only 3% per year (Brault and Caswell, 1993). Many of the great whale populations are now recovering at rates from 7 to 12% per year. Because marine mammal population size is relatively small compared with the fishes of the sea, a harvest that is substantial from an economic point of view is usually unsustainable from a biological point of view. Consider, for example, the Pacific gray whale, which was recently removed from the U.S. Endangered Species List. The recovery of this species is one of the great success stories of marine mammal management and some think that numbers are now approaching historical numbers. Still, there are only 22,000 individuals in this species, which would be considered to be a very small town of humans virtually anywhere on the planet. To put this in perspective, the average catch in the 1970s, which was the most recent period of commercial whaling, was over 27,000 whales/year. During the growth recovery phase for gray whales the population grew at about 3% per year (Buckland *et al.*, 1993). Allowing half of that growth to be harvested would result in 330 whales/year, which is a very small number compared to common commercial catches.

Another reason that marine mammals are vulnerable to extinction is that individual animals seem most likely to return to the same areas to feed and to breed. Great progress has been made in the past two decades in understanding how marine

mammals organize themselves spatially. The ability to photographically identify individuals over many years has revealed that despite the ability of marine mammals to move thousands of miles, many (if not most) individuals come back to the same area each summer to feed and migrate to the same BREEDING grounds (called site fidelity). Data from satellite tags and molecular genetics are adding focus to this same picture: population structure is the rule not the exception. Finding this structure makes us rethink the history of whaling and the more recent history of recovery. Are populations in some areas, like New Zealand that once supported shore-based whaling of humpback whales, failing to recover because all the whales that once went there were killed? If site fidelity is so strong, does this explain why whalers were able to expend about the same amount of effort to catch a whale even though the total abundance of whales was declining drastically? Whalers were simply able to sequentially harvest different feeding grounds like a combine harvesting grain. Such a theory is certainly compatible with many historical whaling records that show the harvest shifting to different places each year.

II. New Risks from Old Vulnerabilities

Because of various protective laws, a current ban on the commercial harvest of whales in the IWC, and the restriction in international trade because of current listings in the Conventional on International Trade in Endangered Species (CITES), commercial harvest of marine mammals on a global scale is not currently the risk factor it once was. However, all the risk factors that made marine mammals susceptible to large-scale commercial harvest (slow population growth rate, concentrations in accessible areas, ease of sighting and capture) make them vulnerable to other risks today. The species most vulnerable to extinction today are a few of the great whales that have failed to recover, the two species of remaining monk seals (*Monachus monachus* and *M. schauinslandi*), and a list of small cetaceans, including many river dolphins. Thus, the species most vulnerable have shifted from the seals and sea lions to the great whales and finally to the small cetaceans.

Once again, the ultimate cause of marine mammals' vulnerability is their life history strategy that leads to slow population growth rate, but in addition to the old risks such as overharvest, a new series of risks are posed by humans that are taking many small cetaceans to the brink of extinction. Recently added risks to marine mammals are entanglement in fishing gear (bycatch), POLLUTION, habitat destruction, and ship/boat injuries. Given all the risks posed to marine mammals, regulation of human activities will continue to be needed to conserve these species. Strong national laws and international treaties have played an important role in conservation and many species are making strong recoveries. Many species, however, fall outside of the purview of such protection and it is notable that many of these are the small cetaceans that are now in serious decline.

III. New Conservation Practices

As human abundance increases there will be increased use of marine natural resources putting humans and marine mammals in competition for food. No one knows the indirect effect of how current fishing practices affect the level of food available to marine mammals. Reduction of pollock has been implicated as one of the causes for the decline in Steller sea lions (*Eumatopias jubatus*) (NMFS, 1992), which resulted in this species being listed as endangered under the U.S. Endangered Species Act. Scientifically it is very difficult to prove either that reduction in prey led to the decline or that a major oceanographic shift led to a reduced capacity of the environment to maintain large numbers of Steller sea lions. Past management required proof of harm, i.e., the burden of proof was that scientists prove human exploitation results in harm to marine mammals. Because these management practices failed, there has been a recent trend to reverse this burden of proof such that the users of natural resources should prove they will not cause harm. Until such proof is provided the use should not be allowed. This is called the "precautionary principle."

This principle is part of the philosophical shift in natural resource management. Experience has shown that better management can result from harvesting more conservatively as our ignorance (reflected in measures of uncertainty) increases. Past management was a failure in both economic and biological terms so there is agreement between those who wish to exploit natural resources and those that wish to preserve them that the philosophical move to incorporate uncertainty into management models is generally good. However, the level of conservatism in the models is a matter of choice, and beyond a certain point conservative management practices are economically costly. For example, allowing no capture of dolphins during tuna fishing would provide the greatest safety to the dolphins and would please animal rights activists, but there is no doubt that such management would be costly to the fishing industry. There is also no doubt that the dolphin populations could sustain some level of bycatch and remain healthy.

The role of conservation biology is to prioritize actions through a scientific analysis of risks and to guide management actions by coupling the policy decisions together with the analysis of data. Conservation biology is developing the new tools needed to create management models that successfully implement public policy. For example, consider the Marine Mammal Protection Act objective to maintain marine mammals as functioning elements of their ecosystem. This seemingly straightforward objective required developing the following tools: a model that incorporated our uncertainty about abundance, kill and population growth rates to determine the number of animals that can be safely killed by humans, defining the unit of conservation that will maintain ecosystem functionality, which in turn required developing new techniques to estimate how animals disperse between different areas, and developing decision analysis techniques that are based on how well the management model performs with respect to management objectives.

Although conservation biology can develop suitable tools, a more fundamental question about the conservation of marine mammals remains: just how precautionary do we want to be? What would we, as the world community of humans, like to see conserved with respect to marine mammals? One objective is to at a minimum conserve the biodiversity of marine mammals,

i.e., assure the continuance of all species. Given current species definitions, this would allow the extirpation of populations of marine mammals in all ocean basins except one. For example, it would be acceptable to allow blue whales to go locally extinct everywhere except in one area, say the population that summers off California. It is likely that those living around the Atlantic ocean basins would find this unacceptable. There are also questions about species definitions: is there only one species of blue whale, if there are subspecies, should they be conserved, and so on. Another objective might be persistence of all species in all ocean basins or river systems. This definition would allow the extirpation of local populations, such as the humpback whales (*Megaptera novaeangliae*) off the east coast of North America. Such a loss would certainly be unacceptable to people in that area that not only enjoy the animals but enjoy a whale-watching industry of economic importance to local communities. Another objective would be to maintain all populations or even to maintain marine mammals as healthy, functioning elements of their ecosystems (an objective of the U.S. Marine Mammal Protection Act).

Thus, conservation is linked to societal values. One of the greatest difficulties in conserving marine mammals as human populations and demands on natural resources continue to grow will be finding acceptable global conservation values that must underlie the international will to regulate our actions that either directly or indirectly affect the lives of marine mammals. Global conservation of the species at highest risk of extinction will take both international will and international financial support to provide direct aid to failing populations and indirect aid through economic alternatives for people directly affected by conservation of an international resource.

Conservation Efforts

RANDALL R. REEVES
Okapi Wildlife Associates, Hudson, Quebec, Canada

Efforts to conserve marine mammals began early in the 20th century. The impetus for these efforts came from the recognition that populations of several highly valued species—fur seals and the sea otter (*Enhydra lutris*)—had been nearly extirpated by hunting. In most instances, self-regulation through market feedback had been the only thing that prevented extinctions. In other words, as the animal populations became reduced by overkill, it became increasingly difficult to hunt them profitably, so the hunting effort declined. This mechanism was clearly inadequate to protect the stocks of whales because modern whaling was a multispecies enterprise. As right whales (Balaenidae) and blue whales (*Balaenoptera musculus*) became scarce, the fleets simply redirected their attention to humpback, fin, and sei whales (*Megaptera novaeangliae*, *Balaenoptera physalus*, and *B. borealis*, respectively), but any right or blue whale encountered would still be killed. By the late 1920s and 1930s, the whaling industry had begun to place limits on oil production and had given full protection to the depleted right whales and gray whales (*Eschrichtius robustus*). Eventually, international agreements emerged to manage the industry on terms more favorable to conservation. It was not until the 1970s, however, that the multispecies problem was addressed properly. Indeed, it is fair to say that efforts to conserve marine mammals were few and far between until the late 1960s and early 1970s.

A discussion of marine mammal conservation can be organized in a number of ways according to different types of threat (e.g., directed hunting, bycatch in fisheries, chemical pollution), on a species or population basis, by geographical region, or chronologically (see Whitehead *et al.*, 2000). The first part of this article is organized according to levels of governance. Conservation efforts have been and should be made at many different levels, from that of global international agreements all the way "down" to the scale of actions by local communities and individual citizens. Thus, some of the efforts to conserve marine mammals at the international, regional, national, and local levels are reviewed, and this review is followed by a discussion of some of the principal threats and the ways these are being addressed. Next is a brief overview of the zoogeography of marine mammal conservation, which considers regional differences in the seriousness of threats and in the ways these threats are being addressed. Finally, an attempt is made to

identify the most seriously threatened marine mammal species and populations.

I. What Is "Conservation"?

This question may seem trivial at first glance, but it is crucial to define terminology rigorously in order to avoid misunderstanding. Here, "conservation" is defined as the preservation of wild populations so that they can continue to replicate themselves, in a natural context, for an indefinite (but long) time into the future. This necessarily means that not only the animals themselves, but also the environments ("ecosystems") that sustain them and even the biotic communities of which they are a part, must be preserved. It should go without saying that maintenance of a few individuals in zoo-like conditions, or the preservation of frozen DNA, are far from what constitutes conservation.

The unit of conservation has traditionally been the species, classically defined as a group of interbreeding natural populations that are isolated reproductively from other such groups (Mayr and Ashlock, 1991). In practice, conservation biologists generally agree that it is insufficient to be concerned only with preserving species. They argue that it is also important to preserve the natural variety within species, including genetic and behavioral variants. One way of achieving this more ambitious objective is by ensuring the survival of all local or geographical populations ("stocks") of a species. There is a substantial and growing body of literature on the "stock" concept as it applies to marine mammals (e.g., Dizon *et al.*, 1992, 1997).

The term "conservation" has a long history and is often cast in three different perspectives: biocentric, economic, and ecologic. *Biocentric* conservation emphasizes the intrinsic value of all life forms and is rooted in religious or philosophical beliefs that place humans on the same plane as other organisms. Although the concept of "animal rights" shares similar roots, it differs from biocentric conservation in that it focuses on the importance of individuals rather than on populations or genomes. Concerns about animal welfare and humane treatment also focus on individuals and are not always central to conservation, as defined here. *Economic* conservation regards wild animal populations as resources to be used for human benefit. A central tenet is sustainability. That is, killing or other forms of extractive, or consumptive, use are allowed and perhaps even encouraged, but only on the condition that such use does not compromise the ability of a wild population to regenerate itself. Finally, *ecologic* conservation places a premium on the maintenance of natural systems and processes. Individuals, populations, and species derive importance from their functional relationships with the communities of which they are a part.

II. International Conservation Efforts

Organized conservation efforts are made at the international level mainly by intergovernmental organizations that are established under the terms of treaties or conventions (Table I). A few nongovernmental organizations (NGOs) also operate on a global basis. Some of these, such as the World Conservation Union (IUCN), International Fund for Animal Welfare (IFAW), and World Wide Fund for Nature (WWF), address a wide range of environmental issues, while a few, such as the Whale and Dolphin Conservation Society (WDCS), are concerned only with the conservation and protection of marine mammals (Lavigne *et al.*, 1999).

The scale of any particular effort depends, first and foremost, on the geographical distribution of the organism(s) being conserved or the threat(s) being managed. There are relatively few international conservation instruments that focus solely on marine mammals. The best known of these is unquestionably the INTERNATIONAL WHALING COMMISSION (IWC), established under the International Convention for the Regulation of Whaling (ICRW) signed in Washington, DC, in 1946 (Gambell, 1999). A global conservation body was clearly necessary to manage the exploitation of the great whales, customarily defined as the baleen whales (Fig. 1) plus the sperm whale (*Physeter macrocephalus*). Most of these animals migrate over long distances and have been hunted on a truly worldwide scale.

Although the IWC's authority as the body responsible for managing whaling worldwide has been challenged in recent years, it is reconfirmed in Agenda 21, an agreement emanating from the United Nations Conference on Environment and Development in Rio de Janeiro in 1992. There is much controversy about the IWC's scope of responsibility. Some member states (e.g., Japan, Mexico, Denmark, and Russia) have traditionally taken the position that "small cetaceans," meaning all toothed species except the sperm whale and the "bottlenose" whales (defined in the IWC schedule as the northern and southern bottlenose whales *Hyperoodon ampullatus* and *H. planifrons*, respectively, Arnoux's beaked whale, *Berardius arnuxii*, and Baird's beaked whale, *B. bairdii*), are not covered by the ICRW and that their exploitation and conservation are national, or at most regional, concerns. This interpretation of the IWC's competence overlooks the fact that many populations of small cetaceans move seasonally across national borders or onto the high seas. It also ignores the close biological relationships among the cetaceans, which means that they face common threats (e.g., bycatch in fisheries, bioaccumulation of pollutants) and are similarly vulnerable to overexploitation (Fig. 2). In the absence of IWC oversight, various bilateral and multilateral instruments have been developed to manage takes of small cetaceans (see Section III) and national programs of full protection or managed exploitation are typical (see Section IV).

Any international agreement is effective only if the parties ensure compliance and enforcement. Typically, sovereign states are unwilling to accede to a convention without assurance of being able to opt out of provisions with which they disagree. Under the ICRW, for example, member countries have 90 days to consider their options before any amendment to the schedule of whaling regulations comes into effect. Once an objection has been lodged, the regulation is no longer binding on the objecting country. It is on this basis that Norway has continued commercial whaling for North Atlantic minke whales (*Balaenoptera acutorostrata*) in defiance of the IWC's global moratorium established in 1986. Japan used another "loophole" to continue whaling. The ICRW allows contracting governments to grant

TABLE I
Current International Conservation Conventions and Institutions

Name of entity	*Year of initiation*	*Location of secretariat or HQ*	*Primary mandate or responsibility in relation to marine mammals*	*Comments on effectiveness*
International Convention for the Regulation of Whaling (ICRW); International Whaling Commission (IWC)	Signed 1946, entered into force 1948: IWC established 1951	Cambridge, UK	Conservation of whale stocks (officially concerned only with baleen, sperm, and bottlenose whales)	Very strong scientific component; controversial but highly effective in 1970–1980; suffered loss of credibility and authority in 1990s
Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES)	Signed 1973, entered into force 1975	Geneva, Switzerland	Regulation and monitoring of international trade in products from species and populations classified as threatened	Highly politicized and rancorous, but continued through 1990s to be largely effective
World Conservation Union (IUCN)	Established 1948	Gland, Switzerland (with country offices)	Maintains red list of threatened species, sponsors specialist groups (e.g., cetacean, seal, sirenian, polar bear, otter), provides advice to CITES and IWC	Specialist groups provide scientific expertise, promote and coordinate conservation research
World Wide Fund for Nature (WWF)	Established as World Wildlife Fund in 1961	Gland, Switzerland (with many national affiliates)	Lobbies for conservation, supports conservation research, and participates in international conservation fora	Influences policies of IWC and CITES, many national affiliates conduct local or regional marine mammal research and conservation programs (e.g., Philippines, USA, Canada, Hong Kong, Malaysia)
TRAFFIC Network (trade monitoring program of IUCN and WWF)	1976	Cambridge, UK (with regional or national offices)	Monitoring international trade in wildlife, works in close cooperation with CITES Secretariat	Important role in documentation of trade, with emphasis on threatened species
Convention on the Conservation of Migratory Species of Wild Animals (CMS; or Bonn Convention)	Signed 1979, entered into force 1983	Bonn, Germany	Conservation of "entire populations or any geographically separate part of the population of any species or lower taxon . . . , a significant proportion of whose members cyclically and predictably cross one or more national boundaries"	Has recognized cetaceans, but not pinnipeds or sirenians, as highly migratory species; see Table II for relevant regional agreements
Convention for the Conservation of Antarctic Seals	1972, entered into force 1978	None, but scientific advice is provided by Scientific Committee on Antarctic Research's Group of Specialists on Seals, based in Cambridge, UK	Conservation of Antarctic seals, regulation of sealing, facilitation of scientific research on seals	First international conservation agreement to be established *prior to* the initiation of exploitation
Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR)	1980, entered into force 1982	Hobart, Tasmania, Australia	Facilitation of recovery of depleted whale stocks; prevention of further irreversible human-caused changes in Antarctic ecosystem	Krill monitoring program, ecosystem focus, strong scientific base
United Nations General Assembly Drift-net Resolution 46/215	1991, took effect end of 1992	None	Elimination of large-scale (longer than 2.5 km), high-seas driftnet fishing (and thus elimination of the large associated bycatch of marine mammals)	More than 1000 vessels were withdrawn from this type of fishing, but drift netting continues inside national 200-nautical-mile exclusive economic zones (and probably to some extent illegally in international waters)

Figure 1 *(Top) A fin whale* (Balaenoptera physalus) *is butchered at a whaling station in Iceland on July 11, 1988 and (Bottom) a young Icelander poses with baleen. Iceland used a scientific rationale to justify continued whaling operations for a few years after the International Whaling Commission's moratorium took effect in 1986. Later, in 1992, Iceland withdrew from the commission. Along with Norway and Japan, Iceland is a strong advocate of a resumption of whaling and the reopening of international trade in whale products. Photographs by Steve Leatherwood.*

Figure 2 *Sri Lankans begin the butchering of a Risso's dolphin* (Grampus griseus) *in August 1985. A diverse array of dolphins and whales are killed in Sri Lanka, partly as a bycatch of net fisheries and partly by direct harpooning. There is no information on stock identity or population abundance for any of the species taken along the coasts of Sri Lanka, but estimates of the total annual kill during the 1980s were in the tens of thousands. Photograph by Steve Leatherwood.*

special permits to take whales for scientific research. Although the IWC's scientific committee reviews and comments on permit proposals, its advice is nonbinding. Thus, Japan has continued to kill 300–400 Antarctic minke whales (*B. bonaerensis*) each year and, since 1994, an additional 100 North Pacific minke whales (*B. acutorostrata*), under research permits issued unilaterally by the national government.

The United Nations Convention on the Law of the Sea (UNCLOS) was ratified in 1982. Rather than strengthening efforts to conserve marine mammals, however, this framework convention has tended to provide states with a rationale for opting out of agreements such as the ICRW. Under the convention, the idea of countries having exclusive sovereign rights to manage resources within 200 nautical miles of their coastlines became firmly entrenched. This has been interpreted to mean that the hunting of coastal stocks of marine mammals should not be subject to international oversight. Also, although Article 65 of the convention calls explicitly for member states to "work

through the appropriate international organizations" for the conservation, management, and study of cetaceans, it leaves considerable latitude to governments in deciding what this means. Canada, for example, withdrew from the IWC in 1982, arguing that a bilateral commission with Greenland suffices as an "appropriate international organization" for the management of beluga (*Delphinapterus leucas*) and narwhal (*Monodon monoceros*) hunting (see Section III) and that the obligation of "working through" an appropriate international body for managing bowhead whale (*Balaena mysticetus*) hunting could be discharged simply by sending an occasional representative to meetings of the IWC Scientific Committee as well as an "observer" delegation to meetings of the commission.

The Antarctic, an area that hosts several endemic seal species and provides seasonal feeding grounds for numerous migratory whale populations, is a global commons. As such, it requires its own international regime of protection and conservation (Kimball, 1999). The Antarctic Treaty system consists of four separate instruments: the initial framework treaty signed in 1959 (entered into force in 1961), the seals convention of 1972, the marine ecosystem-oriented Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) of 1980, and a 1988 convention on mineral resources. As a whole, this system is nearly comprehensive, particularly taking into account the overlapping responsibilities of the IWC and other instruments such as the 1972 Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter (the London Dumping Convention) and the 1973–1978 Convention for the Prevention of Pollution from Ships (the MARPOL Convention). It should provide an adequate legal basis for protecting ANTARCTIC MARINE MAMMAL populations. What it cannot do, of course, is reverse the devastation of the southern stocks of baleen whales caused by the whaling industry. Nor can it protect the seal and whale populations from the ongoing (and possibly worsening) effects of climate change and ozone depletion (see Section VIII).

Another treaty that is relevant to marine mammal conservation is the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). This convention has been in force since 1975 and has provided a high-profile, controversial forum in which many of the most searing conservation issues of the day have been addressed. The economic stakes are often high, and this is certainly the case with trade in whale meat and blubber, which are in great demand in Japan. CITES has essentially no relevance for exploitative regimes in which the products are for domestic consumption only or for those instances in which animals are captured alive and placed in institutions within the country of origin. It becomes relevant only when the animals or their products or derivatives cross international borders. Under CITES, species and geographical populations are subject to listing in one of three appendices. Appendix I species or populations are threatened with extinction, and trade in products from them needs to be strictly regulated. Those in Appendix II are not considered to be in immediate danger of extinction but may become so unless trade is strictly monitored. The third appendix includes species or populations that are subject to national regulation and for which multilateral cooperation is necessary to avoid overexploitation. The goals of monitoring and regulation are achieved through a system of permits and certificates for export or import, issued by national governmental authorities. As of 2000, when the 11th meeting of the conference of the parties took place in Nairobi, Kenya, all of the commercially valuable baleen whales were listed in CITES Appendix I, as were some of the odontocetes, including the sperm whale. Also, a resolution adopted in 1979, calling for CITES member states to honor IWC restrictions on whaling and the trade of whale products, remained in force.

The combined restrictions on trade under CITES and the IWC have not eliminated concern about the role of international commerce in undermining conservation efforts. The meat and blubber from Japanese "scientific whaling" are legally sold in Japan's large domestic market. Also, the blubber from minke whales killed off Norway is not all consumed domestically, and there is strong interest in exporting the surplus to Japan. Forensic techniques developed by geneticists have been used to monitor the species and populations represented in stores and restaurants in Japan, Hong Kong, and the Republic of Korea. A sliver of meat or blubber is sufficient to identify the source to species and in some cases to ocean basin or stock (Dizon *et al.*, 2000). Forensic analyses have revealed that products from "protected" species or populations are sometimes sold. However, it has usually been impossible to prove that these came from animals that were killed illegaly rather than from strandings, bycatch, or stockpiles acquired prior to the IWC moratorium. In a few instances, illegal shipments of whale meat have been intercepted by authorities in Norway, Japan, and Russia before reaching their destination.

An agreement by the U.S. and Japan governments in November 1991 included the following statement: "Data collected in 1990 indicated that over 41 million non-target fish, sharks, sea birds, marine mammals and sea turtles were killed in the Japanese squid driftnet fishery alone." The high-seas squid drift net fisheries in the North Pacific were killing approximately 15,000–30,000 northern right whale dolphins (*Lissodelphis borealis*), 11,000 Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), and 6000 Dall's porpoises (*Phocoenoides dalli*) annually in the late 1980s. Drift nets set for salmon, tuna, and billfish were taking thousands more dolphins, porpoises, whales, and pinnipeds each year. The threats to populations of pelagic cetaceans, pinnipeds, seabirds, and many other organisms posed by large-scale, high-seas drift gill nets were judged to be sufficiently severe and global in scope to necessitate action by the United Nations. This took the form of a resolution, passed by the UN General Assembly in 1991, calling on all member nations to enact a moratorium on such drift netting by the end of 1992 (Northridge and Hofman, 1999). The global ban was a valuable step and undoubtedly helped to avert catastrophic declines in some marine animal populations. What the UN decree could not affect, however, was the use of these nets inside the 200 nautical mile limit of coastal states. Consequently, pinnipeds and cetaceans continue to be killed in large numbers by drift gill nets deployed in coastal waters.

III. Regional and Bilateral Conservation Efforts

In cases involving species or populations with well-defined distributions that cross several national boundaries, multilateral regional bodies have sometimes been established to monitor and manage exploitation (Table II). Included among these are some "international" instruments that are in fact regional because their scope is defined by the limited geographical ranges of the animals involved. For example, membership in the Inter-American Tropical Tuna Commission (IATTC) has been geographically diverse since its founding in 1949 under a treaty between the United States and Costa Rica. Only states with an interest in fishing for tuna in the eastern tropical Pacific Ocean have joined the commission, and over the years this has included France, Japan, Vanuatu, the United States, and Mexico in addition to a number of Central and South American countries. Thus, while the commission is international in the sense of having a geographically diverse membership, its purview is distinctly regional. Similarly, the International Agreement on the Conservation of Polar Bears and their Habitat involves only the northern circumpolar countries where polar bears regularly occur, and it is therefore treated here as a regional agreement.

The 1911 Treaty for the Preservation and Protection of Fur Seals (often referred to as the North Pacific Fur Seal Convention) involved four countries: Great Britain (signing on behalf of Canada), the United States, Russia, and Japan. This was essentially an agreement among the states involved in the exploitation of northern fur seals (*Callorhinus ursinus*), which are endemic to the North Pacific Ocean. Pelagic sealing was banned, and as part of the agreement, Japan and Canada were allocated a portion of the profits from the controlled killing (mainly of "surplus" male seals) on the Pribilof (USA) and Commander (Russia) islands. This treaty lapsed in 1941, when Japan withdrew, and was replaced in 1957 by the Interim Convention on the Conservation of North Pacific Fur Seals. The North Pacific fur seal is frequently cited as a conservation success story. Elimination of pelagic sealing, in combination with regulations limiting the kill at the breeding rookeries, allowed the seal population to make a strong recovery from its depleted state in 1910. The population reached about 2 million in the 1950s but dipped below a million by the early 1980s. Unfortunately, the 1957 convention lapsed in 1984 and has not been replaced. The fur seal population in U.S. waters stood at about a million in the late 1990s, and since 1988 it has been designated as "depleted" under the Marine Mammal Protection Act.

The polar bear (*Ursus maritimus*) treaty mentioned earlier is often cited as an example of an effective international agreement. Discussions among the range states—Canada, the United States, Denmark (on behalf of Greenland), Norway, and the Soviet Union (now Russia)—began in the mid-1960s, when the future of the polar bear was of great concern because of overhunting and habitat deterioration (Lyster, 1985). The three main objectives of the agreement, which was signed in 1973 and took effect in 1976, were to ensure that appropriate restrictions were placed on HUNTING, that polar bear habitat was preserved, and that needed research was conducted in a coordinated fashion. The Polar Bear Specialist Group of the IUCN's Species Survival Commission has served as a *de facto* scientific committee, meeting every few years to share information, discuss research needs, and assess the state of polar bear conservation. At its 12th working meeting in 1997, the group concluded that the total population of wild polar bears was between about 22,000 and 27,000, more than half of them in Canada. It also stressed the need for better protection of female bears and their denning habitat and expressed concern about the high levels of PCBs found in Svalbard's bears.

The multinational hunt for harp and hooded seals (*Pagophilus groenlandicus* and *Cystophora cristata*, respectively) in the northern North Atlantic proceeded without meaningful regulation until the late 1950s, when Norway and the Soviet Union established a bilateral commission to set quotas for commercial takes of harp and hooded seals as well as walruses (*Odobenus rosmarus*) in the northeastern Atlantic. The reach of this agreement has been interpreted as including large areas of the Greenland and Barents seas, Denmark Strait, and waters near the island of Jan Mayen. A similar bilateral agreement pertaining to the northwestern Atlantic was signed by Canada and Norway in 1971.

A succession of regional bodies have become involved in monitoring the North Atlantic seal hunt and assessing the harp and hooded seal populations in order to provide management advice. Starting in the 1960s, a Sealing Panel of the International Commission for Northwest Atlantic Fisheries (later the Northwest Atlantic Fisheries Organization, or NAFO) recommended overall quotas and other conservation measures (e.g., opening and closing dates for sealing from ships) related to the hunting of the western populations. In recent years, scientific advice on harp and hooded seal stocks has been developed by a working group convened jointly by the International Council for the Exploration of the Sea (ICES) and NAFO. This group's advice is presented to the North Atlantic Marine Mammal Commission (NAMMCO), which in turn offers management advice to its members. Canada decides unilaterally on sealing quotas in the western North Atlantic, whereas Norway and Russia continue to allocate quotas in the West Ice (Jan Mayen) and East Ice (White Sea) on a bilateral basis.

NAMMCO is a regional body established in 1992 by several countries who had become frustrated by the IWC's unwillingness to allow the resumption of commercial whaling. Its membership presently consists only of Iceland, Norway, Greenland, and the Faroe Islands, the latter two belonging to the Kingdom of Denmark but with "home rule" governments. Considerable effort has been made to entice Canada and Russia to join, and Japan regularly sends an official observer to meetings of the NAMMCO Council. Although Iceland withdrew from the IWC in 1992, Norway and Denmark have maintained their IWC membership, thus trying to balance their involvement in both the IWC and NAMMCO. In its early years, NAMMCO focused much of its attention on species for which there was little or no direct conflict with the IWC, notably harp and hooded seals, ringed seals (*Pusa hispida*; Fig. 3), gray seals (*Halichoerus grypus*), walruses, long-finned pilot whales (*Globicephala melas*), and northern bottlenose whales (*Hyperoodon ampullatus*).

TABLE II
Regional or Bilateral Conservation Agreements Currently in Effect

Name of entity	*Year of initiation*	*Location of secretariat or HQ*	*Mandate or objectives*	*Comments on effectiveness*
Inter-American Tropical Tuna Commission (IATTC)	1949	La Jolla, California	Initially to document and manage tropical tuna fisheries; since then, expanded to include documentation, mitigation, and regulation of dolphin mortality incidental to fishing operations in eastern tropical Pacific	Operates programs to place observers aboard tuna vessels, reduce dolphin mortality through diagnosis and solution of gear problems, and training for captains and crews; provides mechanism for linking tuna industry with government agencies and environmental NGOs
North Atlantic Marine Mammal Commission (NAMMCO)	1992	Tromsø, Norway	Sustainable use and management of marine mammals in the North Atlantic Ocean	Emphasis on ecological interactions (e.g., rationales for culling marine mammals to protect fish stocks), hunting rights of coastal communities, forum for scientific information exchange
Canada/Greenland Joint Commission on Narwhal and Beluga	1989	None (Ottawa, Canada; Nuuk, Greenland)	Cooperative research and management related to "shared" stocks of narwhals and white whales	Forum for bilateral studies and sharing of information, with management measures left to national authorities and local "comanagement" bodies
Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas (ASCOBANS)	Signed 1991 (concluded under CMS, the Bonn Convention; see Table I), entered into force 1994	Bonn, Germany	Cooperation to achieve and maintain a "favourable conservation status" for small cetaceans in the region	Most effort in the 1990s was directed at estimating abundance and incidental takes of harbor porpoises (and white-beaked dolphins) and seeking ways to reduce bycatch
Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and Contiguous Atlantic Area (ACCOBAMS)	1996 (concluded under CMS, the Bonn Convention; see Table I), not yet in force	Monaco	Cooperation to achieve and maintain a "favourable conservation status" for cetaceans in the region, including the complete prohibition of deliberate taking and establishment of a network of "specially protected areas to conserve cetaceans"	In its early days at the time of this writing
International Agreement on the Conservation of Polar Bears and their Habitat	Signed 1973, entered into force 1976	None; follows rotating chairmanship of IUCN Polar Bear Specialist Group	To prevent polar bear populations from becoming endangered because of hunting or other human activities	Provides a framework for communication and cooperation among circumpolar countries, emphasis on research and monitoring; signatory states are supposed to "enact and enforce such legislation and other measures as may be necessary to give effect to the Agreement"
U.S.–Russia Agreement on Cooperation in the Field of Environmental Protection	1972	None (Washington and Moscow)	Marine Mammal Project, under Area V of the agreement, provides for information exchange, coordination of research activities, and joint or cooperative research	Annual scientific meetings, with focus formerly on Bering and Chukchi sea regions, recently broadened to consider, e.g., Caspian seals, bycatch in Japanese salmon drift nets operating within Russian EEZ

Figure 3 *A Greenlandic hunter with a dead ringed seal tied onto his sled on May 31, 1988. Ringed seals are a staple of many maritime communities in the Arctic. They provide food for people and dogs, and their skins are either used to make clothing or sold for cash. Photograph by Steve Leatherwood.*

However, it remains uncertain whether, and to what extent, NAMMCO will eventually infringe upon the IWC's authority to manage commercial whaling.

An international treaty, the Convention on the Conservation of Migratory Species of Wild Animals (or Bonn Convention), provides a mechanism for regional conservation agreements. Two dealing explicitly with cetaceans have been negotiated thus far. The Agreement on the Conservation of Small Cetaceans in the Baltic and North Seas (ASCOBANS) entered into force in 1994, with a membership that included Belgium, Denmark, Germany, the Netherlands, Poland, Sweden, and the United Kingdom. In its early years, ASCOBANS addressed a wide range of issues related to harbor porpoises (*Phocoena phocoena*), including assessments of abundance and bycatch, pollution, and effects of noise disturbance. A major achievement was the instigation, planning, and completion of a multinational abundance survey of cetaceans throughout the Baltic and North Seas. ASCOBANS has a close working relationship with the IWC and provides the kind of international oversight for small cetaceans, at least in this one region, that the IWC is prevented from offering (see Section II). The other instrument, the Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and Contiguous Atlantic Area (ACCOBAMS), was concluded in 1996 and entered into force in 2001. One provision of this agreement is that parties must prohibit the deliberate killing of cetaceans in their national waters.

Canada and Greenland have adopted bilateralism as a preferred approach to manage the hunting of "transboundary stocks" of white whales and narwhals. In 1989, the two governments signed a memorandum of understanding that recognized the importance of hunting to the Inuit and called for "the rational management, conservation and optimum utilization of living resources of the sea" as reflected in the UN Convention on the Law of the Sea (see Section II). The Joint Commission on Conservation and Management of Narwhal and Beluga meets annually, as does its Scientific Working Group. In addition to management advice directed at government agencies and, in Canada, the Nunavut Wildlife Management Board (a comanagement body established under an aboriginal land-claim agreement), the commission's Scientific Working Group plans and undertakes collaborative research on "shared" stocks of narwhals and belugas.

IV. National Conservation Efforts

In the United States, the Marine Mammal Protection Act was passed by Congress in 1972, and this act has been the cornerstone of a massive domestic commitment to conservation (Baur *et al.*, 1999). Although the MMPA is not the only such law in the world (many countries confer full legal protection to marine mammals), it is undoubtedly the most sweeping of its kind. At the time of the act's passage, a preeminent concern was the annual slaughter of more than 100,000 young harp and hooded seals on the spring pack ice off Newfoundland and in the Gulf of St. Lawrence. Public outrage at film footage of helpless, unweaned seal pups being clubbed to death was probably the most influential single factor in forcing Congress to act. In addition, however, there was growing concern about the deplorable condition of the world's stocks of large whales, especially the blue whale (McVay, 1966). Moreover, controversy swirled around the killing of pelagic dolphins by the American tuna fleet in the eastern tropical Pacific (Gosliner, 1999). The estimated annual kill from 1960 through 1971 had been more than 370,000 dolphins (nearly 4.5 million total during that period), and environmentalists were understandably outraged.

The resulting legislation was both comprehensive and innovative. An immediate embargo was placed on the importation of marine mammal products, with only a few specified exceptions. Deliberate taking was banned, although Alaskan Eskimos and other aboriginal people were allowed to continue hunting marine mammals for food, skins, and other products as long as the main purpose was to meet basic community needs. A strong emphasis in the act was placed on research, and science was accorded a prominent role in influencing how decisions were to be made. Existing federal departments were given the responsibility of implementing the new law, with the Department of Commerce to manage cetaceans and most pinnipeds and the Department of the Interior to manage polar bears, sea otters, sirenians, and walruses. In addition, however, an entirely new and independent federal agency, the Marine Mammal Commission, was established to oversee the process of implementation.

The goals of management, as set forth in the Marine Mammal Protection Act, were to achieve and maintain "optimum sustainable populations" of marine mammals and to reduce incidental mortality from fishing operations (including tuna seining) to "insignificant levels approaching zero." An optimum sustainable population has been defined operationally as having a lower bound at the maximum net productivity level and an upper bound at the unexploited population (carrying capacity)

level. By defining population status in terms of productivity, the act placed the emphasis on the health and stability of ecosystems rather than on economic yield, as had traditionally been the case. The ambitious and lofty goals of the Marine Mammal Protection Act have been pursued over the past quarter century with what appears to be an undiminished national commitment to conservation.

The European Union, functioning as though a single state, has used a more selective approach to achieve certain objectives related to marine mammal conservation. In 1983, the European Community (as it was then called) established a controversial ban on the importation of products from seal pups. The explicit goal was to stop the clubbing of young white-coated harp seals and blue-backed hooded seals, a concern more directly related to animal welfare than to conservation. In combination with closure of the U.S. import market from 1972, the European ban effectively destroyed the profitability of sealskin production in North America and Greenland, with serious unintended economic and social consequences in Eskimo communities where the hunting of ringed seals was a major source of cash income. Canada was forced to stop the commercial hunt for unweaned harp and hooded seal pups, essentially bringing the large-scale, ship-based sealing industry to a halt. For more than a decade, the populations of harp and hooded seals were allowed to recover. Since the mid-1990s, however, Canada's commercial sealing industry has been reinvigorated with government subsidies and aggressive product marketing, particularly focused on the export of seal penises to China and other Asian countries, so the kill of harp and hooded seals has returned to levels not seen since the early 1970s (Lavigne *et al.*, 1999).

The European Community also effectively banned the importation of whale products in 1982–1983 by declaring that all cetaceans would be treated as though they were in Appendix I of CITES (no commercial trade allowed). Greenland, with its special relationship to Denmark, was exempted from the ban, meaning that narwhal tusks could be imported to EU countries under the normal provisions of CITES Appendix II. Thus, although the EU measure caused a steep decline in the value of narwhal ivory from Canada (Fig. 4), it had comparatively little effect on the market for tusks from Greenland, which was traditionally centered in Europe. Having lost access to the American market and much of the European market for narwhal ivory, entrepreneurs in Canada found new buyers in Asia, a pattern similar to that seen with seal products.

National conservation efforts are often influenced by international legal instruments, and such influence can be for either good or ill. The U.S. government, in implementing the Marine Mammal Protection Act, has had to take account of what are sometimes conflicting commitments under international agreements. For example, the United States has always belonged to the Inter-American Tropical Tuna Commission (IATTC), whose primary goal is to maximize tuna catches. A sometimes uneasy alliance has been forged over the years between the IATTC and the U.S. National Marine Fisheries Service, the agency responsible for pursuing the "zero mortality rate" goal for dolphins mandated by the Marine Mammal Protection Act. Although substantial progress had been made toward that goal by the late 1980s, animal protection groups continued to mount

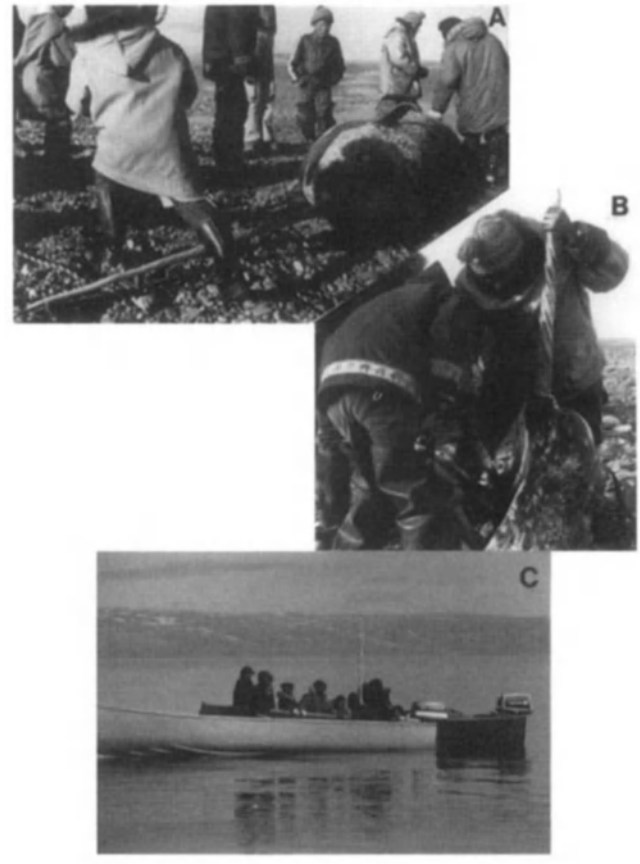

Figure 4 *The long, spiraled tusk of the male narwhal has commercial value and is traded in the global marketplace. Here, Inuk hunters on northern Baffin Island, Canada, have dragged a carcass onto a gravel beach (A) and are proceeding to remove the tusk from the animal's upper jaw (B). In the 1970s, many tusks, like the one shown (C), were sold to a non-Inuk who exported them to Europe (mainly the United Kingdom). August 1975. Photographs by Randall Reeves.*

legal challenges, insisting that the procedure of setting purse seines around dolphins in order to catch tuna should cease altogether. Their efforts led to the "dolphin-safe" labeling of canned tuna and to embargoes on U.S. imports of tuna from countries continuing to "fish on dolphins." The IATTC took the position that by redirecting all fishing effort away from "dolphin sets" and toward "school sets" and "log sets" (neither of which involve dolphin encirclement), the bycatch of other species (e.g., billfish and turtles) and the proportion of undersized tuna in the catch would both increase. In general, the Fisheries Service has tended to assign a higher priority to dolphin protection than has the IATTC, and the working relationship has been strained in recent years because of this and other differences. To make matters worse, Mexico mounted a challenge to the tuna embargoes under the General Agreements on Tariffs and Trade (GATT), insisting that they were unwarranted and unacceptable impediments to free trade. The dispute-resolution panel ruled that the embargoes were indeed incon-

sistent with GATT provisions, and the United States consequently has had to seek a delicate balance between its commitment to marine mammal protection and its support for the principle of free trade (Gosliner, 1999).

In a more positive vein, the IWC has managed to influence the conservation of small cetaceans in Japan, despite Japan's refusal to recognize the commission's authority to impose measures related to the conservation of dolphins, porpoises, and smaller species of toothed whales (Perrin, 1999). A variety of small cetaceans have been hunted in Japanese coastal waters for many decades (Fig. 5). The Subcommittee on Small Cetaceans, a standing subcommittee of the IWC's Scientific Committee, meets annually to review the status of species, particular threats, and technical approaches to eliminating or managing the threats. In their reviews of stocks, the subcommittee has repeatedly found evidence of overexploitation by the Japanese coastal cetacean fisheries. As a result, the government of Japan has been forced, through international pressure from governments and nongovernmental organizations, to implement research programs and management measures that almost certainly would not have been contemplated in the absence of this outside scrutiny.

The most glaring example is the striped dolphin (*Stenella coeruleoalba*). A drive hunt for striped dolphins, in which entire schools are herded toward shore and killed *en masse,* has taken place annually on Japan's Izu Peninsula for more than a century. Catches of as many as 22,000 animals occurred in some years during the 1940s and 1950s. By the 1980s, when the hunters introduced a voluntary catch limit of 5000 dolphins, the annual average catch had declined to less than 3000 per year, presumably because the population was seriously depleted. Finally, in 1989, government quotas were imposed. Although ideally the hunt should have stopped entirely to allow the dolphin population to recover, the issue of overexploitation of striped dolphins has at least helped demonstrate the need for stronger measures by the national government in Japan to prevent other similar disasters.

Figure 5 *Japanese fishermen have hunted small cetaceans for many decades, often driving hundreds of animals toward shore where they are killed en masse. Rough-toothed dolphins* (Steno bredanensis), *shown here, are rarely taken in drive hunts, and even more rarely is a photographer on hand to record the carnage. Photograph by Rusty White, courtesy of Hubbs Marine Research Institute.*

V. Local and Individual Conservation Efforts

Top-down approaches to managing resource use have often failed. The cost of policing human actions is likely to be unacceptably burdensome when local people attribute no legitimacy to the management regime. It is generally agreed that the greater the local or community involvement, the more likely it is that conservation efforts will succeed in the long run (Mangel *et al.*, 1996). Marine mammal hunting communities in the Arctic and in Australia [where dugongs (*Dugong dugon*) are the principal prey species] have been at the forefront of developing cooperative management ("comanagement") agreements. Ideally, such agreements recognize the interests and rights of local people while the broader concerns for conservation from a national or international perspective are represented by central governmental authorities.

The most prominent example is the Alaska Eskimo Whaling Commission (AEWC), which was established in 1977 by whalers in northern Alaska in reaction to the IWC's controversial decision to ban bowhead whaling. After several years of difficult negotiations, marked by threats, lawsuits, and even a grand jury investigation into violations of the agreed bowhead quota in 1980, a cooperative agreement was reached between the AEWC and the National Oceanic and Atmospheric Administration (NOAA), the federal body directly responsible by law for implementing IWC decisions within the United States. Under this agreement, the AEWC has assumed responsibility for managing the hunt, monitoring compliance with the quota and other regulations, and reporting each year's results. Quotas on the allowed number of strikes and landings of bowheads are still negotiated through the IWC.

Singling out the contributions of individuals to the cause of conservation is a questionable proposition. How does one recognize, measure, or compare the value of the conscientious daily efforts of bureaucrats, scientists, writers, educators, fishermen, engineers, veterinarians, lobbyists, lawyers, political activists, and others? Several individuals are mentioned here, but only with the caution that their work, while exemplary, is not necessarily exceptional.

As discussed further later (under Section VII), the rescue and rehabilitation of injured or otherwise incapacitated individual marine mammals can be of questionable conservation value. Nevertheless, in some circumstances, especially when an endangered species is involved, intervention is certainly appropriate. Jon Lien, a professor and researcher at Memorial University in Newfoundland, began working with fishermen in the late 1970s to devise ways of extricating whales, especially humpback whales, from fishing gear. The problem of entanglement was a concern of conservationists because, at the time, humpbacks in the North Atlantic were considered to be endangered (their status has improved since then). It was of concern to fishermen because of the economic losses associated with damaged gear and lost fishing time, as well as the personal danger

involved when dealing with these large animals at sea. Lien gained the confidence of the Newfoundland fishermen and developed a highly successful program for assisting in the safe release of entangled or ENTRAPPED whales. Subsequently, Charles Mayo, David Mattila, and their associates at the Center for Coastal Studies on Cape Cod began rescuing whales from fishing gear on the U.S. coast, with an emphasis on critically endangered right whales (Fig. 6). Disentanglement teams are now integral to right whale (*Eubalaena glacialis*) recovery efforts in the eastern United States and southeastern Canada, thanks to the pioneering efforts of these three scientists. A similar, highly successful program centered on rescuing harbor porpoises, minke whales, and occasionally right whales trapped in herring weirs has been in operation in Canada's Bay of Fundy for more than a decade.

One of the greatest obstacles to conservation can be the difficulty of defining a threat and providing incontrovertible evidence of its effects. Marine debris pollution provides a clear example (Laist *et al.*, 1999). Although it is widely accepted today that marine debris, such as derelict fishing gear and plastic packaging material, is a menace to wildlife, the problem's seriousness was not recognized until the early 1980s. Charles Fowler, a scientist with the National Marine Fisheries Service in Seattle, was engaged in research to determine the cause of the North Pacific fur seal population's continuing decline (see Section III). Despite bureaucratic resistance and the skepticism of scientific colleagues, Fowler pressed ahead with the task of marshaling data to test the hypothesis that entanglement in debris was a major cause of juvenile mortality in fur seals. His painstaking compilation of evidence, together with mathematical models, finally convinced others that at least this one marine mammal species was being affected by debris pollution at the population level. Fowler's work provided the impetus for a chain of events, from beach clean-up campaigns to the signing of international treaties, intended to reduce the ocean's burden of debris and therefore lessen the risks to seals and cetaceans, to say nothing of seabirds, turtles, and other marine wildlife.

Figure 6 *A team from the Center for Coastal Studies in Provincetown, Massachusetts, attempts to cut away fishing line wrapped round the tail of a right whale in Cape Cod Bay on July 24, 1998. Specially designed knives are deployed at the ends of long poles. Note that the men are wearing helmets as a precaution while undertaking this extremely dangerous work. Photograph courtesy of Center for Coastal Studies, Provincetown, Massachusetts.*

One final example of an individual's ability to change the course of conservation policy again relates to dolphin mortality in the eastern tropical Pacific tuna fishery. By the late 1980s, many conservationists had forgotten about this issue, assured that dolphin mortality had been reduced substantially as a result of changes in fishing techniques and the imposition of annual quotas on the number of dolphins from each species that could be killed before fishing would have to cease. In 1987–1988, however, Sam LaBudde, who described himself as an "itinerant biologist," spent 5 months aboard a Panama-registered tuna boat. Although he had signed on as an ordinary seaman and cook, he carried a video camera and clandestinely recorded grisly footage of dolphins being killed. When the scenes were aired on national television, it galvanized public support within the United States for strong measures to be taken against the non-American tuna fleet. While LaBudde's actions can be viewed as either heroic or deceitful, depending on one's point of view, there is no doubting his courage or his influence on the course of conservation.

VI. Protected Areas

The designation of specially protected areas (e.g., reserves, sanctuaries, parks) is a tool increasingly used to achieve conservation goals. Of the many such areas around the world (Table III), relatively few exist for the explicit purpose of benefitting marine mammals. Mexico declared Scammon's Lagoon (Laguna Ojo de Liebre) a refuge for gray whales in 1971, and San Ignacio Lagoon was given similar status in 1979. Also, Mexico established a Biosphere Reserve in the upper Gulf of California in 1993 mainly to protect the highly endangered vaquita (*Phocoena sinus*) and the totoaba, an endangered sea bass (*Totoaba macdonaldi*). New Zealand created the Banks Peninsula Marine Mammal Sanctuary in 1988 to protect Hector's dolphins (*Cephalorhynchus hectori*), like the vaquita an endemic coastal species, from entanglement in gill nets. In 1999, the parliament of the North German state of Schleswig-Holstein established a sanctuary for small cetaceans off the islands of Sylt and Amrum in the North Sea, intended to protect harbor porpoises from the dangers associated with gillnet fishing, jet skiing, and high-speed motor boating. In the United States, the Hawaiian Islands Humpback Whale Sanctuary was declared in 1993, and several other marine sanctuaries were established in large part because of public interest in the marine mammals that use them for feeding, breeding, or both (e.g., the California Channel Islands, Gulf of the Farallones, Monterey Bay, and Stellwagen Bank sanctuaries).

All too often, protected areas are created in response to a public outcry, but without an accompanying ongoing commitment to establish and enforce meaningful restrictions on human activities within them. The marine sanctuary program in the United States, for example, has failed to meet the public's

TABLE III
Protected or Managed Areas Intended, at Least in Part, to Benefit Marine Mammals

Name of area	*Location or country*	*Marine mammals affected*	*Year established*	*Comments*
International				
IWC Indian Ocean Sanctuary	Indian Ocean, 20–130°E and north from 55°S	Mainly baleen whales and sperm whale	1979	Commercial whaling banned
IWC Southern Ocean Sanctuary	Circumpolar south of Antarctic Convergence	Mainly baleen whales and sperm whale	1994	Commercial whaling banned
Oceania				
Point Labatt Conservation Park	South Australia mainland	Australian sea lion	1973	Protects haul-out beach as well as waters to 1 nautical mile offshore
Seal Bay Conservation Park	Kangaroo Island, South Australia	Australian sea lion (New Zealand fur seal also present)	1971 (having existed in other forms since 1954), expanded 1974	Intensively managed to promote tourism and maintain the sea lion population
Banks Peninsula Marine Mammal Sanctuary	East coast of South Island, New Zealand	Hector's dolphin	1988	Prohibits commercial gill netting, limits amateur gill netting
Great Barrier Reef Marine Park	Off Cape York, Queensland, Australia	Dugong, humpback whale, Indo-Pacific hump-backed dolphin, dwarf minke whale	1975	Intensively and complexly managed, with dugong as a major focus of conservation efforts
Great Australian Bight Marine National Park	Approximately 300 km of coastline in South Australia, including waters to three nautical miles offshore	Southern right whale, Australian sea lion	1996	Includes exclusion zone in Head of the Bight where right whales congregate in winter (with their calves), and prohibited areas, each 1 nautical mile radius, around sea lion breeding colonies
Maza Wildlife Management Area	Western Province, Papua New Guinea	Dugong	1978	Intended to protect dugong habitat and manage continued hunting; effectiveness uncertain
Europe				
Northeast Greenland National Park	972,000 sq. km of land in NE Greenland	Walrus, polar bear	1974, expanded 1988	Prevents commercial hunting; restricts mineral development
Wadden Sea National Park of Schleswig-Holstein	German Wadden Sea, east side of North Sea	Harbor porpoise	1999, expanded to include coastal waters of isles of Sylt and Amrum	Bans high-speed water craft and industrial fishing in porpoise "nursery" area
International Sanctuary for Mediterranean Cetaceans	Ligurian Sea, Northwestern Mediterranean Basin	Fin and sperm whales, various smaller odontocetes	1999, by agreement of Italy, France, and Monaco	In initial stages; whale watching regulated, high-speed offshore competitions to be regulated or prohibited, monitoring of cetacean populations
National Marine Park of Alonnissos Northern Sporades	Greece	Mediterranean monk seal	1986	Awareness and enforcement have been effective in reducing monk seal mortality
Nature Reserve of Las Desertas Islands	Madeira Natural Park, Madeira	Mediterranean monk seal	1990	Protection has been effective, and the very small seal population has increased
Valaam Archipelago Nature Reserve	Lake Ladoga, Karelian Republic of Russia	Ladoga ringed seal	1992	Further restrictions needed to reduce disturbance of hauled-out seals by campers
Franz Josef Land State Nature Reserve	NE Russia	Arctic seals and whales, polar bear	1994	Nominal protection from disturbance

(continues)

TABLE III *(Continued)*

Name of area	*Location or country*	*Marine mammals affected*	*Year established*	*Comments*
Asia				
Sha Chau and Lung Kwu Chau Marine Park	Hong Kong	Indo-Pacific hump-backed dolphin (locally called Chinese white dolphin)	1996	Prohibits high-speed watercraft and some kinds of fishing
National Chambal Sanctuary	Chambal River, India	Ganges river dolphin	1978	Primary purpose: protection of gharial (*Gavialus gangeticus*); effectively protects small dolphin population (tens of animals)
Vikramshila Gangetic Dolphin Sanctuary	50-km segment of Ganges River, Bihar, India	Ganges river dolphin	1991	Nominal protection to dolphins, regular surveys
Sind Dolphin Reserve	Indus River between Sukkur and Guddu barrages, Pakistan	Indus river dolphin	1974	Nominal protection to dolphins, regular surveys
Africa				
Saloum Delta National Park and Biosphere Reserve	Central Senegal	West African manatee, Atlantic hump-backed dolphin, bottlenose dolphin	1976?; Biosphere Reserve 1980	Poaching of manatees and bycatch of dolphins and manatees in fisheries occurs, but these and other harmful activities would be worse without the protection provided by park staff
Niumi National Park	Gambia	Atlantic hump-backed dolphin, probably West African manatee	1986	Same as for Saloum
Kiang West National Park	Gambia	Bottlenose dolphin, probably West African manatee	1987	Same as for Saloum; some commercial dolphin watching is facilitated
National Park of Banc d'Arguin	Mauritania; ca. 12,000 km^2, including coastal waters mainly <5 m deep	Mediterranean monk seal, Atlantic hump-backed dolphin, bottlenose dolphin	1976	Artisanal fishing is allowed within the park and probably involves substantial bycatch of marine mammals, but exclusion of industrial fishing and other general protection given to wildlife and fish probably benefits marine mammals to some extent
More than 20 designated protected areas	South Africa coast and nearshore waters	Right whale, various small odontocetes, Cape fur seal	1970s to present	Some explicit protection from disturbance by whale watching and research vessels
North America				
21 manatee sanctuaries	Throughout Florida	West Indian manatee	Florida Manatee Sanctuary Act (1978)	Restrictions on boat speed primarily
Blue Spring State Park	Upper St. Johns River, NE Florida	West Indian manatee		Very effective protection and public education program
Bahía de Chetumal manatee refuge	Mexico	West Indian manatee		
Stellwagen Bank National Marine Sanctuary	Off Cape Cod, MA	Humpback whale and other cetaceans	1993	Fishing activity unrestricted; prohibits sand and gravel mining, dumping or discharging of harmful substances
Saguenay-St. Lawrence Marine Park	Lower St. Lawrence River, Quebec, Canada	White whale (beluga), baleen whales	1998	Zoning for multiple use, provides protection from "harassment" by tourist vessels
Wapusk National Park	West coast of Hudson Bay, south and east of Churchill, Manitoba, Canada	Polar bear	1996	Protects maternity dens and resting areas, facilitates management of bear-watching tourism and of human–bear conflicts

TABLE III *(Continued)*

Name of area	*Location or country*	*Marine mammals affected*	*Year established*	*Comments*
Gulf of the Farallones National Marine Sanctuary	Off San Francisco, CA	Various baleen and toothed cetaceans, otariids, and phocids	1981	Prohibits exploration for oil and gas, waste dumping and discharging; no special restrictions on fisheries
Channel Islands National Marine Sanctuary	Southwest of Santa Barbara, southern California	Various baleen and toothed cetaceans, otariids, and phocids	1980	Prohibits exploration for oil and gas, waste dumping and discharging; no special restrictions on fisheries
Monterey Bay National Marine Sanctuary	350 miles of coastline and adjacent waters, northcentral California	Sea otter, pinnipeds, cetaceans	1992	Prohibits exploration for oil and gas, waste dumping and discharging; no special restrictions on fisheries
Glacier Bay National Park and Preserve	Alaska	Humpback whale	1980	Vessel traffic regulated to prevent whale disturbance
El Vizcaino Biosphere Reserve (includes lagoon whale refuges)	Pacific coast of Baja California Sur, Mexico	Gray whale	Whale sanctuaries designated 1971, 1979, 1980, Biosphere Reserve 1988, UNESCO World Heritage Site 1993	Restrictions on human activity including tourism, fishing; Laguna Ojo de Liebre was world's first whale refuge
Upper Gulf of California and Colorado River Delta Biosphere Reserve	Upper quarter of Gulf of California, Mexico	Vaquita	1993	Nominal protection to vaquitas but fails to address main problem: bycatch in artisanal gillnet fisheries
South America				
Galápagos National Park; Galápagos Islands Marine Resources Reserve and Whale Sanctuary	Galápagos Islands, Ecuador	Galápagos fur seal, Galápagos sea lion, coastal cetaceans	National Park 1979, Whale Sanctuary 1990	Full protection for all wildlife
Fernando de Noronha National Marine Park	Archipelago off equatorial Brazil	Spinner dolphin	1988	Nominal protection to dolphins as well as support for dolphin-watching tourism
Lobos Island Ecological Reserve	Near border of Santa Catarina and Rio Grande do Sul, Brazil	South American sea lion and fur seal	1983	Protected haul-out site
Environmental Protection Area of Anhatomirim/ Bay of Dolphins	Florianópolis, Santa Catarina, Brazil	Tucuxi (marine type)	1992	Nominal protection from harassment
Golfo San José Marine Park (Whale Sanctuary)	Peninsula Valdés, Argentina	Southern right whale	1974	
Provincial Wildlife Reserve of North Point (Punta Norte)	Peninsula Valdés, Argentina	Southern elephant seal	1967	Protects breeding haul-out beach
Provincial Wildlife Reserve of Punta Pirámides	Peninsula Valdés, Argentina	Southern sea lion	1974	Protects breeding haul-out beach
Pacaya-Samiria National Reserve	Peruvian Amazon	Boto, tucuxi, Amazonian manatee	1972, enlarged 1982	Hunting and fishing by local people allowed, nominal protection to animals, some restrictions on commercial exploitation and industrial activity, some dolphin-watching tourism
Mamirauá Sustainable Development Reserve	Western Brazilian Amazon	Boto, tucuxi, Amazonian manatee	1990, upgraded 1996	Strong research focus, hunting and fishing by local people allowed

high expectations, largely because no serious attempt has been made to regulate fishing within the sanctuaries. To the program's credit, though, the dumping of wastes and the exploration for oil and gas have been strictly regulated, and this may be seen as having conservation value for marine mammals and other organisms. So-called "paper parks" and "paper reserves" are probably counterproductive for conservation. They provide false assurance that space and resources have been set aside for wildlife, thereby relieving the public pressure for meaningful conservation action.

Table III does not include the many small sites in the Antarctic and on the sub-Antarctic islands that are designated as specially protected areas or sites of special scientific interest under the Agreed Measures for the Conservation of Antarctic Fauna and Flora (1964), or as nature reserves under national legislative instruments, many of which protect vital haul-out habitat for seals in particular. The Svalbard (Spitsbergen) archipelago in the northeastern North Atlantic was the site of some of the worst excesses of early whaling and walrus killing, yet since 1973 about half of the land area has been declared to be inside nature reserves and national parks, and the Svalbard population of walruses is expanding rapidly.

VII. Strategies to Enhance Individual Survival and Reproduction

It is not often that human intervention can be effective in improving the chances for individual marine mammals to survive and reproduce. Organized programs for rescuing marine mammals that strand (come ashore) alive or that are injured and debilitated do manage to release some animals after rehabilitation. However, the success rate is low, and the conservation value of such programs is questionable. Many strandings represent "natural" mortality. Thus, while intervention may be justified as a humane gesture intended to improve the welfare of the stranded individual animals, it can also be argued that natural processes should be allowed to proceed without human interference. Only in a few special cases does rescue, rehabilitation, and release seem to be making a clear, direct difference in improving the health of a marine mammal population.

Most of the rivers in southern Asia inhabited by river dolphins are partitioned by irrigation dams (called barrages). When dolphins on the upstream side of such dams get too close to the intake structures of adjacent canals, they run the risk of becoming marooned in the canals, unable to return to the safety of the main river channel. In recent years, wildlife officers and conservationists have occasionally attempted to locate and rescue these ill-fated dolphins. In January 2000, at least two Indus dolphins, or bhulans (*Platanista gangetica minor*), trapped in a canal near Sukkur, Pakistan, were successfully caught and returned to the river (Fig. 7). In the same month, a Ganges dolphin, or susu (*Platanista gangetica gangetica*), that had become stranded in a small pool of water along the Damodar River in West Bengal, India, was rescued and safely transported to the Hooghly River for release. Pakistan's WWF office is working to develop a systematic procedure for notification and response, along with a protocol for rescuing river dolphins that enter irrigation canals.

Figure 7 *An Indus river dolphin that had been marooned in an irrigation canal is released back into the main river channel upstream of Sukkur, Sind province, after being rescued by a team of conservationists from Sind Wildlife Department and WWF-Pakistan, January 2000. Photograph courtesy of World Wide Fund for Nature–Pakistan.*

In Florida, several facilities that display captive marine mammals have been collaborating for many years with the U.S. Fish and Wildlife Service to rehabilitate injured or orphaned manatees (*Trichechus manatus*). The animals are cared for and either maintained permanently in educational exhibits or, if judged healthy enough, released back into the wild. A single facility (Sea World in Orlando) was reported to have responded to 160 requests for assistance with distressed manatees from 1976 to 1995. More than half of the animals brought into captivity died, but nearly 60 individuals were eventually returned to the wild. Because virtually all of the injuries to manatees in Florida waterways are caused by human activity (mainly boating), the mortality being "offset" by the rehabilitation program is almost entirely nonnatural (Fig. 8).

Rescue and rehabilitation programs can contribute to conservation in less direct ways, too. For example, as John Reynolds (1999) has pointed out, "Educating people about manatee con-

Figure 8 *This badly injured manatee was rescued at Fernandina Beach, Florida, on November 10, 1997. She and her dependent calf were taken into captivity for medical treatment and rehabilitation. Although the mother died a little more than 5 months later, the calf survived and was released back into the wild in 1999. A record number of manatees (82) died in Florida from watercraft injuries in 1999, and more than 55 had been documented through the end of May in 2000. Photograph by Robert K. Bonde, U.S. Geological Survey–Sirenia Project.*

servation as they watch recuperating animals in a zoo setting can make a strong impression that may do more to encourage actual conservation than reading an article or watching a documentary about manatees." The whale and river dolphin rescue efforts mentioned earlier also serve to heighten awareness, educate people about conservation issues, and inspire actions to prevent further entanglement and entrapment. Reynolds also points out that manatees in captivity have allowed scientists to study their species' reproduction, osmoregulatory capabilities, and sensory abilities. Knowing more about manatee biology and physiology is important for conservation.

Finally, rescue and rehabilitation programs offer opportunities to instrument and monitor animals after release. This can lead to new discoveries about the animals and allow researchers to test new study methods. There are many examples, but one in particular stands out. In 1997 an adult male bottlenose dolphin (*Tursiops truncatus*), nicknamed "Gulliver," stranded in Florida. He was treated for a variety of ailments and, after about 4 months in captivity, released far offshore bearing a satellite-linked transmitter (Fig. 9). Gulliver's travels were impressive. After a week moving northward along the continental shelf, he headed southeast, swimming against the North Equatorial Current. He traversed waters more than 5000 m deep and reached an area northeast of the Virgin Islands before his transmitter stopped working, having covered 4200 km in 47 days. This study showed that bottlenose dolphins can be extremely mobile and that previous assumptions about the distributional limits of pelagic stocks would need to be reconsidered.

Another example of human intervention to enhance survival comes from the northwestern Hawaiian Islands, where biologists from the U.S. National Marine Fisheries Service have captured and translocated endangered monk seals (*Monachus schauinslandi*). In one program on Laysan Island, they caught a number of adult males that had been seen participating in "mobbing," or collective attacks on adult females and juvenile seals. The males were moved by ship to Johnston Island, some 600 miles south of Laysan, and released in the hope that they would survive but not return to carry on their destructive behavior toward other monk seals. In another program, called "Headstart," female pups at Kure Atoll have been collected after weaning and kept in a fenced beach enclosure for several months. The watered portion of the enclosure is kept well stocked with fish taken from nearby reefs, and the young seals have a chance to learn to forage in safety from large sharks, adult male monk seals, and hazardous fishing gear—all potential causes of mortality. The idea is that by the time they are released, they will have survived a critical stage in the life cycle and be ready for independence.

CAPTIVE BREEDING, with the intention of using captive-born young to reestablish a species in its former range or to supplement and reinvigorate a depleted wild population, is often discussed as a conservation strategy. Only one serious attempt has been made to restock a wild population of marine mammals with animals that were conceived, born, and reared in captivity. A number of captive-born harbor seals were released into the Dutch Wadden Sea, where their species is depleted severely (although harbor seals are not considered globally threatened). The released seals were monitored with TELEMETRY devices, and early results suggest that they have survived and adapted reasonably well.

Although captive breeding programs have been discussed in relation to Yangtze River dolphins, or baiji (*Lipotes vexillifer*),

Figure 9 *"Gulliver," an adult male bottlenose dolphin that had been rescued and rehabilitated after stranding, is released from a Coast Guard inflatable off Cape Canaveral, Florida, on May 20, 1997. The satellite-linked transmitter on Gulliver's dorsal fin allowed him to be tracked for 47 days while he traveled to an area northeast of the Virgin Islands, causing scientists to rethink hypotheses concerning offshore populations of this species. Photograph courtesy of Randy Wells, Mote Marine Laboratory.*

and Mediterranean monk seals (*Monachus monachus*), both gravely endangered, none of these programs have come to fruition. A much-publicized "seminatural reserve" was established for river dolphins in a Yangtze River oxbow, but this facility was stocked primarily with finless porpoises (*Neophocaena phocaenoides*) rather than dolphins. The single female baiji introduced to the reserve became entangled in fishing gear and died. No attempt was made to place this female with the lone male baiji in captivity, so there was no prospect of captive breeding. Efforts to capture additional baiji for captivity or for stocking the seminatural reserve have failed.

Translocation efforts played a role in the sea otter's reoccupation of parts of its original range. More than 700 otters were taken from high-density areas in Alaska during the 1960s and early 1970s and released at unoccupied sites in British Columbia, Washington, and Oregon. Populations are now well established in the first two of these three areas. A controversial attempt was also made during the 1980s to establish a new population of sea otters in the California Channel Islands in order to reduce the risk that an oil spill would destroy the mainland population. More than 135 otters were captured and translocated to San Nicolas Island, but by the late 1990s only a few (less than 20) remained, and the program was abandoned.

VIII. Reduction of Environmental Pollution (Chemical and Acoustic)

The role of POLLUTION in impairing the productivity and survival of marine mammals was first realized in the 1970s, when the rate of reproductive failure (premature births, still births, and abortions) in California sea lions (*Zalophus californianus*) was found to be positively correlated with elevated tissue levels of DDT (O'Shea *et al.*, 1999). Also during the 1970s, studies of seals in the Baltic and North seas provided suggestive evidence that organochlorine pollutants pose serious risks to the health and reproductive potential of marine mammals. The production and use of DDT, PCBs, and some other dangerous persistent organochlorine chemicals began to be restricted in North America and western Europe in the 1970s, and there has been a general trend toward further restrictions since then. Unfortunately, however, the problem is far from solved. For example, India continued to produce 4000 metric tons of DDT at least as recently as the mid-1990s, and at least some of the former Soviet states have continued to manufacture and use PCBs. Moreover, the persistent nature of these chemicals means that they continue to be present in the environment, either temporarily sequestered in sediments or recycling in food webs, and therefore marine mammals continue to be vulnerable to their effects. While it must be acknowledged that the principal motivation for banning the release of harmful substances into the environment has had less to do with protecting marine mammals than with protecting human health (and birds, in the case of DDT), there is no doubt that reports of high levels of contaminants in marine mammals have contributed to public concern.

Acoustic pollution is thought to be especially damaging to cetaceans, as they depend heavily on sound for information about their environment, for foraging, and for communication. Noise associated with the exploration, development, and transport of hydrocarbon resources has been a particular source of concern, and many millions of dollars have been invested in studies of effects. In some instances, notably those involving seismic and drilling noise in the Arctic, steps have been taken to minimize the exposure of whales and seals to high-energy sounds. Government agencies and companies have conducted monitoring programs to determine when marine mammals are present in an area so that operations can be suspended or moved as necessary. In a similar vein, the sites and timing of military exercises off the east and west coasts of North America have, in a few instances, been planned with the safety of marine mammals and other marine wildlife as a primary consideration.

Human-induced changes in global climate have been the subject of intense debate in recent years, and it is fair to assume that marine mammals will be among the organisms af-

fected by such changes. The effects are perhaps most obvious for ice-associated species: the phocid seals in the Arctic and Antarctic and the walrus and polar bear in the Arctic. These animals use sea ice as a platform for resting, giving birth, or, in the case of polar bears, hunting. As the extent and thickness of pack ice decrease consequent to global warming, these species are likely to lose critical habitat. Once again, as in the case of toxic chemical pollution, the primary motivation for taking steps to reduce emissions of greenhouse gases and ozone-depleting substances has been concern about human welfare rather than a desire to conserve marine mammals.

IX. Reduction of Conflicts with Fisheries

Fishery policies are the key to many of the most pressing marine mammal conservation problems. While there are examples of effective action to reduce marine mammal mortality in fishing gear, such as the UN ban on high-seas drift netting, the seasonal or permanent closure of certain areas to gill netting, and the development and implementation of deterrence programs using pingers and similar devices, the sad truth is that many critical situations simply continue to deteriorate. For example, although some legal limits have been placed on gill netting and commercial fishing in a portion of the upper Gulf of California, there has been little effective enforcement, and vaquitas remain in jeopardy. In China's Yangtze River, it is illegal to fish with electricity and explosives, yet there is almost no enforcement, and river dolphins and porpoises continue to be killed and injured as unintended victims.

X. Reduction of Disturbance and Direct Harm from Vessel Traffic

Manatees living in Florida's motorboat- and barge-infested waterways are frequently struck and injured, if not killed outright, by watercraft. About 50 Florida manatees are killed by boats each year, and many more are injured and harassed by vessel traffic. Although this problem had long been recognized, it was not until the late 1970s and early 1980s that serious efforts were made to reduce the risk of collisions and disturbance. More than 20 areas have been designated as protection zones for manatees, where vessel speed is regulated and signs warn visitors of the need to exercise caution. In some key manatee congregation areas, all waterborne human activity, including diving, boating, and swimming, is prohibited.

The other marine mammal species that is clearly threatened by ship strikes is the right whale. Where many thousands of North Atlantic right whales were present in the past, all that remains is a small population of about 300 or so centered along the east coast of Canada and the United States. Unfortunately, the whales regularly congregate in deep basins to feed, and these same deep waters are used by large cargo ships, tankers, and military vessels (Katona and Kraus, 1999). Several right whales are killed by ship collisions each year (Fig. 10). This mortality, combined with that caused by entanglement in fishing gear, is considered sufficient to have stalled population recovery and contributed to a recent downturn. Efforts have been made in both Canada and the United States to monitor the seasonal distribution and movements of individual right whales so that vessel captains can be notified to watch out for them. In Canada, consideration is being given to changing ship traffic lanes to reduce the risks to right whales. In the United States, a mandatory ship reporting system was put in place in 1999, requiring all vessels larger than 300 gross tons to report their location, speed, and port of destination when traversing designated right whale critical habitat. In return, they are provided with information on the presence of right whales in their vicinity.

It remains to be seen whether manatees and right whales will be able to withstand the effects of human activities in the nearshore and inshore waters we share with them. Thus far, our own species' recreational and commercial use of the

Figure 10 *This young right whale died after being struck by a ship off the coast of Florida, near Jacksonsville, on January 10, 1993. Although right whales have been protected from whaling since the 1930s, their populations in the Northern Hemisphere have not recovered. One reason is the mortality caused by ship strikes and entanglement in fishing gear. Photograph by Robert K. Bonde, U.S. Geological Survey–Sirenia Project.*

marine environment has been regarded as sacrosanct, and the few gestures made to accommodate the needs of these other species have had to overcome strenuous resistance from boaters, the shipping industry, military authorities, and others.

XI. Giving Economic Value to Living Wild Marine Mammals

In the 1950s, a few nature enthusiasts in southern California began venturing into nearshore waters to watch gray whales. At the time, scientists were just beginning to document the remarkable recovery of these animals—a result of the protection from whaling afforded by the IWC and, in recent years, Mexico's protection of the breeding lagoons in Baja California. Interest in watching whales grew steadily, and by the mid-1970s, conservationists were suggesting that the economic value of this "nonconsumptive" form of use might eventually rival that of whaling. The 1980s and 1990s saw the rapid proliferation of tour enterprises for observing whales and dolphins. Even in the whaling countries of Norway, Iceland, and Japan, whale watching has become a popular and at least locally remunerative form of recreation. In eastern Canada, helicopter tours to the pack-ice pupping grounds of harp seals have been encouraged by animal-welfare groups as a way of demonstrating that seals can generate income without having to be killed.

XII. Zoogeography of Marine Mammal Conservation

Threats to marine mammal species and populations are relatively well understood and are being addressed aggressively in the United States, western Europe, South Africa, Australia, and New Zealand. That is not to say that the problems will all be solved and that threatened species and populations in these areas are safe. In fact, right whales, northern sea lions (*Eumetopias jubatus*), and California sea otters in U.S. waters, Mediterranean monk seals and some local populations of bottlenose dolphins in Europe, dugongs in parts of Australia, and Hector's dolphins in New Zealand are still in trouble. Rather, the point is that elsewhere in the world, by comparison, marine mammal populations are slipping away even before there has been a chance to document their distribution and abundance, or to elucidate their ecological roles.

Table IV lists 20 of the world's most threatened marine mammal taxa. It is important to caution that the list is arbitrary and potentially misleading. For example, it is dominated by taxa that have been relatively well studied, to the exclusion of ones that have been less closely studied. Some seriously threatened populations of finless porpoises, Irrawaddy dolphins (*Orcaella brevirostris*), and hump-backed dolphins (*Sousa* spp.) probably represent valid subspecies, or even species, and should be included, but they are simply not well enough known. Also, scientists have been concerned for many years about the large numbers of La Plata dolphins, or franciscanas (*Pontoporia blainvillei*), being killed accidentally in artisanal gill nets along the east coast of South America (Fig. 11). Until very recently, however, there was no estimate of franciscana abundance, and the information about mortality was not sufficiently precise or accurate to support a proper assessment. Without a strong scientific underpinning to demonstrate the seriousness of the problem, conservationists are unlikely to be able to force governments to act to reduce dolphin mortality. Similarly, manatees in West Africa (*T. senegalensis*) and South America (*T. inunguis*) are hunted, trapped, and caught in fishing gear, but no one has the vaguest idea how many there are or the extent to which their distribution has already been reduced by overexploitation and habitat deterioration. For these and many other situations, there has been little or no active conservation.

Another difficulty is that by limiting the list in Table IV to recognized species and subspecies, many geographical populations are left out. For example, several populations of baleen whales (e.g., western North Pacific gray whales; Okhotsk and Spitsbergen/Barents Sea bowheads) and toothed whales (e.g., Cook Inlet and Ungava Bay belugas, North Island Hector's dolphins) are known to number only in the tens or low hundreds. Their disappearance might be likened to the world losing an entire branch of artistic expression, such as painting or dance. Art would still exist, but there would be a noticeable void, and our lives would be less rich.

Finally, assessing the extent to which different groups of animals are threatened or endangered is extremely complex. It involves far more than simply considering current abundance, or even trends in abundance. In 1996, IUCN attempted, for the first time, to evaluate the conservation status of the world's mammal species and subspecies according to standardized quantitative criteria. This process led to the listing of all four extant species of sirenians (the three manatees and the dugong) as vulnerable, meaning that they face a high risk of extinction in the medium-term future. Of the pinnipeds, one species (the Mediterranean monk seal) is listed as critically endangered, meaning that it faces an extremely high risk of extinction in the immediate future, and two (Hawaiian monk seal and northern sea lion) as endangered, meaning that they face a very high risk of extinction in the near future. Six pinniped species are listed as vulnerable and one as lower risk (near threatened), the latter meaning that the taxon is close to qualifying as vulnerable. Of the cetaceans, 2 species (baiji and vaquita) are considered critically endangered, 6 endangered, 6 vulnerable, 1 lower risk (near threatened), and 14 lower risk (conservation dependent). The last of these designations (which has also been applied to the polar bear) means that the species is the focus of a continuing taxon-specific or habitat-specific conservation program, which, if stopped, would result in the species qualifying for one of the threatened categories (i.e., vulnerable, endangered, or critically endangered) within 5 years. Yet another category, data deficient, was applied to 38 cetacean species. It signifies that there is inadequate information to assess the risk of extinction and acknowledges the possibility that, with further research, one of the threatened categories will be found to be appropriate for the species. In addition to the species listings, 5 pinniped and 12 cetacean subspecies or geographical populations are listed as either endangered or vulnerable.

Endemism is a feature that seems to be associated with vulnerability. Many of the species and subspecies in Table IV are on the list because they occur in only one place, and the smaller that place, the more vulnerable the taxon. The vaquita is limited to the upper portion of the Gulf of California, the baiji to

TABLE IV
Twenty of the World's Most Threatened Marine Mammal Taxa, Including Recently Extirpated Ones[a]

Taxon	*Range states*	*Approx. abundance*	*Main threats*
1. Caribbean monk seal, *Monachus tropicalis*	Mexico, USA, Bahamas, Jamaica, Cuba, Haiti, Dominican Republic, Guadeloupe, and other Caribbean states	Probably extinct	Deliberate killing, loss of habitat due to development
2. Japanese sea lion, *Zalophus japonicus*	Japan, Korea, Russia	Probably extinct	Deliberate killing
3. Baiji or Yangtze river dolphin, *Lipotes vexillifer*	China	Tens	Fishery bycatch, loss of suitable habitat and resources, possibly vessel strikes and disturbance
4. Saimaa ringed seal, *Pusa hispida saimensis*	Finland	200	Fishery bycatch, chemical contamination
5. Mediterranean monk seal, *Monachus monachus*	Turkey, Greece, Italy, Mauritania, Morocco, Western Sahara, Libya, Madeira (Portugal), Tunisia	250–500	Fishery bycatch, shooting by fishermen, loss of suitable pupping and pup-rearing habitat
6. Ungava harbor seal, *Phoca vitulina mellonae*	Canada	120–600	Hunting, changes to habitat caused by hydroelectric development
7. Vaquita, *Phocoena sinus*	Mexico	About 600 (200–1000)	Fishery bycatch
8. Bhulan or Indus river dolphin, *Platanista gangetica minor*	Pakistan	1000	Fishery bycatch, loss of suitable habitat (including habitat fragmentation), accidental movement into canals and other unsafe areas
9. North Atlantic and North Pacific right whales, *Eubalaena glacialis* and *E. japonica*	Canada, USA, Iceland, Norway, UK, Spain, Portugal, France (No. Atlantic population); Russia, Japan, Korea, Canada, USA, Mexico (No. Pacific population)	300–350 in North Atlantic; possibly < 1000 in North Pacific	Ship strikes, fishery bycatch, possibly effects of small population size (depletion from past over-hunting)
10. Antarctic blue whale, *Balaenoptera musculus intermedia*	Australia, New Zealand, Madagascar, South Africa, Namibia, Angola, Gabon, Argentina, Brazil, Chile, Peru	Hundreds	Uncertain, possibly effects of small population size (depletion from past over-hunting)
11. Hawaiian monk seal, *Monachus schauinslandi*	USA (mainly Hawaiian archipelago)	1000–1500	Fishery bycatch, disturbance on pupping beaches
12. California sea otter, *Enhydra lutris nereis*	USA	About 2000	Fishery bycatch
13. Red Sea dugong, *Dugong dugon hemprichii*	Egypt, Saudi Arabia, Yemen, Eritrea, Sudan	Probably low thousands at most, possibly only hundreds	Fishery bycatch, hunting?
14. Susu or Ganges river dolphin, *Platanista gangetica gangetica*	India, Bangladesh, Nepal	Possibly low thousands	Fishery bycatch, deliberate hunting, loss of suitable habitat (including habitat fragmentation), accidental movement into canals and other unsafe areas, chemical contamination
15. Yangtze River finless porpoise, *Neophocaena phocaenoides asiaeorientalis*	China	High hundreds or low thousands	Fishery bycatch, loss of suitable habitat and resources, possibly vessel strikes and disturbance
16. Florida manatee, *Trichechus manatus latirostris*	USA, Bahamas (occasionally)	2500–3000	Vessel collisions, fishery bycatch, exposure to toxic organisms (possibly related to human activities)

(continues)

TABLE IV *(Continued)*

Taxon	*Range states*	*Approx. abundance*	*Main threats*
17. Hector's dolphin, *Cephalorhynchus hectori*	New Zealand	Low thousands	Fishery bycatch
18. Antillean manatee, *Trichechus manatus manatus*	Caribbean and Atlantic mainland coastal states from Mexico to Brazil, Cuba, Puerto Rico, Trinidad, Dominican Republic, and other Caribbean island states	Unknown	Fishery bycatch, deliberate hunting and trapping
19. Ladoga ringed seal, *Pusa hispida ladogensis*	Russia	About 5000	Fishery bycatch, disturbance at haul-out sites
20. Caspian seal, *Pusa caspica*	Russia, Kazakhstan, Turkmenistan, Iran, Azerbaijan	Possibly tens of thousands but rapidly declining	Hunting, fishery bycatch, chemical contamination, loss of suitable habitat and resources, disease

[a]Taxonomy follows Rice, 1998, except for right whale. See Species List.

the mainstem of the Yangtze River, the bhulan to the mainstem of the Indus River, and the Saimaa, Ungava, and Ladoga ringed seals to single networks of freshwater lakes. Scale obviously matters in considering the effects of endemism. A species or population that ranges throughout, or on both sides of, an ocean basin would seem intrinsically less vulnerable than one limited to a single stretch of coastline or a single river or large lake.

Figure 11 *Franciscanas killed accidentally in gill nets near San Bernardo, Buenos Aires, Argentina. For decades, scientists have expressed concern about the scale of this mortality, but very little progress has been made toward assessing the impact on dolphin populations or reducing the bycatch rate. The franciscana is one of several marine mammal species with a restricted distribution (coastal waters of eastern South America between approx. 18°30'S and 41°10'S) that experiences substantial incidental mortality but for which information on abundance and productivity is far from adequate. Photograph courtesy of Pablo Bordino.*

The challenges that lie ahead are truly endless. As the world economy becomes more integrated and as the human appetite for consuming our planet's resources expands, marine mammals will inevitably experience new threats, even as long-standing threats persist. Not only are we in danger of losing numerous populations, some species, and a few genera (e.g., *Monachus, Eumetopias*), several entire families of cetaceans are already at risk, ranging from the "river dolphins" (Lipotidae, Platanistidae, and Pontoporiidae) to the gray and right whales (Eschrichtiidae and Balaenidae). However impressive the array of conservation efforts may seem, on paper, it is far from adequate. Only with a genuine, broad-scale change in how we value the remnants of the world's natural variety and abundance, and thus in how we use and care for the Earth's precious resources, can we hope to head off a cascade of marine mammal EXTINCTIONS in the coming decades.

Convergent Evolution

Emily A. Buchholtz
Wellesley College, Massachusetts

Convergent evolution is the independent development of the same characters or group of characters in species whose common ancestor does not possess them. The resulting similarity in appearance is termed a homoplasy. Convergent evolution is typically associated with adaptation to similar environments. Because the constraints of the aquatic environment are extreme, they provide very powerful selection pressures on animals, such as mammals, that secondarily enter the water from terrestrial environments. Often these animals have independently evolved similar functional solutions in response to the same selective pressures and therefore show convergence in anatomy and/or behavior. Seacows, desmostylians, whales, pinnipeds, hippopotamuses, and otters almost certainly represent separate invasions of aquatic environments by mammals. Some authors believe that pinnipeds, which include sea lions, seals, and walruses, represent not a single but as many as three different invasions of the water.

In contrast to the air, water is very dense, has a high thermal conductance and capacity, and has a very low oxygen concentration. Even marginal marine species must evolve new modes of aquatic locomotion; most exploit aquatic plants or animals as food. Animals that spend most or all of their lives in water often have layers of BLUBBER to conserve heat, higher than average rates of basal metabolism, and a wide range of physiological adaptations that ensure high levels of oxygen uptake, storage, and transport. Because chemicals, light, and sound travel differently in water than in air, chemosensation, vision, and audition are usually modified to allow efficient defense, orientation, and COMMUNICATION.

Ample evidence exists that the highly restrictive marine environment has repeatedly selected for similar characters that enhance life in the water across a wide range of mammalian taxa. Nevertheless, anatomical and/or functional similarity need not imply convergence if the taxa involved are in fact more closely related to each other than they are to another terrestrial lineage. In such a case, the similarities of the two groups could be ascribed to common inheritance. This point, made by Wyss (1989), was used to argue for a single, monophyletic origin of all pinnipeds. To the extent that similar anatomical and physiological traits for dealing with life in the water occur in mammals with different terrestrial ancestors, they are the homoplastic results of convergent evolution. This article presents examples of convergence among marine mammals in locomotor pattern and body shape, sense organ choice and design, and circulatory physiology.

I. Convergence in Locomotor Pattern and Body Shape

All marine mammals had terrestrial ancestors with paraxial appendicular locomotion, and it is probable that transitional,

semiaquatic taxa employed limb-based, paddling locomotor patterns to at least some extent. Fish (1996; Fig. 1) contrasted such drag-based propulsion with the lift-based propulsion of fully aquatic mammals. Lift-based propulsion may employ forelimbs, hindlimbs, or a caudal fin as the lift-generating organ. Despite different swimming proficiencies and speeds, sirenians and cetaceans provide a striking example of the convergent evolution of dorsoventrally oscillating, lift-generating caudal flukes. The swimming style of the (reptilian) Jurassic ichthyosaurs was at least superficially convergent on the same pattern, although oscillation of the caudal fin was lateral instead of vertical.

Many marine mammals, especially those specialized for speed, have smooth, fusiform bodies that enhance movement through the dense aquatic medium. A smooth body reduces viscous drag produced by friction between water and the animal's body, whereas a streamlined, teardrop shape reduces surface area and inertial drag from the pressure differences caused by movement through the water. In test objects, minimum drag is achieved when body length is approximately four to five times body width, and many fast swimmers have evolved these approximate proportions convergently. When the functional constraints of feeding allow it, hydrodynamic shape is often further enhanced by reduction of neck length. The degree of aquatic specialization of both living and fossil mammals can be estimated by measuring the relative length of cervical vertebrae (Fig. 2). Other common convergent changes in body form include the loss of external ear pinnae and the enclosure of external genitalia in body pouches to reduce drag.

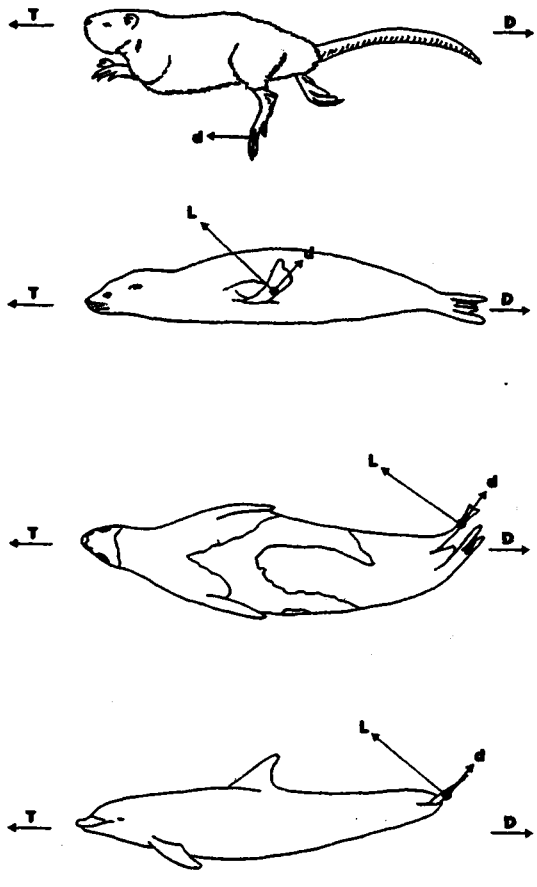

Figure 1 *Propulsive modes in marine mammals, from Fish (1996). From top, paddling (drag-based) in the muskrat* (Ondatra zibethicus), *pectoral oscillation (lift-based) in the California sea lion* (Zalophus californianus), *pelvic oscillation (lift-based) in the harp seal* (Pagophilus groenlandicus), *and caudal oscillation (lift-based) in the common bottlenose dolphin* (Tursiops truncatus). *Drag (d) and lift (L) generated by the propulsive organ contribute to total thrust force (T) and drag force (D). Reprinted with permission of the* American Zoologist.

II. Convergence in Choice and Design of Sense Organs

Transition from land to water is typically accompanied by the modification of the sense organs for efficient use in the new environment. In very broad terms, sight plays a relatively smaller role, and hearing a larger role, in the lives of marine mammals than in those of terrestrial mammals. Nevertheless, most marine mammals see very well, especially in clear water and at short distances. Light is absorbed by water and scattered by suspended material. As a result, vision is restricted at distance, at depth, and in turbid nearshore environments. At least one species of river dolphin (*Platanista gangetica*) is nearly blind. Modification of the terrestrial eye for sight in lighted aquatic environments requires compensation for the lack of corneal refraction. In subaerial eyes, the cornea is a fixed refractor that depends on the different refractive indices of air and corneal tissue to bend light toward the retina. The near identity of the corneal refractive index with that of water makes it virtually useless in aquatic mammals.

Sound travels several times faster in water than in air, making hearing an optimal sense for aquatic communication and

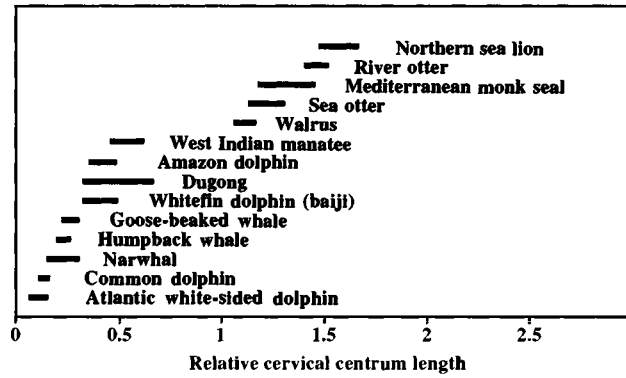

Figure 2 *Convergent reduction of centrum length relative to centrum height of cervical vertebrae in marine mammals (top to bottom:* Eumetopias jubatus, Lutra *sp.*, Monachus monachus, Enhydra lutris, Odobenus rosmarus, Trichechus manatus, Inia geoffrensis, Dugong dugon, Lipotes vexillifer, Ziphius cavirostris, Megaptera novaeangliae, Delphinus *sp.*, Lagenorhynchus acutus*). A short relative length enhances hydrodynamic shape and ease of movement through the water.*

navigation. Long wavelength sound that bends around obstacles is used for long-distance communication in both whales and pinnipeds. The "songs" generated by giant mysticetes may travel hundreds or even thousands of kilometers. Navigation via short wavelength sound is highly developed in odontocete cetaceans. Although short wavelength clicks or chirps are produced by many sea lions, seals, and walruses (*Odobenus rosmarus*) and by the Caribbean manatee (*Trichechus manatus*) (Norris, 1969), their function in either communication or navigation has not been reliably documented.

Adaptation of the terrestrial ear for aquatic hearing presents several significant challenges. These include the increased pressure at depth on the ear drum or tympanum, the impedance mismatch produced by the entry of sound through the air-based middle ear, and the ease with which sound from the environment enters the inner ear directly through the body. Reduction in the size of the tympanum and increases in both the density and the size of the ear ossicles have occurred convergently in whales and pinnipeds. In some cases, sound reaching the middle ear is supplemented or supplanted by sound traveling via the jaw. Both whales and pinnipeds have also responded to the disruption of directional information caused by the transmission of sound via many osseous routes by isolating and insulating the inner ear from the rest of the skull. In whales, this insulation involves not only soft tissue separation, but also the very dense tympanic bone.

III. Convergence in Circulatory Physiology

All marine mammals retain lungs as their dominant organs of gas exchange and are dependent on the air at the water's surface for their oxygen supplies. Despite this restriction, many are capable of dives that persist long after oxygen in the lungs is depleted. They may tolerate such dives by decreasing the heart rate (bradycardia), by utilizing oxygen stored in muscle or blood that has unusually high levels of myoglobin or hemoglobin, and by switching from aerobic to anaerobic metabolism. Additionally, blood may be directed away from the muscles, kidneys, and digestive tract, but its supply maintained or diverted to vital organs that constantly require oxygen, such as the brain and the heart. Hedrick and Duffield (1991) documented unusually high concentrations of red blood cells in serum (hematocrits) in those whales (belugas, *Delphinapterus leucas*) and seals (northern elephant seals, *Mirounga angustirostris*) that employ deep, long-duration dives. Interestingly, high hematocrits are also associated with increased blood viscosity and a reduced oxygen transport capacity, which may preclude fast sustainable swimming in these species. The extensive phylogenetic distance between whales and seals dictates that these similarities must have evolved separately in each group, making them a convincing example of convergent evolution.

Convergent evolution of animals whose aquatic habits demand long periods without breathing extends to the molecular level as well. Joysey (1988) studied the sequence of amino acids in the myoglobin molecule as a means of determining phylogenetic relationships. He found that his phylogenetic reconstructions were in some cases complicated by the occurrence of amino acids that could be associated with similar physiological requirements. When compared with those of terrestrial mammals, the myoglobins of phocids, otariids, penguins, and cetaceans all include additional arginines on surficial sites. Their presence changes the electrical charge of the protein, allowing high-density concentration of myoglobin in the cell.

Courtship Behavior

Bernd Würsig
Texas A&M University, Galveston

Courtship behavior is defined as "the act of wooing a member of the opposite sex" and is thus a limited part of overall mating or reproductive behavior. Courtship is particularly well developed in monogamous animals or those where direct partner choice is important. Marine birds represent especially good examples. Many marine mammals do not so much as woo members of the opposite sex, but instead males appear to force themselves onto females in estrus, often after having worked out dominance/subservience relationships among themselves. Our discussion here will therefore be a blend of pure courtship behavior and other social interactions that must be a prelude for successful mating. The mere recognition of the opposite sex of the same species, e.g., by sound and sight, is considered a part of courtship in this broader definition (Krebs and Davies, 1993).

I. Pinnipeds

Pinnipeds tend to have polygynous mating systems, with one male attempting to inseminate numerous females. Extreme polygyny is especially well developed on solid land or ice and less so on moving pack or loose ice (Stirling, 1983). Males work out dominance relationships among themselves, usually by aggressive interactions and behavioral bluffing. In elephant seals (*Mirounga* spp.), only a few of the very largest and most aggressive males attain a status of dominance and father by far the most offspring on a section of beach. Nevertheless, the female has a choice in who mates with her. When a male mounts her, she protests by squawking loudly. This action attracts other males, and the mounting male may be challenged by one or more males who consider themselves as or more dominant (LeBoeuf and Laws, 1994).

While male displays of dominance are believed to function overwhelmingly in male–male advertisements, a part of intrasexual selection, it is nevertheless possible that male cues may predispose females toward particular males and away from others. This is perhaps most likely in species that use underwater sound for displays, such as the long trills of bearded seals (*Erignathus barbatus*) or the knocking and whistling sounds of walruses (*Odobenus rosmarus*). Such a potential choice by females of males aggregated on a breeding ground may be an example of lekking behavior, but there is considerable debate among pinniped researchers on this topic (Wells *et al.*, 1999).

Those species where single males occur with single females for some time probably consist of males mating with that female and staying with her during her period of estrus. This is termed "female defense," but does not imply true monogamy, as it is likely that the male will leave and search for another female in estrus after some time (also termed serial monogamy). Ringed seals (*Pusa hispida*) on loose ice appear to be serially monogamous. Nevertheless, casual observations indicate that there is much social interaction and sniffing by these males and females when they first meet, and one wonders whether future more detailed studies might find a much more developed courtship than is presently known. After all, males and females in this species are of similar size and strength; the male is therefore unlikely to be able to force himself on the female, and it need not be automatic that a female accepts any male who happens to come by and show an interest in her (Riedman, 1990).

II. Sea Otters

Sea otter (*Enhydra lutris*) males actively defend a near-shore area from other males, but females are free to come into or leave this apparent underwater territory, also called a *maritory*. When a female comes into estrus, she tends to associate with only one male for several days. The male mates with her repeatedly and grips her nose, which becomes heavily bloodied and scarred during mating, with his teeth and claws. This behavior may help to stimulate ovulation, as neck biting does in some other carnivores. It is unclear whether it is simply the goodness of the space that attracts a female to a particular male or whether there is courtship behavior beyond grabbing and biting involved.

The marine otter (*Lutra felina*) of the Chilean Pacific coast probably has a similar maritorial system.

III. Sirenians

The West Indian manatee (*Trichechus manatus*) is the best known of the three extant manatees and one dugong that form the tropical, small, taxonomic order Sirenia (one cold water dugong, Steller's sea cow, *Hydrodamalis gigas*, was extirpated in the 1700s). These manatees aggregate in herds of one female and from 2 to 22 pushing, shoving males. It is believed that the female will therefore mate with more than one male, and it is possible that a form of sperm competition as well as the obvious physical competition for access to the female has evolved. Males also aggregate in herds without females present and with much apparent homosexual mating. Such interactions may be important in practicing the gaining of access to females, what has been termed "scramble competition polygyny." It is also possible, and not mutually exclusive with the idea of practicing for competition, that males are working out dominance hierarchies in the all-male groups. Females move into shallow water to avoid amorous males, and it is possible that females exercise considerable choice of who gets to mate with them by making it impossible for some males to gain access. Manatees also use objects in their environment as traditional "rubbing posts" and rub especially their anal area, which has glandular secretions, on these objects. It is not known whether females in estrus might advertise themselves by chemical smell or taste or whether other communication may take place at rubbing areas (Reynolds and Odell, 1991).

Mating in dugongs (*Dugong dugon*) has not been well described. It appears that at times a single male stays with a single female, whereas at other times, mating aggregations of at least one female and several males occur. Adult male dugongs have small but sharp and hard tusks and can do considerable damage with them to each other and to females. However, it is unknown whether this secondary sexual characteristic functions only as an intrasexual display or as a male to female, or intersexual, display as well. As in manatees, it is likely that females have the capability of at least some choice of mating partner(s), and we therefore assume that some element of "impressing a female," or courtship behavior, may have evolved (Reynolds and Odell, 1991; Wells *et al.*, 1999).

IV. Polar Bears

Polar bears (*Ursus maritimus*) tend to be solitary animals, but males will stay with a female, "guarding" her from other males during a period of estrus. We can assume that these bears, as others, have greeting ceremonies and other interactions during a period of courtship, but details are lacking. Polar bear males have been seen sniffing the tracks of another bear, and it is likely that they—as other bears and many carnivores—find a female in estrus by her smell. It is also likely that multiple copulations are needed to induce ovulation in the female (Stirling and Guravich, 1988).

V. Cetaceans

Whales, dolphins, and porpoises have a diversity of precopulatory behaviors, but how much of these can be described as courtship is unclear. Cetaceans use sound during almost all so-

cial interactions, but vision and touch are well developed and appear of great importance in precopulatory displays. Nevertheless, to date, almost all observations have been from above the surface, and to properly describe courtship behaviors, dedicated focal individual and focal group studies underwater will have to proceed.

A. Baleen Whales

Humpback whales (*Megaptera novaeangliae*) are arguably the best-studied large whale, yet no researcher has reported seeing humpbacks mate. Humpback males on the mating/calving grounds produce series of sounds ("moans, screams, rumbles, etc.") that are repeated in exact fashion after some time. These series are therefore properly called song and may last from about 10 to 30 min per song. Interestingly, every male of an extended area (such as around the Hawaiian Islands, in the Caribbean, or off Japan) sings pretty much the same song. The song evolves during the singing season and is therefore different from the beginning to the end of season. It is presently unknown whether males space themselves underwater by song, whether they attract females by some subtle yet undescribed individual variations in each song, or both. If the latter, the males might be "courting" females by song, although evidence of only males joining each other after singing hints at a male–male aggression function, not courtship. If males space each other by song, perhaps the loudest individual has males farthest from him and may therefore be more eagerly selected by females. However, this is conjecture; it is rather interesting (and somewhat exciting) that there are huge whales out there for which we really still know very little. Humpbacks also aggregate in boisterous surface-active groups of several males and generally only one female. While the males appear to battle for access to the female, it is unknown whether the female mates with a male by his choice or whether she has an active say in who gets to mate with her. A third, potentially alternative, mating strategy appears to be a male who "shadows" a female for hours to several days in the possible hope that she comes into estrus or is in estrus. This association is called a cow-escort group (Wells *et al.*, 1999).

Even less is known about other whales of the taxonomic family Balaenopteridae, such as blue (*Balaenoptera musculus*) and fin (*B. physalus*) whales. These two species produce low-frequency many-second-long moans that travel for tens to hundreds of kilometers. The whales likely communicate with these infrasounds, but whether some aspect of infrasound advertises sexual readiness is not known.

The right whales (*Eubalaena* spp), bowhead whale (*Balaena mysticetus*), and gray whale (*Eschrichtius robustus*) all aggregate into surface active groups of several males and one or a few females. However, these groups are much less aggressive-seeming than those of humpbacks, and one has the impression that males are vying for position near females in a more fluid nonbattling manner. It may be that females incite such aggregations by sound or other displays and that females then have the ability to "choose" the male or males that are most successful in interactions with others. There is some evidence that females at times appear to make it easier for one male than another to gain access to her, but more studies need to be done. At any rate, actual copulations have often been witnessed at the water's surface for the three species mentioned here, and it is therefore known that both males and females have multiple mating partners over the course of hours or days. The social system is therefore a multimate or promiscuous one, but again the cues used to gauge successful courtship behavior are unknown. Bowhead whales during spring migration, when most mating occurs, also sing, but not as long and complicated songs as humpbacks have. Also, it is unknown whether only males sing. Right, bowhead, and gray whale males have larger testes than predicted by body size, which may allow them to "compete" at the sperm level simply by the axiom that the most sperm in the most females is most likely to lead to most successful pregnancies (Brownell and Ralls, 1986).

B. Toothed Whales

The taxonomic group of odontocete cetaceans encompasses a large variety of animals, from the relatively closed societies of killer (*Orcinus orca*) and pilot (*Globicephala* spp.) whales to the large and fluid associations of spinner (*Stenella longirostris*) and pan-tropical spotted dolphins (*S. attenuata*). Still, all toothed whales are social creatures, and all have long-term mother–calf bonds of association. In general, we can guess that those animals where males are morphologically different from females (sexually dimorphic) tend toward polygyny, with the male somehow advertising to males or females to gain greater access than others to females in estrus. Examples would be killer whale males' larger body size and relatively huge erect dorsal fin; sperm whale (*Physeter macrocephalus*) males' huge head and larger size, erupted lower jaw TEETH or "tusks" of male beaked whales; and the enormous narwhal (*Monodon monoceros*) male tusk, not usually present in females.

Sperm whale females stay together in their own matriarchal pods, probably for life, whereas maturing males leave. Therefore, mothers and their female offspring are long-term companions. Mature, large, usually single or "lone" males reapproach these matriarchal pods during the mating season. At that time, some different sounds (from the usual staccato-like clicks that make a pod of sperm whales sound like fat sizzling in a frying pan) are heard, and it is possible that males find the matriarchal group by the calls of females in estrus. It is also possible that the male calls themselves initiate estrus in sexually ready females and/or that the calls are used for inter-male displays.

Species that tend to be generally sexually monomorphic, such as almost all of the smaller dolphins, appear to be multimate or promiscuous. Nevertheless, as one observes these dolphins underwater—and here there is a bit more known as several species have been kept in captivity or have been studied in clear tropical waters—one recognizes that some animals appear to be more preferred partners than others, and that a "pecking" order of who gets to mate with whom may exist. There is much flipper to flipper, tail to belly, rostrum to genital slit, and so on caressing by both males and females, and it is clear that copulation can be initiated by either sex. In these animals, true courtship behavior can be seen, mainly in the form of such caressing but also in interactions by sound. Several dolphin species have larger-than-predicted testes, and it is likely that while both males and females have multiple mating partners, sperm competition exists for these animals as for several species of baleen whales.

A particularly aggressive MATING STRATEGY by males has been clearly documented for Indian-ocean bottlenose dolphins (*Tursiops aduncus*) in Shark Bay, Western Australia. There, several males band together to form a coalition that kidnaps a female from her group, and males repeatedly copulate with her, at times for days. Coalitions attempt to steal females from each other as well. Possible similar situations have been seen elsewhere, but it is unknown whether this behavior, on the margin of "courtship," is a generalized alternative mating strategy (perhaps by subadult males with less chance to mate with females on their own?) or represents cases of an aberrant behavior (Connor and Peterson, 1994).

Crabeater Seal

Lobodon carcinophaga

JOHN L. BENGTSON
National Marine Mammal Laboratory, Seattle, Washington

The crabeater seal may be the most abundant pinniped in the world, existing in the millions around Antarctica. The scientific name is derived from Greek and means "lobed tooth" (*Lobodon*) "crab eater" (*carcinophaga*).

I. Diagnostic Characters and Comments on Taxonomy

Adult crabeater seals are generally about 205 to 240 cm long, with some older individuals reaching up to 260 cm in length. Females may attain a slightly larger size than males. During the summer molting period, adults typically exhibit weights in a range of about 180 to 225 kg. Pups weigh about 35 kg at birth, but can grow to more than 100 kg by the time they are weaned.

The pelts of crabeater seals usually have medium brown to silver hair over most of their body, although darker COLORATION and spotting are not uncommon on the front and rear flippers and flanks (Fig. 1). Because hair fades in color throughout the year, recently molted seals may appear darker than those about to begin their molt, whose pelts can appear silvery white. The body form is relatively slender compared to other phocids, and crabeater seals' faces have a somewhat pointed snout. Crabeater seals have a high incidence of obvious scarring on their bodies, mostly caused by leopard seal (*Hydrurga leptonyx*) attacks (Fig. 2). Adults typically also have small scars from bites around their front and rear flippers (both sexes) and around their lower jaws and throat (mostly males) from intraspecific interactions during the breeding season.

Crabeater seals are highly mobile on ice and, when disturbed, often raise their heads and arch their backs. They can move surprisingly quickly over ice and snow, and on a cold day (when not subject to overheating) they may be capable of outrunning a fit human.

II. Distribution/Range Map

Crabeater seals have a circumpolar Antarctic distribution, spending the entire year in the pack ice zone as it seasonally advances and retreats. Occasionally, crabeater seals are found along the southern fringes of South America, Australia, New Zealand, and Africa, but such sightings or strandings are rare. Genetic analyses suggest that the circumpolar crabeater seal population is panmictic; there are no known subspecies.

Figure 2 *Most crabeater seals possess long, raking scars on their torsos resulting from attacks in their first year of life by leopard seals. Photo by J. L. Bengtson.*

III. Ecology

There is presently no reliable estimate of the total abundance of crabeater seals. Estimates have ranged from 2 to 75 million individuals, although many scientists currently consider a population estimate in the range of 10–15 million may be reasonable. The observed densities of crabeater seals censused in 1983 were lower than densities observed in the late 1960s and early 1970s (4.3 versus 11.4 seals per nm^2 in the Weddell Sea and 1.9 versus 4.9 seals per nm^2 in the Pacific Ocean Sector, respectively). However, it is unclear whether these differences in densities reflected a change in population abundance or a shift in distribution within the sea ice zone. An international research initiative, the Antarctic Pack Ice Seals (APIS) Program, was undertaken in the late 1990s to refine estimates of the abundance and distribution of crabeater seals.

In their first year, crabeater seals experience a surprisingly high mortality rate that may be as high as 80%, which is perhaps double that which might normally be expected. For the approximately 20% of crabeater seals that survive past their first birthday, as many as 78% exhibit large, raking scars on their bodies resulting from previous attacks by leopard seals, suggesting that leopard seals may have a significant negative impact on crabeater seal populations. Most attacks by leopard seals on crabeater seals occur in the crabeater seals' first year; fresh wounds, indicating a recent attack, are rarely seen on crabeater seals that are older than 1 year.

Studies of crabeater seal diet have shown that these seals depend almost exclusively on Antarctic krill (*Euphausia superba*). Most investigators have reported that krill comprise over 95% of the crabeater diet, with the remainder being made up of small quantities of fish and squid. As specialist krill predators, crabeater seals do not seem to switch their prey seasonally.

IV. Behavior

Crabeater seals migrate over large distances in association with the annual advance and retreat of the pack ice. Although they can be found anywhere within the pack ice zone, it is typical to find higher densities of crabeater seals in the marginal ice zone as well as in pack ice that is present near or over the continental shelf. In a peculiar behavioral twist, crabeater seals likely hold the record for any pinniped wandering inland from the coast. Carcasses have been found up to 113 km from open water and as high as 1100 m above sea level. Seals that wander inland become lost and die, may eventually become mummified in the cold, dry Antarctic air, and can remain in this "freeze-dried" state for many decades or centuries.

Similar to other Antarctic pack ice seals, crabeater seals exhibit a daily haulout pattern that generally involves hauling out on ice floes during the middle of the day. However, only about 80% of crabeater seals haul out simultaneously on the ice, even during the height of the molting period in January and February. Haulout patterns also vary markedly among seasons, with as few as 40% of seals hauling out at the peak of daily haulout during winter months.

During daily foraging periods, which normally occur during the night, crabeater seals dive nearly continuously for periods of up to 16 hr. In one study, a single crabeater seal continued diving for 44 hr without interruption. Foraging dives made during crepuscular periods are often deeper than those made during the darkest hours, suggesting that the seals may prefer dark conditions when catching their principal prey, Antarctic krill.

V. Anatomy, Physiology, and Life History

Crabeater seals have finely divided, lobed TEETH, presumably an adaptation to their specialized diet on krill. The multiple cusps of upper and lower postcanine teeth interlock to form a sieve that can be used to filter crustaceans from seawater. A bony protrusion on the lower jaw behind the most posterior postcanine tooth fills the gap in this sieve so that prey cannot escape at the rear of the mouth.

During the breeding season, crabeater seals form "family groups," consisting of a female, her pup, and an attendant male who guards the female from other males until she completes lactation. Pups are born in September and October, with a light brown lanugo that is molted at about 2 weeks of age. Following weaning, the attendant male and the female form a "mated pair" and remain together for an estimated 1 to 2 weeks or until copulation. Females without pups also form mated pairs as they come into estrus. Crabeater seals can live up to 40 years, but adults dying at about 20–25 years is more typical.

VI. Interactions with Humans

Crabeater seals experienced an incident of mass mortality in 1955 in the vicinity of an Antarctic base where sledge dogs were active. Up to 97% of mixed-age aggregations died during that event. It was speculated that a viral infection may have been associated with the die-off, and circumstantial evidence suggests that it may have been caused by a distemper-like virus. Blood samples taken from crabeater seals in the late 1980s confirmed that populations of crabeater seals along the Antarctic Peninsula had antibodies similar to those related to canine distemper and phocine distemper, viruses that were responsible for major epizootic die-offs of harbor seals in the Northern Hemisphere in the late 1980s.

Crabeater seals were harvested commercially twice during the past century: in 1964/1965 by Norway and in 1986/1987 by the former Soviet Union. In both cases, the sealing ventures were judged to be economically unsuccessful. However, the concern generated by the earlier harvest was sufficient to mobilize an international effort to prevent potential overexploitation of the seals. This concern resulted in the Convention for the Conservation of Antarctic Seals, which came into effect in 1978 and provides international oversight for the CONSERVATION and MANAGEMENT of crabeater seals throughout their range.

Culture in Whales and Dolphins

HAL WHITEHEAD
Dalhousie University, Halifax, Nova Scotia, Canada

Evidence is growing that culture is an important determinant of the behavior of whales and dolphins. Among the many definitions of culture, one that is commonly used by evolutionary biologists and is useful when studying the phenomenon in whales and dolphins, is behavioral variation between sets of animals maintained and transmitted by social learning. There are two principal approaches to the study of nonhuman culture. Because some scientists will only ascribe culture to a behavioral pattern if it can be proved to be transmitted between animals by imitation or teaching, they investigate transmission mechanisms experimentally. Others, who use a broader definition of culture encompassing any form of social learning (not just imitation or teaching), look for patterns of behavioral variation in wild populations that cannot be explained by either genetic factors or environmental differences plus individual learning. This has been called the "ethnographic" approach to the study of culture.

The common bottlenose dolphin (*Tursiops truncatus*) has been shown experimentally to posses sophisticated social learning abilities, including vocal and motor imitation, but these have not been closely tied to observed patterns of behavior in the wild. Although social learning of other cetacean species has not been studied experimentally, there is observational evidence for imitation and teaching in some other whales and dolphins, especially killer whales (*Orcinus orca*).

Taking the second, ethnographic, approach, there is good evidence for cultural transmission in several cetacean species. Most notably, the complex and stable vocal (call dialects) and behavioral (foraging patterns and techniques) cultures of sympatric groups of killer whales have no known parallel outside humans and represent an independent evolution of cultural faculties. Although evidence is less firm, sperm whales (*Physeter macrocephalus*) also seem to have important group-based cultures, which include distinctive dialects. Perhaps most remarkable of all cetacean cultures is the song of male humpback whales (*Megaptera novaeangliae*). All males on any breeding ground sing nearly the same song, but it evolves over periods of months and years. This evolution is usually gradual, but over

a 2-year period, the males off eastern Australia unanimously adopted the radically different western Australian song, which they had heard from a few itinerant males.

Several factors may be implicated in the apparent importance of cultural transmission of behavior among cetaceans. Long lives, prolonged parental care, and substantial cognitive abilities are often associated with the evolution of cultural faculties, and these are generally characteristic of cetaceans, as well as other cultural animals, such as primates and some birds. The wide movements of cetaceans and the greater variability of the marine biotic environment relative to that on land, as well as the stable matrilineal social groups of some species, are potentially important factors in the evolution of some of the more unusual aspects of cetacean culture.

Culture can affect the evolution of other aspects of the lives of animals. There have been a number of suggestions for gene–culture coevolution in cetaceans, and culture may be implicated in some of their unusual behavioral and life history traits. For instance, it has been proposed that the separation between "resident," fish-feeding and "transient," mammal-feeding forms of killer whales (which now show morphological and genetic differences) was originally driven by culture. Another suggestion is that cultural selection may have caused the low diversity of mitochondrial genes found in matrilineal whales, as these genes and beneficial cultural traits may have been inherited together by daughters from their mothers. Culture may also be implicated in mass strandings, as well as in the pronounced menopause shown by killer and pilot whale females (which is known only from humans among noncetaceans).

The focused study of culture in whales and dolphins is just beginning. Despite denials from those who demand experimental proof of imitation or teaching before attributing culture, there are strong indications that, in common with humans and chimpanzees, much of the behavioral repertoire of many cetaceans is learned socially and constitutes culture. Culture may also be an important attribute of other marine mammals, with the foraging techniques of sea otters (*Enhydra lutris*) perhaps forming the clearest example.

Cuvier's Beaked Whale

Ziphius cavirostris

JOHN E. HEYNING
Natural History Museum of Los Angeles County, California

The original description of *Ziphius cavirostris* is based on a partial cranium collected near the village of Fos, France, in 1804. In his species description, Cuvier mistakenly identified the specimen as a fossil because he thought the skull was "petrified." The specimen actually represents part of a skull, including a densely ossified rostrum with a well-developed prenarial basin of an adult male. This basin, or cavity, on the top of the skull just anterior to the bony nares led to the trivial name of *cavirostris*. The densely ossified rostrum is found in adult males of Cuvier's beaked whale and mesoplodont beaked whales (Fig. 1). The function of this rock-hard snout is unknown, but it has been postulated to either reinforce the skull when males fight or serve as a sound conduit. The most common English names for Z. *cavirostris* are Cuvier's beaked whale and the goose-beaked whale, both of which are in wide usage.

The general body shape of Z. *cavirostris* is similar to other beaked whales with a rather robust, cigar-shaped body. The falcate dorsal fin is relatively small and set approximately two-thirds of the body length posterior to the rostrum. The flippers are also relatively small, narrow, and can be tucked into a slight depression or pocket along the body wall. This flipper pocket is also found in other ziphiids and is assumed to allow the flippers to be held tight against the body while swimming. As with other ziphiids, the flukes are proportionately large and, as a rule, lack the distinctive medial notch found in all other cetaceans. The head is rather blunt in profile with a small, poorly defined rostrum that grades into a gently sloping melon region. There is no significant difference in total length between sexes for Z. *cavirostris*, with an average adult size of 6.1 m. There are several reports of specimens that exceed 7.0 m in length, but virtually all of these appear to be either estimates of lengths or based on misidentified animals. The largest accurately measured specimen of Z. *cavirostris* is an adult male that measured 6.93 m from the Falkland Islands. There is one pair of throat grooves that converge, but do not meet anteriorly. Beaked whales feed primarily by suction and these grooves allow the throat region to expand as they slurp in their prey.

The pigmentation pattern for male Z. *cavirostris* is a dark slate gray over most of its body with a distinctively white head. This white coloration continues slightly posterior along the dorsum. This appears to be the pattern found in most mature males (Fig. 2). Adult females tend to vary in general color from a dark gray to a reddish-brown, with a slight lightening of the skin on the head. This is not as dramatic a contrast as in males and does not appear to extend posteriorly on the dorsal aspect of the body. Usually there are some distinctive patterns of dark pigment on the head of adult females. The eye is typically dark and there is a highly variable pair of dark crescents surrounding the

Figure 1 *As males of* Ziphius cavirostris *become sexually mature, they begin to reabsorb bone in front of the nasal passages, creating over time a distinct cavity or prenarial basin seen easily in this dorsal view (right). Adult females and immature males lack this basin (left).*

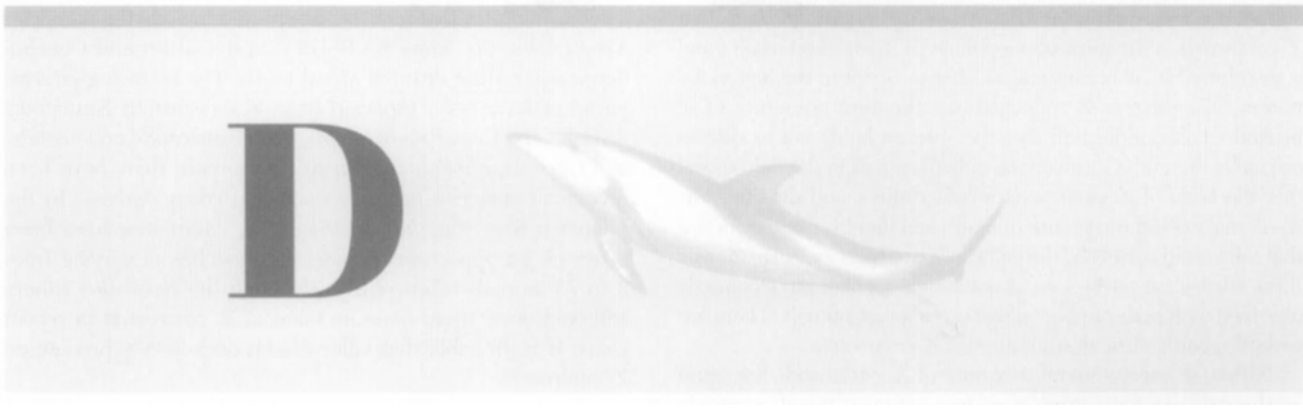
eye, one anteriorly and one posteriorly. Newborns are dark black or bluish-black above and lighter below. This pigmentation pattern is very similar to that found on young beaked whales of the genus *Mesoplodon* and may represent the primitive pigmentation pattern for the calves of many ziphiids. Light oval patches and linear marks are quite common on the skin of Z. *cavirostris*, which can give an animal a mottled appearance. The oval patches on ziphiids have been attributed to scars left by lampreys or cookie-cutter sharks of the genus *Isistius*. Linear marks have been attributed to scars resulting from the teeth of males raking along the skin during intraspecific fighting. The only erupted teeth are the apical pair in adult males, and linear scars are most prevalent in mature males.

As with most uncommon cetaceans, the distribution of Z. *cavirostris* is known primarily from strandings. This type of information may be somewhat biased, especially with regard to the

Figure 2 *This dead, stranded* Z. cavirostris *shows the whitish head characteristic of adult males. Photo by W. Perrin, National Marine Fisheries Service.*

abundance for a particular area. Stranding records indicate that Z. *cavirostris* is the most cosmopolitan of the beaked whales and is distributed in all oceans and most seas except in the high polar waters. Strandings of Z. *cavirostris* are the most numerous of all beaked whales, indicating that they are probably not as rare as originally thought. Observations of live animals in the field reveal that the blow of Z. *cavirostris* is low, diffuse, and directed forward, making sightings more difficult, and there is some evidence that they avoid vessels by diving. These two facts may explain why these whales are rarely seen at sea. Single animals are frequently observed with pods ranging in size up to seven animals. There are several records of mass strandings of Z. *cavirostris*.

Although most general accounts of Z. *cavirostris* list squid as the primary prey item, very few actual stomach contents have been analyzed, and care must be invoked in any interpretation. Stomach contents from Z. *cavirostris* caught off Japan varied consistently with a predominance of squid from animals taken in waters slightly under 1000 m in depth, but fish are the most abundant prey item found in animals in deeper waters. This evidence has been interpreted to suggest that Z. *cavirostris* is somewhat opportunistic in its feeding habits. Most of the prey items listed are open ocean, mesopelagic, or deep-water benthic organisms, concurring with the idea that Z. *cavirostris* is an offshore, deep-diving species.



Ectoparasites that have been reported include the barnacles *Xenobalanus* sp. from the flukes and dorsal fin and *Conchoderma* sp. on the erupted apical teeth. The following internal parasites have been reported from Z. *cavirostris*; Nematoda, *Anisakis* sp., *Crassicauda boopis*, and *Crassicauda crassicauda*; and Cestoda, *Phyllobothrium* sp. In the past, there have been few small cetacean fisheries that have taken *Ziphius*. In the Japanese *Berardius bairdii* fishery, Z. *cavirostris* have been taken on an opportunistic basis with catches of varying from 3 to 35 animals taken yearly. Although the *Berardius* fishery still continues, there been no takes of Z. *cavirostris* in recent years. It is probable that killer whales occasionally predate on Z. *cavirostris*.

Dall's Porpoise

Phocoenoides dalli

THOMAS A. JEFFERSON
Southwest Fisheries Science Center, La Jolla, California

Dall's porpoise is one of the better-known species in the family Phocoenidae. Largely because many individuals have been killed in fisheries recently, much has been learned of the biology of this species throughout its range in the North Pacific Ocean (Houck and Jefferson, 1999).

I. Characters and Taxonomic Relationships

Typical of the porpoise family, Dall's porpoise has a stocky body with a short, wide-based, triangular dorsal fin (Fig. 1). The dorsal fin is slightly falcate at the tip, but the entire fin may be canted forward in large adult males. The tail stock is deepened, especially in adult males. There is an extremely short, poorly defined beak. The flippers and flukes are small, and the fluke blades may also be canted forward.

Figure 1 *A Dall's porpoise swims just below the surface on a calm day in Monterey Bay, California. Because of their normally high-speed swimming, clear views such as this are somewhat uncommon.*

The color pattern is diagnostic. "Dall's" are largely dark gray to black with a large, ventrally continuous white patch that extends up about halfway on each flank. In addition, there is light gray to white frosting or trim on the upper part of the dorsal fin and on the trailing edge of the flukes. Some other light patches may exist, particularly around the base of the tail stock.

There are two major color morphs: one with a flank patch that extends forward to about the level of the dorsal fin (*dalli* type) and the other with a flank patch extending to about the level of the flippers (*truei* type). These forms were variously called separate species and subspecies in the past, but most recent work suggests that they are in fact color variants, with little or no other phenotypic difference. However, genetic analyses have confirmed that they do appear to form separate populations (Escorza, 1998).

Dall's porpoises reach maximum known lengths and weights of about 239 cm and 200 kg. Males grow longer and heavier than females, and adult males have secondary sexual characteristics (mentioned earlier). There is a great deal of geographical variation; size, shape, and coloration differences have been documented among different areas of the species' range.

The SKULL of the Dall's porpoise is larger than that of most other phocoenids and may reach 340 mm. The rostrum is wide at the base and relatively short (Fig. 2). There are prominent "maxillary shields" that make an angle of about 130° with the rostrum axis. The TEETH are extremely small, the smallest of any species of cetacean. They often do not rise above the level of the gums and are considered by many to be rudimentary.

Recent studies of mtDNA suggest that the previous classification of Dall's porpoise and the spectacled porpoise (*Phocoena dioptrica*) in the same subfamily was erroneous (Rosel *et al.*, 1995). These two species do not appear to be closely related, and their similarities may be the result of CONVERGENT EVOLUTION.

II. Distribution and Ecology

This species is found only in the North Pacific Ocean and adjacent seas (Bering Sea, Okhotsk Sea, and Sea of Japan),

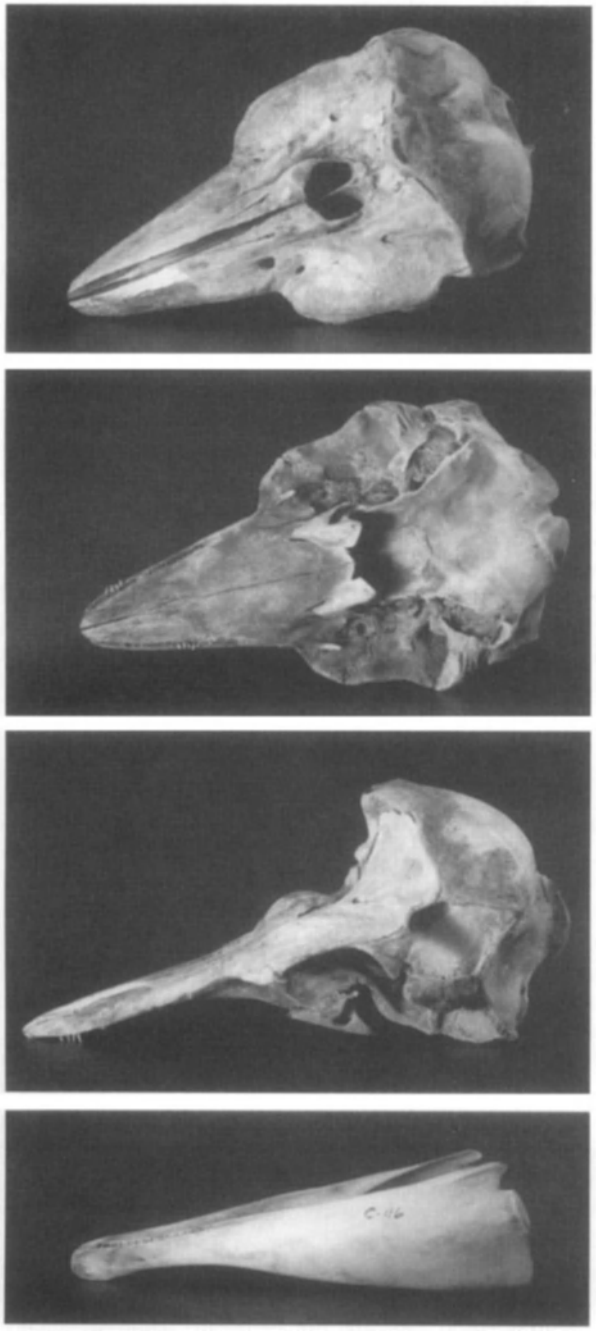

Figure 2 *Dorsal, ventral, and lateral views of the cranium, and a lateral view of the mandible, of a Dall's porpoise from central California.*

from about 32°–35°N (southern California and southern Japan) in the south to about 63°N (central Bering Sea) in the north. Up to 10 different populations and stocks are recognized, based on studies of morphology, genetics, and ecological parameters (see Amano and Miyazaki, 1992; Escorza, 1998). Sex-biased dispersal and migration patterns have been elucidated from molecular genetic analyses (Escorza, 1998).

This is an oceanic species that is found in deep offshore waters but also in deeper nearshore and inshore waters along the west coast of North America. There are seasonal inshore–offshore and north–south movements in both the eastern and western Pacific (Forney and Barlow, 1998), but in most areas these are very poorly defined.

Prey species include a wide variety of fishes and cephalopods. The most common prey items include small schooling fishes (such as herring, anchovies, mackerels, and sauries), mesopelagic fishes (such as myctophids and deep-sea smelts), and squids. KRILL, decapods, and shrimps have been found in some stomachs, but these are not considered to be common prey items. Amano and Miyazaki (1992) found that the skulls of porpoises grew to larger sizes in areas with higher productivity, suggesting that food availability affects growth.

Dall's porpoises in some areas appear to feed preferentially at night on vertically migrating fish and squid associated with the deep scattering layer. They are thought to be probably deep divers and capable of feeding at great depths.

III. Behavior and Life History

Small groups are most common, although large aggregations of several hundreds to about 1000 have been reported on occasion. Groups of over 20–30 porpoises are rather uncommon. Very little is known of the group structure of this species except that group composition is probably quite fluid.

These are very fast-swimming and active porpoises. They are often seen moving very quickly, slicing along the surface, creating a sloppy, V-shaped splash. These are called roostertail splashes (Fig. 3). Dall's porpoises are willing and capable bow riders and will converge on the bow of a fast-moving boat from all around. They have even been seen to "snout ride" on bow waves pushed forward by the heads of large whales.

Growth and reproductive parameters have been estimated for several populations in the central and western Pacific. Length at birth is about 100 cm. Estimates of length and age

Figure 3 *Most often when Dall's porpoises are seen at sea, they are swimming very fast and "roostertailing," as this porpoise is doing while riding the bow wave of a vessel in Southeast Alaska.*

at sexual maturity range from about 172 to 187 cm and 4 to 7 years for females and from 175 to 196 cm and 3.5 to 8 years for males (Houck and Jefferson, 1999; Ferrero and Walker, 1999). Gestation lasts about 10–12 months, and the length of lactation is not well known (but is most likely shorter than 1 year). The calving season is in the summer for all populations that have been studied to date, although some calves may be born outside the main season.

An intergeneric hybrid between a Dall's porpoise and a harbor porpoise (*Phocoena phocoena*) has been described (Baird *et al.*, 1998). Free-ranging animals resembling the confirmed hybrid are regularly observed around Vancouver Island, British Columbia, suggesting that such hybridization events may not be all that rare.

IV. Interactions with Humans

A number of threats to Dall's porpoise populations have been identified, including environmental POLLUTION and habitat alteration. However, the most serious threats are the various fisheries kills of this species. These include directed kills in Japanese waters and INCIDENTAL CATCHES in various fisheries (most prominently oceanic drift net fisheries) throughout the range. The most heavily impacted populations have been those in the central and western North Pacific.

Small numbers of Dall's porpoises have been kept in captivity in oceanaria and research institutes in the United States and Japan, but most individuals have not survived long. They are not currently sought after for captive display.

Delphinids, Overview

Rick LeDuc
Southwest Fisheries Science Center, La Jolla, California

The family Delphinidae is one of three extant (with Phocoenidae and Monodontidae) families in the cetacean superfamily Delphinoidea (which also includes three extinct families, Kentriodontidae, Odobenocetopsidae, and Albireonidae).

The popularity of oceanic dolphins (family Delphinidae) is arguably among the highest for wild animals, both for the general public and for scientists conducting research. However, despite this, they are very poorly understood compared to most terrestrial mammals of similar size. For most species of delphinids, basic aspects of their evolution, physiology, ecology, behavior, and population structure are virtually unknown. For the biologist, this presents real challenges and opportunities for dolphin research, not just to understand individual species, but also toward a better understanding of how they fit into marine ecosystems.

I. Taxonomic Overview

Delphinids likely arose in the mid- to late Miocene (11–12 mya) from kentriodontid-like ancestors and quickly radiated into many different morphological and ecological types. This early radiation produced precursors of many modern forms; many of the early delphinid fossils can be assigned to extant genera, particularly *Tursiops*. Today the Delphinidae is the most speciose family of marine mammals, with 34–36 recognized extant species arranged into 17–19 genera. At present, there is much uncertainty about the evolutionary relationships among the species of delphinids. Of the many recent classifications that have been proposed, two are depicted here. One represents a more traditional view of dolphin taxonomy (Table Ia) and the other a recent provisional classification based on molecular phylogenetic analyses (Table Ib). It should be mentioned that the latter classification is considered tentative and is based on analysis of a single gene. A more highly resolved representation of systematic relationships among delphinid species is not currently available. Also, there will no doubt be additional revisions proposed in the future, especially involving the apparently paraphyletic genera *Stenella* and *Tursiops*. In part, this changing nature of delphinid taxonomy is due to the new molecular and analytical tools currently available to researchers, but it also reflects the uncertainties about evolutionary relationships that have long been recognized by morphological systematists but have yet to be addressed.

II. Morphology

Dolphins have the typical morphological characteristics of toothed whales, such as spindle-shaped bodies, single external blowholes, telescoping of the skull such that the maxillary bones overlap the frontals in the supraorbital region, left-skewed cra-

TABLE 1
Two Recent Classifications of the Family Delphinidae

a. A classification of the family Delphinidae from Perrin (1989) reflecting a traditional view of species interrelationships

Family Delphinidae
- Subfamily Steninae
 - *Steno bredanensis*
 - *Sousa chinensis*
 - *S. teuszii*
 - *Sotalia fluviatilis*
- Subfamily Delphininae
 - *Lagenorhynchus albirostris*
 - *L. acutus*
 - *L. obscurus*
 - *L. obliquidens*
 - *L. cruciger*
 - *L. australis*
 - *Grampus griseus*
 - *Tursiops truncatus*
 - *Stenella frontalis*
 - *S. attenuata*
 - *S. longirostris*
 - *S. clymene*
 - *S. coeruleoalba*
 - *Delphinus delphis*
 - *Lagenodelphis hosei*
- Subfamily Lissodelphinae
 - *Lissodelphis borealis*
 - *L. peronii*
- Subfamily Cephalorhynchinae
 - *Cephalorhynchus commersonii*
 - *C. eutropia*
 - *C. heavisidii*
 - *C. hectori*
- Subfamily Globicephalinae

nial asymmetry, polydonty, and homodonty (in most). In some species, there has evolved a secondary reduction in the number of teeth, often seen as an adaptation for feeding on squid. The evolution of the delphinoid lineage saw the development of elaborate systems of pterygoid sinuses and better-isolated earbones, probably increasing their ability to echolocate and perhaps giving them an advantage over some of the other odontocete groups of the Miocene. The ancestors of the delphinids, the kentriodontids, were small dolphins with short to medium length rostra and, unlike most modern delphinoids, had symmetrical cranial vertices. The development in the Delphinidae of asymmetry in the cranial vertex and in the premaxillary bones suggests a further refinement of their echolocation capabilities and may partly explain their evolutionary success. The most noticeable difference between delphinids and their closest relatives, the phocoenids (true porpoises), is that the latter have spade-shaped teeth, whereas delphinids have conical or peg-like TEETH, as do most other odontocetes (toothed whales). They also differ from phocoenids in the shape of the facial region of the SKULL, including having a more distinct vertex. Within the Delphinidae, the most obvious variation among species relates to the feeding apparatus: the development of the rostrum, jaws, and teeth. There

is a broad spectrum of rostrum lengths and widths, tooth counts, and tooth sizes, reflecting the range of ecological niches occupied by the different species. For example, total tooth counts range from less than 10 in Risso's dolphin (*Grampus griseus*) (which has no teeth in the upper jaw) to 250 in the spinner dolphin (*S. longirostris*).

Delphinids also show wide variation in their external morphology. Only a few species (e.g., killer whale, *Orcinus orca;* pilot whales, *Globicephala* spp.) are dramatically sexually dimorphic, although many others may have more subtle dimorphism in body size and shape, coloration, and dorsal fin shape. In size they are small to medium cetaceans, with adults ranging from less than 1.5 m (*S. longirostris roseiventris* from the Gulf of Thailand, some species of *Cephalorhynchus*) to over 9 m (killer whale). Beak length varies widely, from very long on some (e.g., Indian Ocean common dolphin, *Delphinus tropicalis*) to very short on others (e.g., white-beaked dolphin, *Lagenorhynchus albirostris*). The external beak is completely absent in a number of delphinid genera, particularly in *Orcinus, Globicephala, Feresa, Pseudorca,* and *Peponocephala.* Those species that lack a beak often have heads that are rounded or even bulbous in profile. In most delphinid species, the dorsal fin is pointed and falcate, although it is triangular in some subspecies of *S. longirostris* and in male *O. orca,* round in Hector's dolphin (*C. hectori*), and even forward canted in males of the eastern spinner dolphin (*S. longirostris orientalis*). The dorsal fin is completely missing in the right whale dolphins (*Lissodelphis* spp.), and some hump-backed dolphins (*Sousa* spp.) have a pronounced hump at the base of the dorsal fin. The color patterns of delphinids are similarly varied, from bold black and white patterns (e.g., *O. orca* and some of the *Cephalorhynchus* spp.) to complex patterns of black, white, and gray (e.g., *Delphinus* spp. and *Stenella* spp.) to rather simple patterns of black (e.g., *Globicephala* spp.) or gray (e.g., *Sousa* spp.). The complex color patterns exhibited by some delphinids are composites of various elements, including stripes, capes, overlays, spots, and blazes. Regardless of their overall color and pattern, all dolphins tend to have a countershaded aspect, where the ventral surface is lighter than the dorsum. This countershading reduces an animal's visibility in the marine environment, where the ambient light comes from above. Besides being a mechanism for species recognition, the more complex patterns may also play a role in camouflage against waves at the surface or against the dappling of light penetrating the water.

III. Distribution and Habitat

As a group, the family Delphinidae reaches its highest diversity in tropical and warm temperate latitudes. There are numerous species with pantropical distributions and others that occur in tropical waters but are limited to one or two ocean basins. For example, the Atlantic spotted dolphin (*Stenella frontalis*) and the Clymene dolphin (*S. clymene*) are limited to the lower latitudes of the Atlantic Ocean, whereas the Indo-Pacific bottlenose dolphin (*Tursiops aduncus*) and the Irrawaddy dolphin (*Orcaella brevirostris*) only occur in the Indian and west Pacific Oceans. In colder areas one can find species in the genera *Globicephala, Cephalorhynchus, Lissodelphis,* and *Lagenorhynchus* (including *Sagmatias* and *Leucopleurus* of Table Ib). Interestingly, new genetic evidence suggests that the majority of these cold-temperate species appear to be closely related (subfamily Lissodelphininae in the classification of Table Ib). Only one recognized species, the long-finned pilot whale (*G. melas*), has an antitropical distribution, although some antitropical species pairs [e.g., *Lissodelphis* spp., and the dusky and Pacific white-sided dolphins *Lagenorhynchus* (or *Sagmatias*) *obscurus/obliquidens*] have been hypothesized as being single species with antitropical populations. Only one species, *O. orca,* ranges into high latitudes near the polar ice. Indeed, occurring also into mid- and low latitudes, this species is probably the most cosmopolitan of all the cetaceans.

Within this broad range of geographic distributions, delphinids occupy an equally diverse array of habitats. Many species occur far offshore in deep water, where the specifics of their ecological requirements are poorly known. In fact, in tropical seas, only the cetacean fauna of the eastern tropical Pacific has been studied extensively and systematically, and some differences in the species composition have been observed in different water masses. Here, areas with a stable mixed layer and a shallow thermocline are frequented by *Stenella attenuata, S. longirostris,* and the rough-toothed dolphin (*Steno bredanensis*), whereas areas with more variable conditions and some amount of upwelling contain species such as the short-finned pilot whale (*G. macrorhynchus*), short-beaked common dolphin (*Delphinus delphis*), striped dolphin (*Stenella coeruleoalba*), and melon-headed whale (*Peponocephala electra*). In any ocean, some of the offshore species may also range closer to the coast (e.g., *D. delphis*) or even have populations or sister species that are restricted to the coastal waters or the nearshore habitat [e.g., the long-beaked common dolphin (*D. capensis*), coastal populations/species of *Tursiops* spp]. In a few cases, coastal populations may ascend a short distance up rivers, but only two species [the tucuxi (*Sotalia fluviatilis*) of eastern South America and *Orcaella brevirostris* of the Indo-West Pacific] regularly occur far upstream. Both of these riverine species also have marine coastal populations.

IV. Social Organization and Behavior

All dolphin species are social to some degree. However, characteristic group sizes for the different species range from small pods of just a few individuals to large schools numbering in the thousands. Due to the difficulty of observing dolphins in the wild, especially those occupying offshore habitats, very little is known about the BEHAVIOR and social organization of most species. The populations that have been studied over longer time scales (e.g., *Orcinus orca* in the northeast Pacific and *T. truncatus* in the western Atlantic) are those that form relatively stable and small social groups within a short distance of the coast and whose movements do not regularly take them out of their study areas. Using photos to identify individuals via fin markings and color patterns, and supplementing observations with genetic data, associations of individuals and their genealogical relatedness have been recorded and monitored over generations. In these populations, some long-term associations and patterns have been noted. For example, it appears that bonds between individuals in a pod and/or between individuals

and a particular area (philopatry) tend to be stronger for females than males; the society can even be considered matrilineal for *O. orca*. A similar pattern was inferred from molecular data on *G. melas* in the North Atlantic. However, one must be cautious in extrapolating these social patterns to other delphinid species. For example, some species that occur on the high seas are found in schools that number in the thousands, and these associations appear much more fluid in their composition. In fact, social patterns observed for inshore groups of species like *T. truncatus* and *O. orca* may not even reflect the organization of offshore populations of the same species. What little is known about the social organization of offshore dolphins comes from direct observations of school sizes and life history data collected from mass strandings and fishery kills. In the few pelagic species studied (primarily *Stenella attenuata* and *S. longirostris*), there is evidence for promiscuity, strong mother–calf bonds, and some segregation by age and sex both within and between schools.

In addition to their intraspecific social organization, most dolphin species are seen at least occasionally in the company of other species. One famous association is between *S. attenuata* and *S. longirostris* in the eastern tropical Pacific, an aggregation that also includes yellowfin tuna (*Thunnus albacares*) and numerous species of seabirds. Other associations are frequently observed, such as *P. electra* associated with Fraser's dolphin (*Lagenodelphis hosei*) or *Tursiops truncatus* with *G. macrorhynchus*. A few species, such as the northern right whale dolphin (*Lissodelphis borealis*), have been observed with a wide variety of marine mammals, including mysticetes and pinnipeds.

Most of the information on the behavior and cognition of individual dolphins comes from studies of captive animals, primarily of *T. truncatus*. Apart from humans, dolphins have the highest ratio of BRAIN SIZE to body mass of any animal. Their intelligence and behavioral versatility are legendary and are still being explored. Using controlled experiments, dolphins have been shown to be capable of understanding complex commands, including the incorporation of abstract concepts and variations of syntax, and of devising novel behaviors of their own volition. Although behavioral activities in the wild are more difficult to interpret, there are well-documented observations of cooperative hunting (e.g., *O. orca*) and play behavior (e.g., *T. truncatus*). In fact, *T. truncatus* has been observed surfing in many coastal areas, and many dolphin species are avid riders of the bow wakes of ships and large whales. Some species regularly perform aerial maneuvers such as high leaps and flips and, in the case of *S. longirostris*, spins. At the present time, the function of many of these behaviors can only be guessed at. Dolphins also have an array of vocalizations, such as clicks, whistles, and squeals, that are used in part for their well-developed echolocation and in part for communication. However, only those species kept in captivity have been studied extensively. For the rest, due to the logistic difficulties of collecting data on fast-swimming dolphins in the pelagic realm, the vocalizations of only a few species have even been recorded, and those vocalizations are difficult to understand in terms of functionality.

V. Feeding

Ecologically, dolphins have also radiated dramatically. There are species that forage on fish, squids, and/or other invertebrates. A few species (e.g. *O. orca*, false killer whale, *Pseudorca crassidens*) even take mammalian prey, including large whales and pinnipeds. While some have fairly specific diets, a few species have rather broad tastes. In those species that eat a wide variety of prey items, one type of food (e.g., fish vs squid) may predominate. For some species (e.g., *S. coeruleoalba*), the preferred food type varies among populations, whereas in others (e.g., *S. attenuata*), it may even vary among individuals within a population, depending on their sex and life history stage. Perhaps the most dramatic segregation of foraging strategies is seen in the populations of *O. orca* in the eastern North Pacific, where two distinct groups exist sympatrically: one specializing on mammals and the other on fish. Individual species of delphinids usually forage in a particular part of the water column, specializing in epipelagic prey (e.g., *S. attenuata*), mesopelagic prey (e.g., *Lissodelphis* spp.), or even benthic prey (e.g., some species of *Cephalorhynchus*). The few measurements of swimming speeds (often anecdotal) suggest that some may exceed 20 knots in short bursts, although prolonged cruising speeds are generally on the order of 5–9 knots (9–17 km/hr). Direct data on diving depths for wild delphinids are practically nonexistent. However, *S. longirostris*, a relatively small species, is thought to dive to at least 200–300 m, based on an analysis of prey items. Greater depths are no doubt possible for larger species (e.g., *Globicephala* spp.) that feed mainly on larger squid. In fact, a trained pilot whale (*Globicephala* sp.) is thought to have reached 610 m in an experimental situation. At the other extreme, certain populations of two dolphin species have been known to intentionally beach themselves in pursuit of prey. In one case, groups of *T. truncatus* drive and pursue schooling fish onto the beach, and in the other, *O. orca* beach themselves to take pinnipeds hauled out near the water's edge. The behavioral adaptability of dolphins may be best illustrated by those species who incorporate human activities into their foraging, such as the *Sousa chinensis* that feed on trawl discards or the *O. orca* that raid long lines for their catch. Along the Gulf of Mexico coast of the United States, there are even some *T. truncatus* that feed within shrimp trawl nets, many of whom are "caught," released, and netted again.

VI. Life History

As with many aspects of dolphin biology, there is much that is unknown about the reproductive biology of most species, although many of the parameters seem to be correlated with body size. Estimated ages at sexual maturity range from about 6 (*D. delphis*) to 16 (*O. orca*) years. Like most mammals, when the age at sexual maturity differs between the sexes, it is usually the females that reach maturity at a younger age. Like other cetaceans, dolphins bear single young. Gestation periods are rarely well documented and are thought to range from about 9 to 16 months, although most have a period of less than a year (16 months was an estimate for *G. melas*). Most species appear to show at least some seasonality to their breeding, although this varies in degree. Estimates of calving intervals similarly vary, even among populations within species or among studies, ranging from just over a year for many species to approximately 8 years in one study of *O. orca* from the eastern North Atlantic. Reliable estimates of longevity are quite rare, but range from

around 20 years for smaller species up to about 60 years for females of the larger species. In the large species, which tend to be more sexually dimorphic, females may live 15–20 years longer than the males. The causes of natural mortality, when they can be ascertained, are usually attributed to parasites and pathogens or to predation by killer whales or sharks.

VII. Abundance and Conservation

Some delphinid species are no doubt the most numerous of cetaceans, occurring in schools of thousands in large portions of the world ocean. Reliable global estimates for most species do not exist, but in the eastern tropical Pacific alone, some species (*Stenella attenuata, D. delphis*) number in the low millions. At the other end of the spectrum, species with restricted ranges (e.g., *C. hectori*) may have total population numbers of only a few thousand. Despite (and in some cases because of) their general abundance, dolphins face numerous anthropogenic threats. They are still hunted in some parts of the world by harpoon, drive fisheries, or nets. Two well-known examples are the drive fisheries for *S. coeruleoalba* in Japan and for *G. melas* in the Faroe Islands. There are many other dolphin fisheries still in operation, mostly in developing countries, often despite the protection of assorted laws and treaties. Usually the meat from intentional takes is for human consumption, although in some areas it is used as bait in crab pots or shark long lines. In addition to the mortalities from directed fisheries, many dolphins are also taken incidentally in the course of other fishing operations. The dolphin mortality from the eastern tropical Pacific tuna purse seine fishery has been well studied and greatly reduced in recent years. However, many dolphins of a variety of species are still caught in coastal and offshore gill nets all over the world. It is difficult to accurately assess the severity of these threats to dolphin populations given that the extent of the mortality can only be roughly guessed at in most cases and the sizes of the affected populations are largely unknown. Nevertheless, mortality from fisheries bycatch may present major threats to some dolphin populations.

Compounding these direct kills are indirect effects from human activities. In some areas, large-scale fishing operations may adversely affect dolphin populations, either by direct competition for prey or by alteration of a region's ecology. Pollution also undoubtedly takes its toll on dolphin health, particularly in coastal areas, either by direct poisoning effects or by making the animals more susceptible to pathogens and parasites. Subtle effects on fitness such as decreases in reproductive capacity or shortened life spans are almost impossible to detect, but large-scale mortalities are difficult to ignore and are not at all unusual. There have been mass STRANDINGS in recent years along the Mediterranean coast, in the southeastern United States, and in the Gulf of California in Mexico. These large-scale die-offs often involve multiple species (although one species usually predominates) and may occur over periods of several months. It is difficult to determine if such mass mortalities are increasing in frequency in recent years because historical events may not have been documented adequately. It is also difficult to assess their impact on dolphin populations. Nevertheless, they are a cause for concern if for no other reason than as indicators of the declining health of marine ecosystems.

Delphinoids, Evolution of the Modern Families

LAWRENCE G. BARNES
Natural History Museum of Los Angeles County, California

The odontocete families usually included in Delphinoidea are Kentriodontidae, Odobenocetopsidae, Albireonidae, Delphinidae, Phocoenidae, and Monodontidae. Among these, only the last three have Recent (=living) representatives and are discussed in this article. Odobenocetopsidae and Al-

bireonidae are small families, consisting of a few known fossil species. The fossil kentriodontids are diverse and are the basal delphinoid family.

I. Family Monodontidae: Belugas, Narwhals, and Relatives

The family Monodontidae includes two living Arctic species: the living beluga (*Delphinapterus leucas*), in the subfamily Delphinapterinae, and the tusked narwhal (*Monodon monocerus*), in the subfamily Monodontinae. The SKULLS of these two cetaceans are similar, with the tusk of the narwhal differentiating them superficially. The fossil record of Monodontidae extends back to the Late Miocene (circa 11 or 12 Mya). Monodontids appear most closely related to the porpoises of the family Phocoenidae and to the dolphins of the family Delphinidae, but detailed study of their interrelationships has yet to be made.

Fossil representatives of Delphinapterinae, animals having a relatively narrow and slightly downturned snout like that of the modern beluga, *Delphinapterus*, have been collected from deposits bordering the western North Atlantic and from California and Japan.

Fossils of latest Miocene and Pliocene members of the extinct, aberrant, broad-headed monodontid *Denebola* are known from coastal sites in central and southern California and various localities in Baja California. The skull of this genus is broad and the snout is wide, flat, and blunt, causing it to mimic the skull of the pilot whales (family Delphinidae, genus *Globicephala*). Phylogenetic analysis is needed that would elucidate the relationships of this group to the other monodontids. We do not yet understand the evolutionary origin of the bizarre spiral-tusked narwhal of the Arctic because no fossils have been found.

The fossil record of the Monodontidae demonstrates that the group was much more numerous, diverse, and widespread in the past than it is now and that it was characteristic of the temperate and subtropical latitudes of the North Atlantic and the North Pacific oceans. No monodontid has been found in the Southern Hemisphere. The fossil distribution is seemingly paradoxical to the present strictly Arctic distribution, and the living monodontid species are relics. Past members of the family may have occupied the ecologic niches of several species of modern dolphins. The sole surviving species have relict distributions in a possibly marginal habitat.

II. Family Delphinidae: Dolphins

The modern, mostly pelagic dolphins of the family Delphinidae are the most diverse living family of Cetacea and are nearly cosmopolitan in the world's oceans. The family includes a taxonomically and ecologically diverse range of small to large species with long or short rostra, and narrow or broad rostra. Rostral shape and numbers and size of TEETH are related to diet, with the various species ranging from generalists, to predators, to squid eaters. Common names reflect the animal's sizes: some of the large "dolphins" are called pilot whales (*Globicephala* spp.) and killer whales (*Orcinus orca*), and smaller species are called dolphins, such as *Delphinus* spp. All Delphinidae are unified by skull osteology, especially details of the left-skewed asymmetrical cranial vertex and narial region, the basicranium, and the periotic.

Although the delphinids are the most diverse group of living cetaceans, they are surprisingly rare in the fossil record. The oldest documented delphinid is Late Miocene (about 10 to 12 million years ago) in age from southern California, and delphinids are not very common in subsequent latest Miocene and Pliocene deposits. All pre-Late Miocene supposed fossil delphinids are now known to be members of other odontocete families.

The present abundance of delphinids is apparently the result of explosive evolution that probably occurred in the later part of the Pliocene, resulting in the replacement of the earlier more diverse kentriodontids, phocoenids, and monodontids. The rather abrupt appearance of Delphinidae, in relative abundance, in Pliocene time is a notable phenomenon in cetacean evolution.

Morphology of the earliest fossil delphinid indicates that the family probably arose from within the primitive, extinct family Kentriodontidae, but no definitive study has been made that would prove this.

III. Family Phocoenidae: Porpoises

The true porpoises of the family Phocoenidae have a fossil record dating back to the Late Miocene, or about 11 or 12 million years ago. All pre-Pliocene fossil records of this family from the Atlantic realm are suspect. Phocoenids have a raised eminence on each premaxilla anterior to the nasal openings, a lobe of the pterygoid air sinus extending dorsal to the orbit between the frontal and maxillary bones, and anteriorly retracted posterior premaxillary terminations. The short rostra, rounded crania (paedomorphic characters) and spatulate teeth of living phocoenids only appear in the more recent members of the group, known from the Late Pliocene and more recently. Late Miocene phocoenids have longer snouts, more prominent cranial crests, and conical tooth crowns, all of which are primitive characters, which the early phocoenids share with kentriodontids or delphinids. Phocoenids were much more diverse in the past than now, and in rocks dating from 3 to 12 million years ago around the North Pacific margin their fossils are more diverse and more abundant than those of delphinids.

The oldest apparent phocoenid is represented by a single periotic of Middle Miocene age from Baja California Sur, Mexico. In morphology it closely matches the holotypic periotic of the most primitive named phocoenid, *Piscolithax tedfordi*, also from Baja California, which is considerably younger (latest Miocene, circa 9 Mya). However, *P. tedfordi*, while being the most primitive named phocoenid is for its time a relict taxon, because the somewhat more derived *Salumiphocaena stocktoni* from southern California is about 10–12 million years old. *Piscolithax* was a large phocoenid, approximately the size of extant *Tursiops truncatus*, and had relatively large and wide pectoral flippers.

Piscolithax and other relatively primitive genera of Phocoenidae, some with unusually long rostra, have been discovered in Late Miocene and Pliocene deposits in coastal Peru. There is no published fossil record that would elucidate the origins of the living genera *Neophocaena*, *Phocoena*, and *Phocoenoides*.

Dental Morphology (Cetacean), Evolution of

MARK D. UHEN
Cranbrook Institute of Science, Bloomfield Hills, Michigan

Modern cetaceans exhibit some of the most highly derived dentitions in all of Mammalia. Living odontocetes exhibit a wide variety of conditions from some of the highly polydont delphinids to the complete lack of teeth in some monodontids. Living mysticetes completely lack teeth as adults. Add to this even more divergent conditions in fossil mysticetes, odontocetes, and their early forebears, the archaeocetes, and the result is a broad range of conditions in which is embedded the story of how modern cetacean dentitions arose from the more typically mammalian teeth.

Acreodi (Mesonychia + Triisodontidae) is currently thought to be the sister taxon to Cetacea based on paleontological evidence. Some molecular studies have indicated that Cetacea is nested within ARTIODACTYLA, possibly with Hippopotamidae as its sister taxon. Acreodi are diphyodont and heterodont, with a plesiomorphic dental formula of 3.1.4.3/3.1.4.3. Their incisors are single rooted and in an arc across the front of the jaw. Mesonychians and cetaceans all have reduced trigonids and talonid basins, and lack an M_3 hypoconulid.

I. Archaeocetes

Archaeocetes are diphyodont and heterodont with their incisors in line with the cheek teeth and separated by diastemata. The anterior TEETH are conical and single rooted, and the premolar series forms a morphological gradient from the anterior teeth to the posterior premolars along with an increase in size such that P_3 or P_4 is usually the largest upper or lower tooth. Upper and lower P_1 may be single or double rooted, depending on the taxon, and the other premolars are double rooted (but see Albright, 1996). The premolars are generally equilaterally triangular in lateral view. The lower molars have steep mesial edges and more gradually sloping distal edges. The lower molars lack trigonid basins and retain hypoconids but have lost the talonid basin. The lower molars also have a vertical groove on their mesial margins. The tooth row is closed in this region such that there are no diastemata between the teeth, and the next anterior tooth rests in the groove of the distally adjacent molar. Archaeocetes often exhibit vertical wear facets on the buccal surfaces of the lower molars that resulted from contact with the lingual surfaces of the upper cheek teeth during chewing (O'Leary and Uhen, 1999).

A. Nonbasilosaurid Archaeocetes

Nonbasilosaurid archaeocetes have a dental formula of 3.1.4.3/3.1.4.3 that they share with mesonychians and other early mammals and that distinguishes them from the later basilosaurids. Nonbasilosaurid archaeocetes have a paracone (mesial) and metacone (distal) on the buccal margins of their molars, and a protocone projecting lingually. Pakicetids have single-rooted P_1s, which distinguish them from ambulocetids. Ambulocetids have a protocone lobe on the upper molars that is smaller than that in pakicetids and larger than that in remingtonocetids and protocetids (Thewissen *et al.*, 1996). Remingtonocetids have labiolingually narrow incisors and premolars; upper molars large and narrow, sometimes lacking a lingual third root, and crenulations on the cutting edges of the teeth, which distinguishes them from other nonbasilosaurid archaeocetes (Kumar and Sahni, 1986). Protocetids have robust teeth with upper molars having three roots and the cheek teeth lacking accessory denticles. (Fig. 1, but see *Georgiacetus* later).

B. Basilosauridae

Basilosaurids have a number of synapomorphies that distinguish them from other archaeocetes. Upper and lower first premolars are replaced in dorudontine basilosaurids, but it is unclear how broadly this character is distributed within the archaeocetes (Uhen, 2000). Basilosaurids lack M^3, giving them a dental formula of 3.1.4.2/3.1.4.3. The cheek teeth of basilosaurids have accessory denticles along their mesial and distal margins, flanking an apical cusp. These apical cusps are homologous with the paracone on the uppers and paraconid on the lowers. It is unclear whether any (or all or none) of the accessory denticles are homologous with more primitive mammalian cusps. There are usually no accessory denticles on the mesial margins of the lower molars (for exceptions, see Uhen, 1996). While accessory denticles of the size and number seen in basilosaurids are unknown in earlier cetaceans, *Georgiacetus* possesses small incipient accessory denticles on some of the cheek teeth. Also, accessory denticles similar to those of basilosaurids can be seen on dP_4 of *Pappoce-*

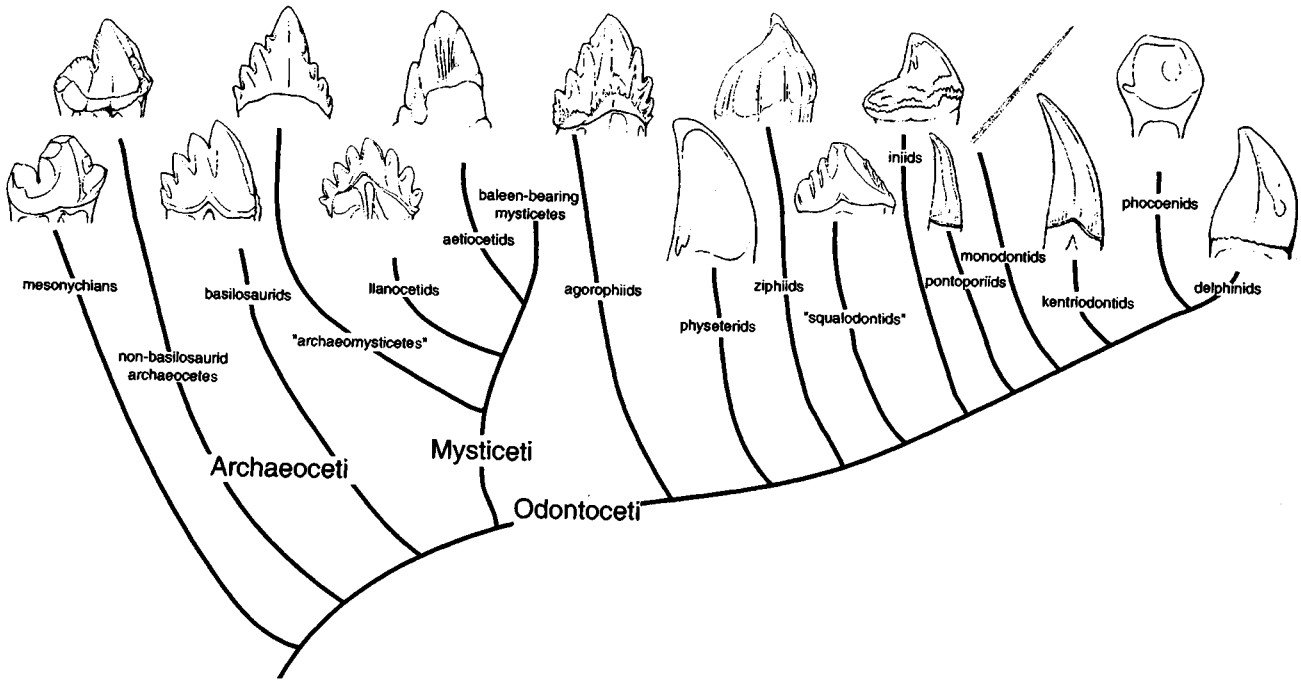

Figure 1 *Phylogenetic relationships of cetaceans with examples of dental morphology. For those cetaceans with heterodont teeth, lower molars (posterior cheek teeth) are shown.*

tus lugardi. The lingual posterior root found on the upper posterior cheek teeth of earlier cetaceans is fused to the buccal posterior root on these teeth in basilosaurids, as shown by the presence of a groove in the root and a lingual expansion of enamel on the crown, which lacks a trigon basin and protocone.

II. Mysticeti + Odontoceti

The fossil record of archaeocetes ends in the Late Eocene. Mysticeti and Odontoceti can be distinguished from archaeocetes based on the presence of some kind of telescoping (Barnes, 1984), but telescoping can hardly be used as a synapomorphy of Mysticeti + Odontoceti, as telescoping is manifested in different ways in each group and is almost certainly not homologous between them. Monophyodonty may serve as a synapomorphy for Mysticeti + Odontoceti. Even though modern mysticetes lack teeth as adults, they develop embryonic tooth buds that are later resorbed (Karlsen, 1962). In addition, early fossil mysticetes have well-developed teeth as adults (Emlong, 1966; Mitchell, 1989; Barnes and Sanders, 1996a,b). Even a late-occurring archaeocete has been described that may be monophyodont (Uhen and Gingerich, 2000). Early mysticetes and odontocetes are similar to archaeocetes in that they are heterodont, with a morphological gradient from conical, single-rooted anterior teeth to triangular (or rounded) multirooted cheek teeth with accessory denticles.

A. Odontoceti

Modern odontocetes can be generally characterized as being polydont and monophyodont, with single-rooted teeth that grow throughout life, but there are numerous counterexamples to these generalizations in both modern and fossil cetaceans (discussed later). The earliest odontocetes show only limited polydonty, with *Agorophius* having 8 and *Xenorophus* with 10 teeth (Fordyce, 1982 and references therein). Polydonty could have originated by intercalation of deciduous and permanent teeth and could have been further increased in later odontocetes by the addition of supernumerary teeth, but it would be difficult to explain why no odontocete is known that exceeds three teeth in the premaxilla under this scenario (Fordyce, 1982). The recent description of early mysticetes with one extra molar in each quadrant (Barnes and Sanders, 1996a,b) may indicate that polydonty arose prior to the split of Mysticeti and Odontoceti by the terminal addition of teeth, although many other toothed mysticetes appear not to possess polydonty at all (Emlong, 1966; Fordyce, 1982).

All modern and fossil odontocetes are thought to be monophyodont (Fordyce, 1982). It is unclear whether the teeth of modern odontocetes are homologous with the deciduous or adult teeth (or both) of archaeocetes. A newly described archaeocete that appears to possess adult teeth in a skeletally juvenile individual suggests that the teeth of all Mysticeti + Odontoceti may be adult teeth, but Karlsen (1962) suggested that the embryonic tooth buds of mysticetes were homologous with the deciduous dentition of more primitive mammals.

Early odontocetes Agorophiidae (including *Xenorophus*), Simocetidae, Waipatiidae, and Squalodontidae are all considerably heterodont. Their anterior teeth are conical with long, single roots. These teeth grade into teeth with a more triangular shape with multiple accessory denticles on the anterior and posterior edges of the teeth and two roots. The most posterior lower cheek teeth may lack accessory denticles on their anterior edges. These differences in tooth form are reminiscent of the differences along the tooth rows of archaeocetes, but the teeth are smaller compared to the size of the skull.

Physeteroidea includes two genera, *Physeter* and *Kogia*. Modern physeteroids usually lack upper teeth (or have tiny upper teeth that do not erupt), but some fossil representatives (such as *Scaldicetus*) have similarly sized teeth in the lower and upper jaws (Hirota and Barnes, 1994).

Ziphiidae are thought to have secondarily reduced the dentition from a primitively polydont condition. One modern species, *Tasmacetus shepherdi*, and additional fossil species are polydont. In some other modern species, the females usually lack erupted teeth, and males have one tooth on each side of the lower jaw and none in the upper jaw. The teeth of male ziphiids take on different forms in different species.

Iniidae have rugose heterodont teeth that are expanded lingually in the posterior portion of the jaw. Monodontidae have very reduced dentitions. Male narwhals (*Monodon monoceros*) have a single, long, spiral tusk, usually on the left side with a small unerupted tooth on the right. Females usually have two unerupted teeth. Both male and female belugas (*Delphinapterus leucas*) generally have nine teeth in each upper and eight in each lower row. One related fossil, *Odobenocetops*, has a walrus-like skull with one large tusk-like tooth and another shorter tusk on the opposite side (de Muizon, 1993). Members of the extinct Kentriodontidae have small conical teeth that are generally homodont, a feature shared with one of their likely descendants, the Delphinidae, but not with another, the Phocoenidae, which have numerous small spatulate teeth or (in one species) peglike vestigial teeth that may be embedded in gum tissue.

B. Mysticeti

Despite the lack of teeth in modern mysticetes, they are thought to have evolved from toothed ancestors in part because they develop tooth buds as embryos that are later resorbed (Karlsen, 1962), and many tooth-bearing early mysticetes are known from the Oligocene epoch (Fordyce and Barnes, 1994). All post-Oligocene mysticetes are baleen-bearing and lack teeth (Fordyce and Barnes, 1994).

One group of toothed mysticetes includes species with archaeocete-like teeth (Fordyce, 1989; Barnes and Sanders, 1996a,b). This group could be delimited to include *Llanocetus denticrenatus* from the late Eocene of Antarctica (Mitchell, 1989). Mitchell (1989) placed *Llanocetus* in the family Llanocetidae, which he included in a new infraorder Crenataceti from which he excluded all other toothed mysticetes known at the time. *Kekenodon onamata* and *Phococetus vasconum* may also be members of this group (Fordyce, 1992). The teeth of this group are similar in size to those of archaeocetes, and the cheek teeth are similarly double rooted and have accessory denticles. Some species have an extra molar in each quadrant over the count of basilosaurids, yielding three upper and four lower molars (Barnes and Sanders, 1996a,b). These teeth may have been used to filter food from seawater, as the teeth generally lack wear resulting from tooth/food contact (Mitchell, 1989).

The second group of toothed mysticetes includes species that all have tiny teeth that are conical anteriorly and have tiny denticles posteriorly, but are all single rooted. All of these species have been placed in the Aetiocetidae. Some aetiocetids have the plesiomorphic number of teeth for archaeocetes (11), whereas others are polydont. Aetiocetids are not thought to have had baleen and may have used their small teeth for filter feeding. The small, toothed mysticete *Mammalodon* from the Late Oligocene or early Miocene of Australia may be related to the aetiocetids, but it is difficult to compare in part because it is known only from the type specimen, and its teeth are highly worn (Pritchard, 1939; Fordyce and Barnes, 1994).

The earliest baleen-bearing mysticetes that lack teeth are placed in the Cetotheriidae, but this taxon has long been recognized as a wastebasket taxon in need of serious revision. The earliest cetotheres are from the Late Oligocene (contemporaneous with toothed mysticetes) and have worldwide distribution. Cetotheres may be ancestral to balaenopterids, but their relationship to other modern mysticete families is unclear.

Desmostylia

Daryl P. Domning
Howard University, Washington, DC

The Desmostylia are the only completely extinct order of marine mammals. They were HIPPOPOTAMUS-like amphibious herbivores (Fig. 1) that were confined to the North Pacific Ocean and are known only as fossils of Oligocene and Miocene age. [For comprehensive references to the published literature on desmostylians, see Domning (1996).]

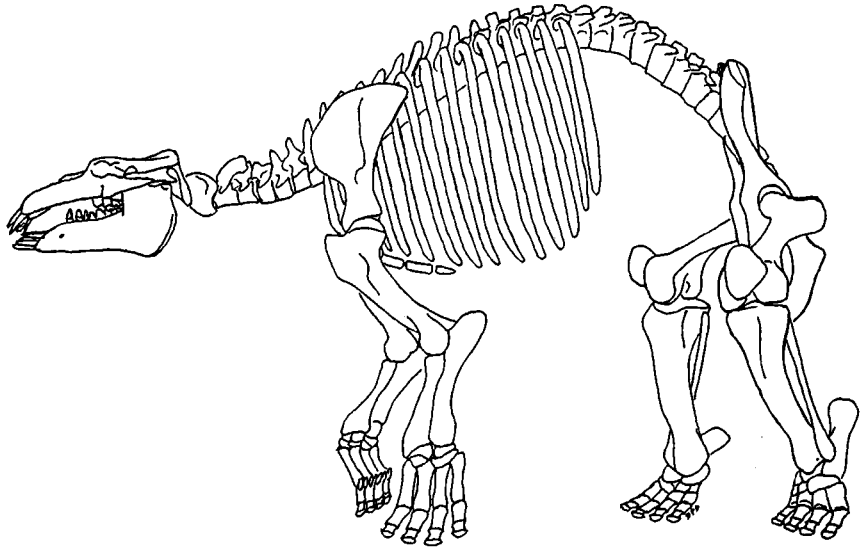
I. Desmostylian Relationships, Origins, and Distribution

Desmostylians have undergone more of a taxonomic odyssey than perhaps any other mammals. Although they were placed initially (and afterwards, most commonly) among either the Sirenia or the Proboscidea, various authors later assigned them to the Monotremata, Marsupialia, Multituberculata, or an order of their own. The latter view prevailed only in 1953. Today they are classified in the supraordinal group Tethytheria, together with the living Sirenia and Proboscidea; the Proboscidea are probably their sister group. The teeth of the most primitive desmostylians closely resemble those of anthracobunids, early tethytheres, which are sometimes considered true proboscideans.

Because the most primitive known desmostylians, as well as other early tethytheres, are found in Asia, this continent, bordering the eastern part of the ancient Tethys Sea, is likely to have been the area where this order arose, probably during the Paleocene or Eocene. However, desmostylians do not appear in the fossil record until the Late Oligocene, less than 30 million years ago. By that time they had already spread to the North American shore of the Pacific; and from then to their extinction some 20 million years later, they inhabited the North Pacific littoral from Japan to Baja California.

II. Anatomy and Mode of Life

The desmostylian skull (Fig. 2) features a more or less long, narrow, and little-deflected rostrum; dorsally protruding orbits; a stout paroccipital process; an external auditory meatus nearly enclosed ventrally by contact of the posttympanic and postglenoid



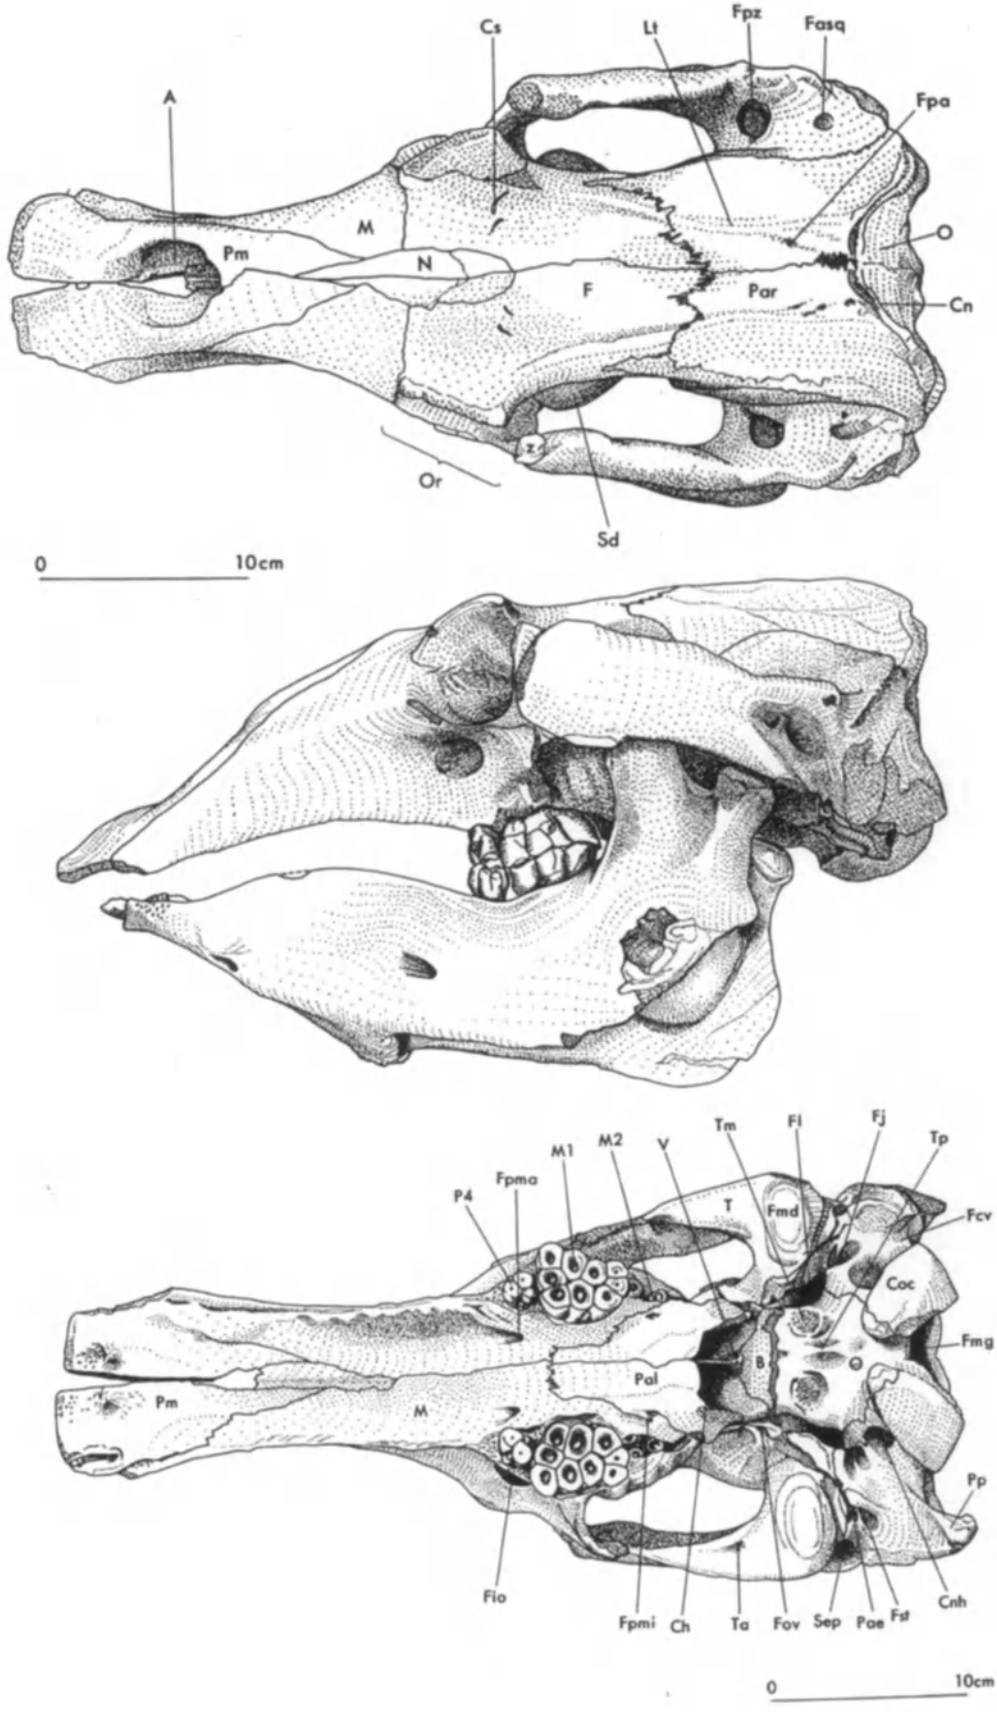


Figure 1 *Skeleton of* Paleoparadoxia tabatai, *a Miocene desmostylian, in terrestrial pose. Total length is about 2.2 m. processes; and a large epitympanic sinus opening into the temporal fossa. The dental formula is primitively 3.1.4.3, with procumbent, transversely aligned incisors and canines; the lower canine is especially enlarged. The fourth lower deciduous premolar is primitively trilobed. The body (Fig. 1) is stout and compact, with a relatively short neck, a deep thorax, a broad sternum with paired plate-like sternebrae, a strongly arched lumbar spine, and a very reduced tail. The limbs are robust, with considerable torsion in the tibia and an ankle joint that is oblique to the tibial shaft (conditions also seen to varying degrees in many noncursorial land mammals). The metacarpals are longer than the metatarsals. The bones show some osteosclerosis (increased density) but no pachyostosis (increased volume).

Controversy over desmostylians' structure and posture has even surpassed the disagreements over their classification. Once complete skeletons were discovered, showing that they possessed four stout limbs and were capable of some sort of locomotion on land, paleontologists and artists created a startling variety of reconstructions, including ones resembling hippopotami, tapirs, sea lions, crocodiles, and creatures unlike anything else (see Inuzuka, 1982). The interpretations presented most recently and defended in the most detail have portrayed them as hauling out in the manner of sea lions (Repenning), as walking with the limbs sprawled in a "herpetiform" stance (Inuzuka), or as keeping the legs under the body in a more conventional land-mammal fashion, with resemblances to ground sloths (Domning, 2001; Fig. 1).

In contrast, their aquatic behavior has occasioned little argument. Their style of swimming is generally agreed to have been like that of polar bears; i.e., alternate paddling with the forelimbs while the hindlimbs were used for steering. Because desmostylian fossils are found exclusively in marine deposits, there has also never been any doubt expressed that they were strictly marine mammals, despite the lack of clearly aquatic specializations in their skeletons.

The peculiar, heavily enameled tooth structure of the more highly derived desmostylians has occasionally led to suggestions that they fed on molluscs or other shelled prey. However, these teeth tend to be high crowned, like those of grazing ungulates, rather than low, broad, and pavement-like as seen in animals that do crush shellfish. Moreover, the TEETH of earlier desmostylians closely resemble those of undoubted herbivores. Hence a diet of marine plants for all desmostylians is now generally conceded.

III. Diversity

Only about six genera and fewer than a dozen species are currently recognized in this order (Table I). They could be grouped into at least two families, but conflicting schemes of family-level classification have not been completely reconciled. All these taxa, so far as is known, had broadly similar postcranial skeletons, and they are distinguished mainly by details of SKULL and dentition. The cladistic relationships of the desmostylian genera are generally agreed to be as follows: (*Behemotops* (*Paleoparadoxia* (*Cornwallius* (*Desmostylus, Kronokotherium,* and *Vanderhoofius*)))). The relationships among the latter three genera have yet to be clarified.

The most primitive form named so far is the Late Oligocene *Behemotops,* an animal nearly the size of a Nile hippopotamus and with low-crowned, anthracobunid-like teeth. The Miocene *Paleoparadoxia* (Fig. 1) is similar, but has a more retracted nasal opening, fewer premolars, and a long postcanine diastema. *Cornwallius,* another Late Oligocene genus, shows a tendency for the molar cusps to become more columnar. This trend continued in the Miocene with the genera *Kronokotherium, Vanderhoofius,* and *Desmostylus;* the latter name, meaning "bundle of columns," expresses the appearance of a molar in these most highly derived and characteristic members of the group (Fig. 2). The procumbent incisors and canines are variously reduced, sometimes leaving only the large lower canines as digging organs, and the adult cheek dentition comprises only molars.

The diversity of desmostylians was constrained by their limited geographic range and dietary opportunities. Apparently they were adapted to cooler climates than the tropical sirenians, but they seem to have succumbed to competition from these more fully aquatic herbivores as soon as hydrodamaline sirenians evolved the ability to spread into the cool home waters of the desmostylians.

TABLE I
Genera of Desmostylia and Their Temporal Range

Genus	*Range*
Behemotops	Late Oligocene
Paleoparadoxia	Early to Late Miocene
Cornwallius	Late Oligocene
Desmostylus	Early to Late Miocene
Kronokotherium	?Early to ?Middle Miocene
Vanderhoofius	Middle Miocene

Dialects

JOHN K. B. FORD
Fisheries and Oceans Canada, Nanaimo, British Columbia

Consistent variations in the underwater vocalizations of marine mammals can exist among individuals, groups, or populations. Differences in vocal patterns between geographically isolated populations have been described in several species of pinnipeds and cetaceans. Good examples are regional variations in the vocal repertoire of the Weddell seal (*Leptonychotes weddellii*) (Thomas and Stirling, 1983) or the major differences in the songs of humpback whales (*Megaptera novaeangliae*), in different ocean areas (Payne and Guinee, 1983). These types of variations have occasionally been referred to as dialects, but are more appropriately termed geographic variations (Conner, 1982). Such differences likely result from long-term geographic and, therefore, reproductive isolation, leading to genetically determined distinctiveness, although the potential for cultural variation cannot be ruled out. Pinnipeds and cetaceans are among the few mammalian orders in which vocal mimicry and learning have been documented (Janik and Slater, 1997). Transmission of vocal patterns across generations may thus depend more on cultural than on genetic mechanisms. Copying errors and other forms of cultural mutation and drift may be responsible for at least a portion of the vocal differences between distant populations. Geographic variation in vocal patterns most likely represents epiphenomena, or by-products, of social and genetic isolation.

Vocal learning is most probably the primary mechanism involved in the evolution of dialects among local, interacting populations or groups of marine mammals. Dialects are well known in birds, but appear to be quite rare among marine mammals or, for that matter, mammals generally. They have only been described in two marine mammal species: killer whales (*Orcinus orca*) and sperm whales (*Physeter macrocephalus*). In British Columbia, matrilineal kinship groups, or pods, of "resident" killer whales have repertoires of 7–17 call types that vary among pods (Ford, 1989, 1991). All pods have distinctive features in their call repertoires, and thus each has a unique dialect. Certain pods share a portion of their call repertoires with others, and these are considered to belong to the same acoustic clan, each of which is acoustically distinct. Pods belonging to different clans have overlapping ranges and interact frequently, despite having very different call repertoires. New pods form by gradual fission of older, larger pods, along maternal lines. This process appears to be accompanied by divergence of common dialects, thus dialects reflect the historical matrilineal genealogy of pods within clans. Evidence indicates that minor though significant repertoire divergence exists among closely related matrilines within pods (Deecke *et al.*, 2000; Miller and Bain, 2000). Dialects likely serve as acoustical "badges" that help maintain cohesion and integrity of matrilineal groups. Genetic studies by Barrett-Lennard (2000) suggest that dialects in British Columbian killer whales also serve as a mechanism promoting outbreeding. Group-specific dialects have also been found in Norwegian killer whales (Strager, 1995) and are to be expected in other populations of the species that are strongly matrilineally organized.

The other cetacean species with group-specific dialects, the sperm whale, tends also to live in matrilineal groups, although these lack the long-term stability seen in "resident" killer whales. Sperm whale groups were found to have repertoires that consistently varied in the proportional usage of different coda types and classes (Weilgart and Whitehead, 1997). No coda type was unique to any particular group. As in killer whales, groups of sperm whales with distinct dialects interact regularly. Geographic variations in coda repertoires were also noted in different oceans and in different areas within oceans, but such variations were weaker than those observed in group-specific dialects within local regions.

Diet

Nélio B. Barros
Mote Marine Laboratory, Sarasota, Florida

Malcolm R. Clarke
Cornwall, United Kingdom

The ancestors of present-day marine mammals moved into water, possibly to escape competition on land for food resources, to escape predation, or to take advantage of relatively abundant food supplies in the seas. Most likely, it was a combination of factors. Eventually, the development of echolocatory capabilities in odontocetes (toothed whales) and physiological adaptations for deep and prolonged dives allowed for the exploration of deep waters in search for food. Some groups of cetaceans, such as beaked whales, were able to evolve the ability to dive to great depths and take advantage of food resources unavailable to other predators. From a presumed terrestrial insectivore diet, marine mammals switched largely to fish, squid, and shrimp as main prey (in addition to other crustaceans, mollusks, and zooplankton organisms).

I. Methods of Study

A variety of different methods have been used to gain insight into what marine mammals eat. Their aquatic lifestyle usually limits direct observations of feeding, except in shallow waters in geographical areas where water visibility is good. The following methods have been used to draw inferences on marine mammal diet.

A. Direct Observations of Feeding

This method is limited to what can be observed above the surface, from a vessel, from a vantage point on land, or from the air. Although much can be learned from these observations, especially when made systematically in a particular area, subsurface feeding behavior is generally not observed, and the picture obtained on feeding is incomplete, at best. Prey that present aerial behavior (e.g., mullet, flying fish) tend to be overrepresented, whereas bottom-dwelling species (e.g., toadfish, flatfish, octopus) are underrepresented.

B. Traditional Methods

The traditional method to study marine mammal food habits has been the analysis of food remains present in vomit or scat from living animals, and the stomachs and intestines of stranded animals. This method relies on the finding and identification of structures representing a typical meal, e.g., fish bones and the jaws of cephalopods, often referred to as "beaks" due to their resemblance to beaks of parrots. Fish ear stones (or otoliths), in particular, are diagnostic structures in the identification of prey because their size and shape vary considerably from species to species (Fig. 1). Fish otoliths are calcareous structures (their primary composition is calcium carbonate) and are more resistant to digestion than bones. In life, they are housed in capsules inside the fish's skull, and their main function in a fish is to provide information on balance and sound reception. Each species of fish has three pairs of otoliths (the sagitta, lapillus, and asteriscus). With a few exceptions (e.g., catfish), the largest pair of otoliths (the sagitta) is also the one most distinctive and recognizable, and the one used in species identification. Similarly, cephalopod beaks possess morphological features that vary and can be used in the identification of species (Fig. 2). Although the upper beaks have some taxonomic value, the lower beaks are generally the ones used in prey identification. Beaks are composed of chitin, a similar material to our fingernails and to mammal horns and are not dissolved by digestive processes. Otolith and cephalopod beak lengths correlate well with the length and weight of the animal from which they came; relationships with their weights are described by a power curve. These allow reconstruction of the original meal by weight. Estimates can then be made of consumption of particular prey species by single mammals and, sometimes, their populations. The relationships relating otolith/beak length to animal length are best described by straight lines, which indicate the target lengths of prey species.

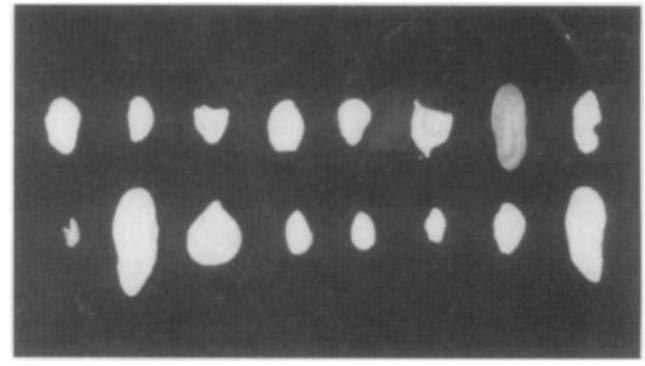

Figure 1 *Fish ear stones (otoliths) of different sizes and shapes retrieved from stomachs of bottlenose dolphins stranded in Florida.*

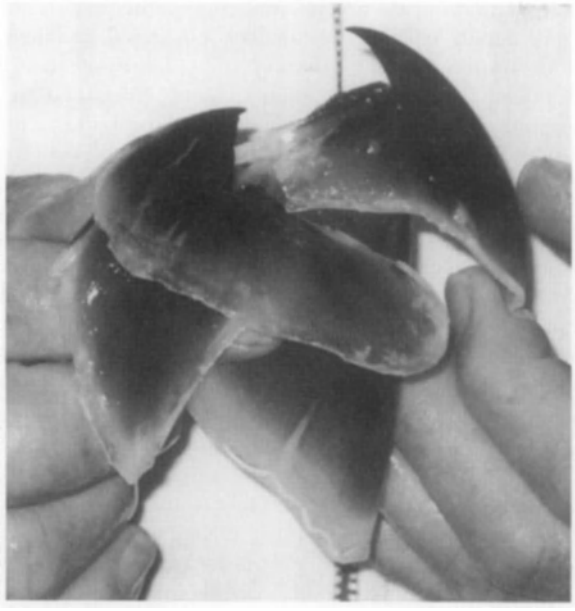

Figure 2 *Cephalopod lower (left) and upper (right) jaws or "beaks" from a giant squid* (Architeuthis).

The advantages of this method are (1) knowledge of prey composition and size classes allows for understanding spatial and temporal distribution of predators; (2) studies of predator–prey dynamics are possible; (3) prey species may be very poorly sampled by humans using other methods, and diets can give considerable information on the species in an area available to predators; (4) changes in diet during growth and over time can be monitored; (5) analysis requires low cost or little equipment; and (6) samples can be collected from carcasses in an advanced stage of decomposition.

The disadvantages of this method are (1) prey with no hard parts (e.g., invertebrates) will be underrepresented; (2) different digestion rates of prey can make calculations of reconstructed meal sizes complicated (fish otoliths can last for about a day in the gastrointestinal tracts of marine mammals, whereas squid beaks may accumulate for several days); (3) there can be potential bias in using feeding data gathered from stranded (possibly sick) animals, as they may not be representative of the population at large; and (5) a comprehensive reference collection of hard structures (fish otoliths and cephalopod beaks) of the most common prey in a particular area is of great advantage in species identification, but is not always available.

C. Use of Novel Tools (New Technology) to Understand Feeding Ecology

1. Stable Isotopes The principle of this method is that ratios of heavier vs lighter isotopes of particular elements (carbon, nitrogen, oxygen, sulfur) in tissues of predators can be traced to those of their prey as they are assimilated through the diet. The following are advantages of this method: (a) it is ideal to detect shifts in diet; (b) different tissues of the predator yield information reflecting the feeding history relative to the last days, months, or the entire life of the animal; these data can be used to gain insights into the distribution, movements, and migratory habits of the animal; (c) isotopic ratios of carbon reflect those of the primary producers in the area; isotopic ratios of nitrogen are indicative of the trophic level occupied by the organism, which are helpful in understanding habitat utilization and trophic relationships; and (d) historical reconstruction of values through time can yield intra- and interannual variability in feeding. The disadvantages of this method are that a reference database for the isotopic signature of prey is needed and the cost of the equipment used in the analyses is high.

2. Fatty Acids The fatty composition of a prey is species specific and, as these compounds are assimilated through the diet and accumulated in fatty tissues of predators (e.g., blubber of marine mammals), they can be used as tracers of diet. Fatty acids analysis can be useful in (a) reconstructing diets in time and space; (b) population studies of various marine mammal species using different feeding grounds; (c) studies of energetic transfers between mother and their offsprings; and (d) the application of the technique to free-ranging animals, which can be done by the relative noninvasive collection of tissue (e.g., through biopsy darts). Similarly to stable isotopes, this method requires a reference database for the chemical signature of the various prey species, and the cost of the equipment is high. In addition, there is stratification of fat in the outer and inner blubber layer of marine mammals, and incomplete sampling of the BLUBBER layer may yield misleading results of dietary information. Additional variability may be associated with what part of the body the sample is taken, making interstudy comparisons difficult.

3. Molecular Identification of Prey This method involves the genetic identification of material from scats, stomach contents, and gut bacteria, which must be separated prior to analysis. The disadvantages of this method are that a reference database for the genetic signature of prey is needed and it has yet to be widely applied to marine mammal dietary studies.

4. Video-Taping Studies (Using "Critter Cams") of Animals Feeding at Depth This method has the following advantages: (a) it documents the actual feeding behavior of the predator, and the identity of the prey species can be verified by the images; (b) prey behavior during detection and capture can be documented; and (c) different feeding strategies can also be observed (e.g., cooperative feeding). Among the disadvantages: (a) only captures of a few species can be observed; (b) ambient light must be relatively bright and the water must be clear; (c) there is difficulty in the attachment and recovery of the equipment (video camera); and (d) there are high costs associated with the equipment and its operation.

In summary, although identifying and measuring items in vomit, scats, and stomach contents have many disadvantages, it provides more information at considerably less cost than other methods and cannot be replaced effectively by any other method at present.

II. Diets in General

Marine mammals, all together, eat a great variety of animals from minute crustaceans, less than 1 mm long, to giant squids,

over 15 m in length. These live in a wide range of habitats, from the shallow shelf seas and estuaries to over 2000 m deep in the deepest oceans, from near the water surface to the ocean bottom. The animals consumed vary in texture from soft-skinned and gelatinous octopods to hard-scaled, muscular fish and vary in mobility from sedentary clams to jet-propelled squids. The three species of manatees (*Trichechus* spp.) and the dugong (*Dugong dugon*) of the order Sirenia rely on sea grasses and river plants; they are grazers in the true sense.

All this variety in food organisms has led to many specializations in structure. Most obviously, the mouth has developed a great variety of tooth numbers, sizes, and shapes or, for those eating very small organisms, a special filter made of horny plates, frayed on one edge, called "baleen." Various species dive to greater depths, so permitting an extension of their feeding grounds from the continental shelves, down the continental slopes, to depths exceeding 2000 m. Similarly, thickening of their fatty blubber layer has permitted further extension of their feeding grounds into the cold waters of the Antarctic and Arctic. The diet of any species reflects its adaptations; its mouth adaptations make it possible for it to catch certain types and sizes of prey. The actual species in the diet depends on its own and the prey's depth and geographic distribution.

Another property of the food is quality. Crustaceans, fish, and cephalopods vary in protein, fat, and mineral constituents and proportions. Marine mammal species can sometimes shift between these three groups during a year, as supply fluctuates or during their own migrations, but this may well drastically affect their physical condition and health. Even within one of these major groups the protein content, for instance, may vary greatly so that change to another species of prey as the main food item might affect the predator markedly. This is likely to be important when the mammal shifts from a diet of shellfish, which are very muscular, to deep-living oceanic fish, which are generally lower in protein content. Similarly, shelf-living cephalopods are mainly soft bodied, have weak muscles, and are low in protein so that twice as much has to be eaten. The high acidity and presence of ammonium salts in high concentration in some soft-bodied squids also probably require special adaptations of digestive processes.

The food of rarer marine mammals, and species that have not been caught for their oil, is not well known. Knowledge depends on information from occasional strandings, and stomach contents are often difficult to collect because of the size of the carcass. Debris from the stomachs only occasionally includes complete, readily identifiable, prey animals. Usually, information on diet has to be obtained from hard pieces, mainly fish otoliths and cephalopod beaks.

A. Cetaceans

1. Baleen Whales (Mysticeti) These possess baleen plates, and all but the gray whales collect swarming animals by skimming through the water or by gulping. They therefore primarily eat shoaling plankton or small nekton together with a few larger animals, such as fish and squids, caught with the shoals.

A. RIGHT WHALES (BALAENIDAE AND NEOBALAENIDAE) The five species have very long baleen plates hanging from the roof of the mouth, whose finely frayed inner edges can trap very small plankton. They mainly eat small crustaceans ranging from minute copepods less than 1 mm long, favored by the bowhead whale (*Balaena mysticetus*) of the northern seas and the pygmy right whale (*Caperea marginata*), to small euphasiid crustaceans called "krill" as much as 25 mm long, eaten by the southern right whale (*Eubalaena australis*). The bowhead is also known to eat a small molluscan called a pteropod.

B. GRAY WHALE (*ESCHRICHTIUS ROBUSTUS*) This species has very tough baleen plates that become worn, particularly at the right side, by rubbing on the sea floor from which it principally sucks, by piston action of its tongue, bottom amphipod crustaceans but also mollusks and bristle worms.

C. RORQUALS (BALAENOPTERIDAE) The eight species have shorter baleen plates than right whales and generally favor larger prey than copepods. Blue whales (*Balaenoptera musculus*) eat midwater crustaceans, mainly KRILL, in the Antarctic and other euphausiid species in the North Pacific and North Atlantic. The fin whale (*B. physalus*) eats krill in the Antarctic but in the North Pacific it broadens its diet to include fish such as clupeids, muscular squids, and a copepod. It eats the fish capelin in the North Atlantic. Humpback whales (*Megaptera novaeangliae*) eat mainly krill or "lobster krill" in the Southern Hemisphere, but mainly anchovies and cod in the Northern Hemisphere. Assorted squid are also eaten by humpback whales. The sei (*B. borealis*) whale eats 20 species of densely shoaling midwater crustaceans, including krill and copepods, in addition to anchovy, cod, and assorted oceanic squids. Minke whales (*B. acutorostrata* and *B. bonaerensis*) eat assorted crustaceans in the Arctic and Antarctic seas, and also fish, including anchovy, in the North Pacific and herring in the North Atlantic. They also take assorted midwater squid in the south tropical seas and appear to rely more on fish than other baleen whales. Bryde's whales (*B. brydei* and *B. edeni*) eat crustaceans, including krill, but also various fish, including mullet and anchovy in the Southern Hemisphere and anchovy in the North Pacific.

2. Toothed Whales (Odontoceti) Within this group, comprising seven families and 52 species, teeth are developed and the main prey items are fish and cephalopods. The cetacean species that live on the continental shelf eat muscular fish, such as herring, pilchards, whiting, and soles; muscular cephalopods, such as inshore squid, cuttlefish, and octopods, are occasionally taken as well. Odontocetes living in the deep ocean eat mainly lantern fishes and soft-bodied, often gelatinous, squids. Around oceanic islands, both lantern fishes and more muscular species, such as horse mackerel and trumpeter fish, are often taken.

A. DOLPHINS (DELPHINIDAE) In 45% of the species in this family, cephalopods comprise over 75% and fish less than 25% of the diet. In 24% of the species, cephalopods comprise 50–75% and fish 25–50%. Depending on the species of dolphin, the diet can be muscular species living on the continental shelf, as for many populations of the short-beaked common dolphin (*Delphinus delphis*) and the common bottlenose dolphin (*Tursiops truncatus*); or as in spinner (*Stenella longirostris*) and spotted dolphins (*S. attenuata* and *S. frontalis*) the diet may include many soft-bodied oceanic species. However, on the whole, dolphins favor muscular squid rather than soft-bodied ones, even in oceanic waters; this also applies to pilot whales (*Globicephala* spp.). A few species include other prey

groups in their diet, e.g., Commerson's dolphins (*Cephalorhynchus commersonii*) eat some krill and killer whales (*Orcinus orca*) also prey on seals and other cetaceans.

B. PORPOISES (PHOCOENIDAE) In half of the species in this family, cephalopods comprise over 75% and fish less than 25% of the diet. In the other half of the species, cephalopods comprise 50–75% and fish 25–50%. Being inshore cetaceans, food consists of common (often economically important to humans) species: muscular inshore squid, cuttlefish, and octopus, as well as fish such as herrings, whitings, and bottom-living soles.

C. BEAKED WHALES (ZIPHIIDAE) In over half the species of beaked whales, more than half of the food is cephalopod and the rest is fish. These whales are deep divers and at least one species favors soft-bodied squids. The number of teeth is very reduced in this family and, in one species, the two teeth in the lower jaw grow over the upper jaw and limit it to a narrow gape. It is remarkable that this does not seem to inhibit capture of oceanic squids.

D. NARWHAL AND BELUGA (MONODONTIDAE) The diet of the narwhal (*Monodon monoceros*) includes fish such as Greenland halibut and polar cod, muscular squid, and shrimp. The suggestion that the long tooth of male narwhals is regularly used to stir prey from the mud is unlikely to be true. Belugas (*Delphinapterus leucas*) feed on fish such as capelin and sand lance, as well as larger species such as cod and flounder. Sand- and bottom-living worms show that they probably feed on the bottom as well as in midwater.

E. SPERM WHALES (PHYSETERIDAE AND KOGIIDAE) All three species feed mainly on squids, although a few fish are taken, including large sharks. Sperm whales (*Physeter macrocephalus*) eat mainly deep-living oceanic squids and most of these are soft-bodied or gelatinous, luminous, and weak swimmers. Contrary to common belief, the average weight of their prey is not great, varying from 0.5 kg off South Africa to 7 kg in the Antarctic, although some large sperm whales can eat squids over 15 m in length. Pygmy and dwarf sperm whales (*Kogia breviceps* and *K. sima*) eat some of the same species as their larger relative but, because they spend some time on continental shelves, they also include muscular, shelf-living squids and octopods.

F. RIVER DOLPHINS (INIIDAE, PONTOPORIIDAE, LIPOTIDAE, PLATANISTIDAE) This group includes four species of dolphins, three of which inhabit the freshwater systems of major rivers in South America, China, and the Indian subcontinent. The fourth species has a marine distribution and is found in coastal waters of the Atlantic coast of South America. The riverine species feed on a variety of freshwater fish (including sharks) and prawns, and occasionally also prey on other groups, such as freshwater turtles. As cephalopods are strictly marine in distribution, they are not part of the diet of riverine dolphins. The marine species in this group (the "franciscana," *Pontoporia blainvillei*) eats mainly bottom-dwelling fish, coastal species of cephalopods, and several species of shrimp.

B. Pinnipeds (Seals, Sea Lions, Walruses)

All but 2 of the 36 species of pinnipeds (seals and sea lions) probably include both fish and cephalopods in their diet. The exceptions inhabit freshwater systems where cephalopods do not occur. Most pinniped species inhabit coastal regions or seas close to oceanic islands, which partly influences their choice of diet.

1. Fur Seals and Sea Lions (Otariidae) Of the 16 species, 10 take benthic cephalopods and 11 eat midwater squids. At least 14 eat muscular cephalopods and at least 3 of these eat oily squids while only 1 eats soft-bodied squids. Three species consume all these on the continental shelf while 8 eat them in oceanic waters.

A. NORTHERN FUR SEAL (*CALLORHINUS URSINUS*) On the continental shelf this species eats primarily small shoaling fish and muscular squids. In offshore waters, they eat mainly muscular oceanic squids.

B. GUADALUPE FUR SEAL (*ARCTOCEPHALUS TOWNSENDI*) They eat oceanic cephalopods and lantern fish.

C. JUAN FERNANDEZ FUR SEAL (*A. PHILIPPII*) They apparently eat muscular, oceanic squids.

D. GALAPAGOS FUR SEAL (*A. GALAPAGOENSIS*) This species mainly eats muscular, oceanic squids.

E. CAPE AND AUSTRALIAN FUR SEALS (*A. PUSILLUS*) They eat both shelf and oceanic fish and cephalopods, as well as both midwater and bottom species. They favor muscular rather than soft-bodied cephalopods.

F. NEW ZEALAND FUR SEAL (*A. FORSTERI*) This species eats midwater fish and muscular cephalopods, but also takes penguins.

G. ANTARCTIC FUR SEAL (*A. GAZELLA*) They eat mainly krill in the Antarctic, but further north take oceanic fish, as well as muscular and soft-bodied squids.

H. SUB-ANTARCTIC FUR SEAL (*A. TROPICALIS*) They eat oceanic squids, both muscular and soft-bodied.

I. STELLER SEA LION (*EUMETOPIAS JUBATUS*) They eat muscular, bottom octopods as well as oily oceanic squids and polar cod.

J. CALIFORNIA, GALAPAGOS AND JAPANESE SEA LIONS (*ZALOPHUS CALIFORNIANUS, Z. WOLLEBAEKI,* AND *Z. JAPONICUS*) These species eat shelf-living, muscular squids and octopods, as well as muscular, oceanic squids.

K. SOUTH AMERICAN SEA LION (*OTARIA FLAVESCENS*) They eat mainly on bottom and midwater shelf fish but also take some shelf cephalopods.

L. AUSTRALIAN SEA LION (*NEOPHOCA CINEREA*) This species eats shelf octopods and cuttlefish.

M. NEW ZEALAND SEA LION (*PHOCARCTOS HOOKERI*) This species eats shelf fish, cephalopods, and crustaceans.

2. Earless (true) Seals (Phocidae) This group eats a variety of fish, cephalopods, and crustaceans of both inshore and oceanic species, depending on their locality. Of the 19 species, at least 15 eat muscular cephalopods, 5 eat oily species and 4 eat soft-bodied squids. Some slight deviations from this pattern are given.

A. HARP SEAL (*PAGOPHILUS GROENLANDICUS*) This species eats mainly fish and crustaceans, especially amphipods and euphausiids, although both bottom and midwater oceanic cephalopods are also taken.

B. BEARDED SEAL (*ERIGNATHUS BARBATUS*) They eat mainly bottom shelf invertebrates, such as clams, and also fish, in addition to a few species of octopods.

C. GRAY SEAL (*HALICHOERUS GRYPUS*) Gray seals eat schooling fish, squids, octopods, and occasionally sea birds.

D. CRABEATER SEAL (*LOBODON CARCINOPHAGA*) They eat krill almost exclusively.

E. ROSS SEAL (*OMMATOPHOCA ROSSII*) Ross seals eat oceanic species of fish and squids of both muscular and soft-bodied species.

F. LEOPARD SEAL (*HYDRURGA LEPTONYX*) This species eats krill, fish, soft-bodied squids, and occasionally mammals.

G. WEDDELL SEAL (*LEPTONYCHOTES WEDDELLII*) They eat mainly cephalopods, including muscular and soft-bodied species, and bottom octopods.

H. ELEPHANT SEALS (*MIROUNGA ANGUSTIROSTRIS* AND *M. LEONINA*) These species eat oceanic species, including muscular, soft-bodied, and oily species and, seasonally, shelf squids.

3. Walrus (Odobenus rosmarus) These are benthic feeders in shallow Arctic seas at depths less than 100 m. Their main food is clams but they also eat a small quantity of bottom octopods and have been known to attack other seals.

C. Sea Otter (*Enhydra lutris*)

These eat bottom invertebrates on the continental shelf, usually very close to shore, including clams, sea urchins, and other invertebrates.

D. Polar Bear (*Ursus maritimus*)

This species eats mainly harp seals but also feeds on other seals, young beluga and narwhal, young walrus or sick animals, and fish such as Arctic char. Polar bears also feed on terrestrial species of mammals and birds, on carcasses of bowhead and gray whales, and occasionally on humans. Polar bear males are known to kill and eat cubs of their own kind, possibly in order to incite the female to come into estrus again rapidly.

E. Sirenians

The manatees and dugong feed on tropical grasses and roots and rhizomes in nearshore areas in saline environments and on water hyacinths, water lilies, and other vegetation in rivers and lakes. The extinct Steller's sea cow (*Hydrodamalis gigas*) was a cold-adapted species, last found off the Kamchatcka Peninsula in far east Russia; it fed on cold water kelp.

Distribution

JAUME FORCADA
Southwest Fisheries Science Center, La Jolla, California

The majority of marine mammals are found in marine environments; some are found in rivers and estuaries and a few in freshwater lakes. Amphibious marine mammals (the pinnipeds, sea otters, and polar bears) also occur on land and ice. Distribution is the part of ecology that deals with how they use different geographic ranges in space and time. The complexity of distribution patterns of individuals or aggregations of individuals depends on how the different factors affect the species' habitats, biological requirements, interactions with other organisms, and the patchiness of the environment.

I. Distribution Patterns and Preferences

Marine mammals are found in almost all the different marine environments, and their distribution varies according to the physical, chemical, and biological characteristics of the water masses. The effects of oceanographic phenomena, wind-induced movements (e.g., water currents, local divergence, and upwelling areas and water fronts) and the topography, can be used to characterize distribution. In the case of pinnipeds, the breeding and molting habitats on land or ice also characterize their distribution. In the polar bear, breeding and cub-rearing habitats are also relevant.

In freshwater environments, marine mammals are found in rivers and lakes. Examples of riverine species are the river dolphins (Platanistidae, Iniidae, Lipotidae, and Pontoporiidae) and the manatees. A few Phocidae live in freshwater inland lakes: the Saimaa seal (*Pusa hispida saimensis*) in Finland; the Caspian seal (*Pusa caspica*) in the Caspian Sea; the Baikal seal (*Pusa sibirica*) in lake Baikal; and the Ungava (common) seal

(*Phoca vitulina mellonae*) in freshwater lakes of the Hudson Strait.

In marine environments, distribution can be generally described as coastal (in estuarine or near shore waters), neritic (in waters on the continental shelf), or oceanic (in waters beyond the continental slope, in the open seas or oceans). Examples of marine mammals that reside primarily in coastal waters are populations of bottlenose dolphins (*Tursiops* spp.), sea otters (*Enhydra lutris*), and dugongs (*Dugong dugon*). Primarily neritic species include gray whales (*Eschrichtius robustus*), harbor porpoise (*Phocoena phocoena*), and California sea lions (*Zalophus californianus*). Primarily oceanic species include the sperm (*Physeter macrocephalus*) and beaked whales (family Ziphiidae). These generalizations should be used with caution, as many species occur in multiple habitats. Some species shift from one habitat to another seasonally, such as the switch from neritic feeding grounds to coastal migratory routes and breeding grounds by gray whales. Some species have populations that reside in a variety of habitats, such as the bottlenose dolphin, which occurs in coastal, neritic, oceanic, and, occasionally, riverine habitats.

Marine mammal distribution can also be classified according to general geographic areas. These are characterized by latitudinal bands and average water temperatures. Thus, marine mammals have tropical and/or subtropical, temperate, Antarctic, or Arctic distributions. Some species can be strictly included in just one of these categories, such as exclusively Arctic species: bowhead whales (*Balaena mysticetus*), polar bear (*Ursus maritimus*), narwhal (*Monodon monoceros*), and beluga (*Delphinapterus leucas*), but, again, other species often have multiple classifications. A clear example are the baleen whales that migrate from cold high latitudes to tropical low latitudes. Some species, such as the killer whale (*Orcinus orca*), are found in all the marine waters of the world, from the Equator to the Arctic and Antarctic. Finally, similar and closely related species may occupy different latitudinal (hemispheres, ocean basins) or longitudinal (different oceans and seas) ranges. Examples of pairs of similar species that occur in different hemispheres are the northern (*Hyperoodon rostratus*) and southern (*Hyperoodon planifrons*) bottlenose whales and the northern (*Mirounga angoustirostris*) and southern (*Mirounga leonina*) elephant seals. An example of very similar cetacean species with different distribution preferences within the same ocean basin are the long- and short-finned pilot whales (*Globicephala melas* and *G. macrorhynchus*).

Detailed data on distribution are provided in the species account of this encyclopedia and therefore only overall patterns by taxa are given in this section to avoid redundancy. Additional detailed description of marine mammal distribution can be found in Gaskin (1982) for cetaceans, in Riedman and Estes (1988) for the sea otter (*Enhydra lutris*), in Riedman (1990) for pinnipeds, in Reynolds and Odell (1991) for sirenians, and in Wiig *et al.* (1995) for the polar bear.

A. Cetaceans

Cetaceans live permanently in aquatic environments. They can be found in all the oceans and most of the seas of the world, and distribution patterns vary between and within families. The Balaenidae, the Balaenopteridae, the gray whale, the sperm whale, and the killer whale are found in polar, temperate, and tropical waters. They are found in the Northern and Southern Hemispheres, except gray and bowhead whales, which are only found in the Northern Hemisphere. As noted earlier, other strictly northern and also Arctic species are the narwhal and beluga. The pygmy right whale (*Caperea marginata*) is only found in the Southern Hemisphere. Most delphinids live in tropical and temperate waters of both hemispheres. More tropical Delphinidae are *Stenella attenuata, S. longirostris, S. frontalis, Steno bredanensis, Sotalia fluviatilis, Globicephala macrorhynchus, Pseudorca crassidens, Peponocephala electra,* and *Feresa attenuata.* Other tropical odontocetes are the pygmy (*Kogia breviceps*) and dwarf (*K. sima*) sperm whales, Irrawaddy dolphin (*Orcaella brevirostris*), and many Ziphiidae. Most Phocoenidae live in temperate or subtropical waters with some species exclusively in the Northern Hemisphere (*P. phocoena, P. sinus,* and *Phocoenoides dalli*) and some exclusively in the Southern Hemisphere (*P. spinipinnis* and *P. dioptrica*). All Delphinidae of the genus *Cephalorhynchus* live in temperate waters of the Southern Hemisphere. Of the river dolphins, the Amazon River dolphin, *Inia geoffrensis,* lives in the large lakes and tributaries of the Amazon and Orinoco basins. The franciscana (*Pontoporia blainvillei*) lives in the coastal central Atlantic waters of South America, but is commonly found in the mouth of the rivers and ocean waters surrounding estuaries. Similarly, the tucuxi is distributed in both fresh and marine waters. The two subspecies of the family Platanistidae (*Platanista gangetica gangetica* and *P. g. minor*) live in the major rivers of India and Pakistan, the Indus and Ganges, and the baiji (*Lipotes vexillifer*) lives in the Yangtze and formerly lived in some of the lakes along this extremely large inland river system.

B. Pinnipeds

Pinnipeds are amphibious mammals and spend most of their life in aquatic environments. However, they must return to land or ice for breeding (giving birth and rearing their offspring) and molt after breeding. Other possible reasons for hauling out are resting, THERMOREGULATION, and escape from predators. Some common characteristics of nonaquatic habitats are space availability, isolation from predators, and proximity to food supply. Pinnipeds with tropical and temperate distributions find these conditions in isolated ROOKERIES or beaches of remote places, which often are in islands. Ice characteristics condition the distribution and activity patterns of pinnipeds; pack ice offers a more constant substrate than fast ice, which varies highly seasonally in extension. Some pinnipeds reproduce in fast ice, such as the hooded seal (*Cystophora cristata*), and the duration of lactation and rearing of their young strongly depend on ice conditions. In general, seasonal changes in oceanographic conditions and ice cover condition the distribution of pinnipeds in the pack ice.

Among the Phocidae, geographical or latitudinal distributions include the Arctic, sub-Arctic, and temperate areas, subtropical and tropical areas, and sub-Antarctic and Antarctic areas. Antarctic seals are the Weddell (*Leptonychotes weddellii*), crabeater (*Lobodon carcinophaga*), leopard (*Hydrurga lep-*

tonyx), and Ross (*Ommatophoea rossii*) seals. A sub-Antarctic and Antarctic seal is the southern elephant seal. In the Northern Hemisphere, tropical and subtropical species are the Hawaiian (*Monachus schauinslandi*), Mediterranean (*Monachus monachus*), and the extinct Caribbean (*Monachus tropicalis*) monk seals. Sub-Arctic and temperate-water seals are the gray (*Halichoerus grypus*), harbor (*Phoca vitulina*), and northern elephant seals. Arctic and sub-Arctic seals are the harp (*Pagophilus groenlandicus*), hooded, bearded (*Erignatus barbatus*), ringed ribbon (*Histriophoca fasciata*), spotted (*Phoca largha*), Baikal (*Pusa sibirica*), and Caspian seal. Among phocids, harp, hooded, bearded, ribbon, spotted, Ross, and leopard seals breed in the pack ice; the crabeater and ringed seals breed in pack and fast ice; the southern elephant seal breeds on land and fast ice; the Baikal and Caspian seals on fast ice; the harbor and gray seals on land and ice; and the northern elephant and the monk seals breed on land. Phocids with coastal and continental shelf distribution are the harp, harbor, gray, bearded, ringed, ribbon, spotted, Weddell, crabeater, leopard, and Mediterranean monk seals. Continental slope and oceanic seals are the Hawaiian monk, northern and southern elephant, Ross, and hooded seals. The walrus (*Odobenus rosmarus*, family Odobenidae) breeds on the pack ice and occurs in waters of the continental shelf. All the Otariidae breed and rear their offspring on land. Most of them disperse after breeding and therefore have neritic and oceanic distributions depending on season and reproductive status. Many Otariidae have subtropical or tropical distributions, such as the California (*Zalophus californianus*) and Galapagos (*Z. wollebaeki*) sea lions and the Guadalupe (*Arctocephalus townsendi*) and Galapagos (*A. galapagoensis*) fur seals. The Steller sea lion (*Eumetopias jubatus*) is found from Arctic to temperate waters of the eastern North Pacific. The other sea lions are distributed in tropical and sub-Antarctic waters in the Southern Hemisphere: the Australian (*Neophoca cinerea*), New Zealand (*Phocarctos hookeri*), and South American (*Otaria flavescens*) sea lions. In the Southern Hemisphere, all the fur seals are found in temperate or sub-Antarctic waters: the New Zealand (*Arctocephalus forsteri*), South African (*A. pusillus pusillus*), subantarctic (*A. tropicalis*), Australian (*A. pusillus doriferus*), Juan Fernandez (*A. philippi*), and South American (*A. australis*) fur seals. Only the Antarctic fur seal (*A. gazella*) can be strictly considered sub-Antarctic or Antarctic. In the Northern Hemisphere, the northern fur seal (*Callorhinus ursinus*) is found in the sub-Arctic and temperate North Pacific.

C. Sirenians

All the Sirenia are found in tropical or subtropical waters. The manatees have restricted ranges in different oceans and river systems. The west Indian manatee (*Trichechus manatus*) is found from southern North America and Caribbean to northern South America, in the western Atlantic, and the Amazon manatee (*T. inunguis*) in the Amazon drainage. In the eastern Atlantic, the African manatee (*T. senegalensis*) is found in western Africa, from Senegal to Angola. Manatees are coastal, although they may be found in continental shelf waters, transiting between islands, in the Caribbean. The dugong (*Dugong dugon*) is the most widely distributed sirenian, in the Indian and the western Pacific oceans, with a preference for shallow coastal bays.

D. Polar Bear and Sea Otter

The polar bear has a circumpolar distribution, mostly above the Arctic circle. It uses coastal, neritic waters, and breeds and rears its offspring on ice. Ice is also important for polar bears as a platform to travel, especially in the ice floes, between foraging areas and areas where they give birth and rear their young and as a substrate to hunt seals. The sea otter is found in the Pacific coasts of North America and Russia, essentially in temperate and sub-Arctic waters. It lives near shore and comes ashore on Aleutian Islands. Its distribution is conditioned by predators (e.g, killer whales) and food availability, such as the prey they usually use in kelp forests (e.g., sea urchins and abalone).

II. Factors Affecting Marine Mammal Distribution

Marine mammal distributions are affected by demographic, evolutionary, ecological, habitat-related, and anthropogenic factors. Demographic factors include the ABUNDANCE, AGE, and sex structure of the marine mammal populations and the reproductive status and life cycle of individuals. Evolutionary factors include morphological, physiological, and behavioral aspects of the species' adaptations. Ecological factors include biological production and use of prey, distribution of prey and predators, and competitors. Habitat includes factors such as water temperature, salinity, density, thermocline depth, and the type of substrate and the bathymetry. Anthropogenic factors are the human effects that alter the natural distribution of marine mammals, including pollutants, human-induced sounds, and incidental and direct kills. Distribution is the product of factors that act in a parallel or interactive way over different scales of space and time on each species, and sometimes on groups of species. As an example, baleen whale distribution depends on their ability to exploit planktonic organisms (evolutionary), the oceanographic characteristics of the water masses where they feed (habitat), and the trophic level they exploit (ecological).

A. Demographic Factors

The dynamics of marine mammal populations can determine distribution changes and patterns. The number of individuals that live in particular areas depends on the capacity of those areas to sustain their biological requirements. In general, the most critical requirements are prey availability and energy. The depletion of food resources by marine mammal populations influences the movement or dispersal to other areas. The age and sex structure of marine mammal aggregations also affect the distribution patterns. Habitat requirements for breeding females or females with offspring are not the same as those of adult males. In the case of odontocetes, females with calves may require coastal areas with locally abundant food resources and protection from predators. Adult males, not having to care for their offspring, are less limited in terms of movements and distribution range. In offshore dolphins, large cohesive aggregations may be required by breeding females for protection in

the open ocean and foraging distances will be greater due to patchiness of their prey. In the case of pinnipeds, distributional differences according to age and sex classes and reproductive status are related to the seasonality of their life cycles, their adaptation to aquatic feeding, and their need to periodically return to land to breed. In breeding colonies, individuals will gather seasonally to mate, give birth, and nurse their pups over variable periods of time according to species. After the breeding season, pinnipeds often display age-related differences in habitat use and foraging areas. Dispersal according to age and sex classes is often associated with these characteristics.

B. Evolutionary Factors

All factors related to the secondary aquatic adaptation of marine mammals influence their distribution to some extent. Diving capacities in terms of duration and maximum depths allow particular species to exploit different habitats. In the case of sperm whales or elephant seals, deep diving allows access to prey unavailable to the shallower diving dolphins or porpoises. Hence, their distribution is associated with deep canyons and other deep ocean areas. In sperm whales, this ability also requires complex social systems that ensure the protection of newborns or youngsters, particularly while mothers spend long times underwater in search of prey. Another notable physiological adaptation is thermoregulation, which allows marine mammals to extend their distribution ranges from the warm equatorial waters to the coldest high latitudes. Efficient insulation and body temperature regulation systems allow the polar bear and the sea otter to spend a substantial part of their life at sea and survive in cold waters. The relative inability to regulate body temperature adequately in colder water of neonates is a hypothetical factor that leads baleen whales to migrate from the cold feeding grounds to the warmer calving grounds. Morphological adaptations, such as the feeding apparatus of baleen whales, also influence their distribution. As active filter feeders, they can capture planktonic (e.g., copepods, krill) or schooling (e.g., sand lance, capelin, herring) prey, which are abundant in the particular areas where whales distribute. Finally, the cohesiveness of large dolphin schools and the sensorial integration of individuals allow them to range in offshore areas, find food actively and efficiently, and obtain protection from predators.

C. Ecological Factors

Marine mammal distribution is in great measure related to prey distribution. The ability to exploit different trophic levels and resources classifies different marine mammals from top predators, such as the killer whales, to low-trophic level feeders, such as northern right whales or manatees. Marine mammals can be considered as either specialists or generalists, and these two aspects imply differentiated distribution patterns. Manatees, being specialist feeders, have restricted distributions where sea grass meadows provide continued food. Despite often being categorized as specialists, odontocetes or phocids tend to use a wide range of prey items. Thus, they can be distributed over wider ranges and change their distribution seasonally according to the availability of their prey. The killer whale, as a species, has a broad diet, yet different populations have more specialized diets: transient killer whales feed mainly on pinnipeds and other marine mammals but must range widely to maintain this diet, whereas resident killer whales feed on large fishes such as salmon. In both instances, the distributions of the whales are synchronized to the life cycles of their prey. The transients concentrate seasonally near pinniped rookeries, whereas residents live near the mouth of salmon-spawning rivers. In other cases, marine mammals tend to use the same home range, such as coastal bottlenose dolphins, feeding on different prey species that change their distribution seasonally. In this case, distribution patterns must be studied and interpreted at a finer scale. Interspecific competition is an additional ecological factor determinant of variable distribution. Violent attacks on harbor porpoises by bottlenose dolphins have been reported in their common range in the North Sea. Finally, predation plays an important role in the selection of habitats and distribution areas by marine mammals, especially those of smaller size, such as ringed seals. This species appears to select the fast ice to avoid predation by polar bears.

D. Habitat-Related Factors

Marine mammals are usually found in waters with high densities of principal prey species. These waters are characterized by the physical conditions that facilitate the accumulation of these prey. Relevant oceanographic variates characterizing marine mammal habitats are water temperature, salinity, density, chlorophyl concentration, and thermocline depth. These characteristics are related to upwelling fronts, often related to differences in species distribution. As an example, spinner and spotted dolphins range in the same areas of the eastern tropical Pacific, often traveling in the same schools. They occur in the same overall ocean area as common and striped dolphins, but appear to have preferences for water masses of different oceanographic characteristics (Reilly, 1990). Ocean topography and bathymetry are often related to local oceanographic phenomena that influence marine mammal distribution. Underwater canyons, marine ridges, and irregular topographies concentrate prey for deep divers such as sperm whales or elephant seals. In contrast, mysticetes often have preferences for shallow waters with high topographic variation. In these waters their prey accumulates at frontal interfaces between mixed and stratified waters. The ice is also a critical habitat element for marine mammals; the seasonal and highly dynamic changes of ice cover determine their patterns of change in distribution. It provides shelter during reproduction for pinnipeds, access to seasonally abundant food, and also delimits the distribution ranges of some cetaceans, such as the bowhead whale.

E. Anthropogenic Factors

Human alteration of habitats can change marine mammal distributions significantly. Marine mammals that haul out on land are particularly affected by habitat encroachment by human development. The three species of monk seals have suffered substantial changes in their original distributions, and one of them, the Caribbean monk seal, became extinct because of this. In the case of the Mediterranean monk seal, a major change in habitat preferences occurred as a result of human development, but also of deliberate kills for human uses. The

seals changed their haul outs from open beaches to difficult-to-access caves, often with underwater entrance. This has created severe habitat fragmentation. Commercial exploitation has also affected marine mammal distributions greatly. Whale stocks were reduced to the point that many original distribution areas are not used anymore. Overfishing of prey items has led to changes in marine mammal distributions. Pollution of coastal areas has degraded many original marine mammal habitats, thus affecting their original distributions. Human-induced changes in local water temperature have changed the seasonal distribution of the Florida manatee (Reynolds and Odell, 1991). This population previously migrated to warmer waters in winter but now uses the thermal vents in waters close to power plants and has changed migration patterns substantially. Expanding sources of sound in the ecosystem (e.g., large ship traffic, naval experiments) and pollution may also affect marine mammal distribution.

III. Movements and Seasonality

The distribution of marine mammals changes seasonally as their biological and ecological requirements change. Marine mammals respond to changes in the environment, such as in temperature, ice coverage, and prey availability. Daily requirements in terms of energy or protection against predators depend on the reproductive status and the season; these are clearly not the same for females with nursing offspring as for solitary males. Movements are a response to changes in the environment and the biological requirements of a species. In tropical areas, movements are expected to vary according to the patchiness of the environment. Distances covered in short periods of time may vary depending on the conditions, but a very marked seasonality is not commonly found. In high latitudes, changes during the cold winter affect the distribution of marine mammals, their tolerance to physical conditions, and their life history requirements. Thus, seasonality is more marked.

Movements can be classified as migration, dispersal, and daily travel. Migration is the seasonal change between two geographic locations that is related to species reproductive cycle, changes in temperature, and prey availability. Dispersal is the movement from the place of birth to other areas in which individuals reach a feeding area, join a breeding population, or find another group of individuals with which to spend the next stage of its life. The classification of movements may be somewhat arbitrary because marine mammals do not always follow strict periodic patterns. They instead respond to the limitations of the environment in providing constant food or other requirements. Short-scale movements are difficult to detect and must be put in the context of the species life cycle before being classified. A typical example of migration is the one of baleen whales; humpback whales undertake long-distance travels, often thousands of kilometers, between the tropical calving grounds in winter and the high-latitude feeding grounds in summer. In contrast, most Otariidae have dispersal movements from their birth colonies toward different feeding areas or other breeding colonies when they reach sexual maturation. In any case, movement patterns vary among individuals, according to their age, sex, and reproductive condition. A prereproductive young whale may delay its departure from the high-latitude feeding grounds to extend the feeding season, whereas a pregnant female must leave for the low-latitude calving grounds to give birth to its offspring.

A. Cetaceans

Cetaceans spend their entire life in aquatic habitats and are in constant movement. Understanding their seasonal distribution is more difficult than in pinnipeds for technical and logistical reasons: the manipulation and tagging of animals is less efficient and more expensive. Thus, classifying movements as dispersal or migration is even more confusing, except in some well-studied populations of baleen whales. Their life patterns and cycles make the concept of dispersal a little ambiguous, however, because seeming residency, site fidelity, or habitat discreteness may be just apparent, short-term attributes of their distribution. Only migration in large whales is known from long-term studies. Studies on migration range from the examination of catch statistics of whaling operations to the use of modern TELEMETRY technology. Contrary to classic accounts of whale migration, the most recent studies show how movements vary across whale populations and species. Mysticetes appear to have periodical migrations with relatively consistent patterns over the years. Seasonal movements in odontocetes are far less consistent over time, including those of the sperm whale, which has been classified as a migratory species with marked seasonal patterns. In general, as in other marine mammals, factors inducing migration are the biological cycle, greatly determined by reproductive needs, and factors in the environment (e.g., prey availability, changes in water temperature). These factors may trigger the start of seasonal movements, although not all individuals will respond in the same way.

Annual migrations are best known for species with more coastal ranges, such as the gray, right, or humpback whales. However, virtually all mysticete species are known to migrate. No data are available for the pygmy right whale. Most mysticetes have latitudinal migrations, from tropical breeding grounds to high(er) latitude feeding grounds. In breeding grounds, mating and calving take place. Migratory species are right, blue (*Balaenoptera musculus*), fin (*B. physalus*), sei (*B. borealis*), humpback, and gray whales. Bowhead whales also migrate, but their longitudinal movements are equal to or greater than their latitudinal changes, and they never leave Arctic waters. Bryde's (*Balaenoptera edeni*), common minke (*B. acutorostrata*) and Antarctic minke (*B. bonaerensis*) whales, however, have less clear movement patterns. Bryde's whales spend most of the year in warm tropical waters and calving does not have the same marked seasonality seen in other balaenopterids. This indicates a possibly different reproductive cycle, in which both whales feed and mate year round. In this case, whale movements are more similar to those of many odontocete species, in constant search for food, with variable utilization of prey, and different prey types through the year. Among the best known migrations are those of the gray and humpback whales. Gray whales migrate annually from feeding grounds in the Arctic to their calving areas in the lagoons of Baja California in Mexico. Interannual changes in the timing

and numbers reaching the different migratory destinations have been observed. The migration of humpback whales is also very well studied, and sperm whales are the best example of long-range migration in odontocetes.

Movements in odontocetes have different scales depending on geographical areas, family, and species. It is generally accepted that most movements are in response to prey availability, and the largest movements, often called migration, occur in oceanic odontocetes. In the eastern tropical Pacific, movements are reported to be wide. Several species of *Stenella* had daily movements of 53 km/day and hundreds of kilometers over months, and these reflected seasonal changes in distribution. Dolphins moved inshore, toward the American continent, in fall and winter and offshore in spring and summer (Perrin, 1975). Other methods, such as line transect surveys in California, have shown how several dolphin species have different patterns of abundance and distribution depending on the season. Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), Risso's dolphins (*Grampus griseus*), common dolphins (*Delphinus* spp.), and northern right whale dolphins (*Lissodelphis borealis*) were less abundant in summer than in winter, and significant north/south shifts in distribution were reported for Dall's porpoises and common and Pacific white-sided dolphins. Significant inshore–offshore differences were found for the northern right whale dolphin. Some dolphin species show variable distribution patterns, such as bottlenose dolphins or killer whales. Difference in patterns has been attributed to different varieties or ecotypes of the same species. In the case of bottlenose dolphins, a well-studied coastal population (Scott *et al.*, 1990) showed a year-round residency with slight seasonal changes within the population home range. It has been argued that dolphins in Florida follow the mullet migrations into the Gulf of Mexico during the fall. Short-term movements have also been observed in a resident bottlenose population in east Scotland. In contrast, Atlantic offshore bottlenose dolphins, described as a possible different form, have wider movements and a broader distribution (Wells *et al.*, 1999).

B. Pinnipeds

Migration is not uncommon in pinnipeds, and the advent of new telemetry has helped describe the migratory movements of several species. Dispersal is very common in pinnipeds and depends on the abundance of prey, its energy content, and the seasonality of prey distribution. In addition, their reproductive cycle mandates that individuals return to land or ice to give birth, nurse, and rear their offspring and molt. Pinnipeds also haul out for resting, thermoregulation, and to escape predators, among other reasons. If the environment provides constant food resources, such as in some tropical areas, there will not be a clear need to disperse. In contrast, pinnipeds living in high latitudes will be more dependent on ice cover, availability of seasonally changing prey, reproduction, and population size. These will create density-dependent effects, such as dispersal and distributional changes. Thus, dispersal can vary with latitude, based on the stability of prey resources.

Phocids appear to migrate more than otariids, as they generally live in higher latitudes, where the environment (e.g., the ice cover) is more variable (Bowen and Siniff, 1999). For otariids that live in tropical areas with a more constant environment, habitat regulates the growth of the standing colonies and conditions of dispersal. Otariids also have longer lactations and rearing periods than seals. Their breeding behavior and requirements in terms of habitat are also different, allowing them to stay longer in the breeding colonies. Periodic events that lead to drastic changes in food availability or other environmental limitations, such as the El Niño southern oscillation (Trillmich and Ono, 1981), also favor dispersal. Among otariids, only the northern fur seal has a well-studied and distinctive migration.

Both elephant seal species and the hooded and the harp seals are good examples of migratory seals. Northern and southern elephant seals spend between 8 and 10 months at sea each year, with long-distance migrations between breeding and molting sites. Both species have two long migration trips between postbreeding and postmolting areas. The northern elephant seal migration, of between 18,000 and 21,000 km, is the longest reported for any mammal.

Harp and hooded seals have interannually variable distribution patterns, dependent on the time of the year, the geographic location, and the density of individuals in the breeding colonies. Harp seals live in colonies in the subarctic pack ice, where breeding takes place. The largest population of this species is in Newfoundland. Individuals from this population start their southward migration in late September along the coast of the Baffin Islands and go eastward through the Hudson Straits, reaching Labrador between October and December. There are variations in migration timing and patterns between age classes.

Gray seals from numerous colonies in the British Isles and gray seal pups disperse widely during the first year. Adult seals show high variability in their movements along the coasts of Scotland, especially in postbreeding periods and after the molt, from March to May. Although long-distance travel by adults occurs, short travel at close range from particular haul outs is more common. Juveniles tend to spend longer periods at sea. (Hammond *et al.*, 1993).

C. Sirenians

The best-studied movements by sirenians are of manatees in waters of Florida. Water temperature is a major determinant of seasonal movements of Florida manatees, and dispersal is higher in warmer months. In winter, manatees tend to aggregate in areas of warmer waters, such as natural freshwater springs or the outfalls of power plants (Reynolds and Odell, 1991).

D. Polar Bear

Seasonal movements in polar bears have been reported in all their distribution range. Long-range movements also occur and are mostly related to the ice cover and extent. PREDATION on seal pups also influences movements, and bears disperse more during pinniped pupping seasons. In summer, when ice melts in many areas, bears move to land, where they remain for a few months, before leaving in November–December. Pregnant females stay longer on land.

IV. Study of Marine Mammal Distribution

The study of distribution depends on each species' habitat and its abundance, so that scale is a significant factor. Distribution changes have to be interpreted in space and time, and different methods are to be used according to species range and density. The distribution of a species occupying an extensive ocean area is best studied by air- or shipboard surveys following systematically placed transects. In surveys, visual and/or acoustic data on species are collected according to predetermined protocols. Oceanographic variates and data on position of individuals can be incorporated in spatial modeling (Hedley *et al.*, 1999). Results of this modeling on repeated surveys can be compared to study seasonal patterns and changes over time (Forney and Barlow, 1998). In species that live in fragmented habitats and that are not abundant, knowledge of the location of animal aggregations is essential. In these cases, the best possible information is obtained from telemetry studies using high-frequency radio tags, satellite-linked radio tags, and geolocation time-depth recorders (Bowen and Siniff, 1999). The use of telemetry devices is also essential in understanding seasonal movements and patterns. The life of the batteries and permanence of the tags in the animals are critical to the duration of the studies. The study of habitat, an integral part of distribution, changes with the species life time because of the above-mentioned factors. It is difficult to monitor a cohort of animals, ideally tagged since birth, because of the long average life span of marine mammals. In practice, the general distribution patterns of a marine mammal population are the sum of the individual specific movements over space and time. Monitoring just a few animals over a restricted time duration (e.g., that of a telemetry device battery) produces partial information on the overall patterns and may show a high variability between individuals. Therefore, inferences at the population level must be made cautiously to avoid biased perceptions of the species distribution.

Diving Behavior

Brent S. Stewart
Hubbs–SeaWorld Research Institute, San Diego, California

Except for the polar bear (*Ursus maritimus*), all marine mammals feed exclusively in aquatic environments, and mostly in the world's oceans. The depths at which they hunt for and capture prey and the time spent submerged vary among pinnipeds, cetaceans, sea otters, and sirenians as a function of physical and physiological adaptations among these taxa, environmental conditions (e.g., coastal or pelagic, tropical or polar, season), and body size, age, and health of individuals. All are ultimately tied to the sea surface to periodically breathe, yet natural selection has operated to minimize the time needed there and to maximize the amount of time that may be spent submerged hunting and capturing prey. What has become known in recent years is that these animals spend substantial parts of their lives moving within the water column to relatively great depths and some over vast geographic areas in search of food. Among the amphibious pinnipeds, these aquatic foraging bouts may extend, with minor interruptions, for several weeks to several months, punctuated by periods of several days to weeks on land or ice when no feeding occurs when these animals rest, molt, or breed. For the less amphibious sea otters (*Enhydra lutris*), diving and foraging periods may be separated by periods spent sleeping or resting at the sea surface rather than on land. Among the wholly aquatic cetaceans and sirenians,

foraging bouts may last several hours or perhaps days, interrupted by periodic resting periods at the sea surface. Individuals of some species, particularly sperm whales and many mysticete cetaceans, may fast during migrations or in particular breeding areas. Although the diving performance and the patterning of individual dives or sequences of dives vary among species, what has become apparent for all marine mammals is that little time is spent at the surface between successive dives to exchange gases (i.e., unload carbon dioxide from tissue and blood and and restore tissue oxygen stores). This allows for sustained, repetitive diving and hunting, and is made possible by physiological adaptions for conserving heat and oxygen and by anatomical adaptations that promote effective movement in the aquatic environment (e.g., reducing drag through streamlining and efficient propulsion mechanisms).

I. Methods of Studying Diving Behavior

The simplest method for studying the diving behaviors of marine mammals is direct observation of the timing and location of appearances of individuals at the sea surface, the number of breaths taken there, and the duration of the animal's disappearance under water before reappearing. With some assumptions and strong inference, much can be deduced about what animals are doing while hidden beneath the ocean surface. Indeed, most early knowledge of diving, feeding, traveling, and migratory behaviors was based on such interpretations.

Other techniques for documenting diving behavior have used radio transmitter and telemetry instruments, operating at different radio frequencies. Sonic transmitters, operating at relatively low frequencies or wavelengths, allow the tracking of animals when they are submerged by placing a microphone (hydrophone) beneath the sea surface to listen for and orient to these signals (Fig. 1). Higher frequencies are used for in-air detection and tracking but generally yield less detailed observations, mostly when an animal reached the surface and how long it spent there. Durations are inferred from periods of radio silence, as transmissions that occur when the animal is submerged will generally be reflected downward from the sea surface and so not be capable of detection in air. When vocalizing underwater, some marine mammals may also be tracked with hydrophones to detect and localize those sounds. All of these techniques require constant tracking and observers must be within a few hundred meters (surface observers) or kilometers (observers in aircraft), as the signals attenuate quickly.

During the past several decades, and in particular during the 1990s, an enormous amount of information has been added to those simple observations due to technological developments and their application to free-ranging marine mammals. For example, in the late 1960s and early 1970s, an encapsulated mechanical photographic device was used in the Antarctic to study the diving patterns of Weddell seals (*Leptonychotes weddellii*). That instrument provided a continuous trace on photographic film of the depth of the seal versus time. The spooled film was pulled at a known rate past a small radioactive particle, which rested on a pressure-sensitive arm. Thus a two-dimensional record was made on the film of depth versus time. From these records came the first long-term (about 7 days continuous, based on film capacity) data on the vertical movements of marine mammals in the open ocean. Those instruments, called time-depth recorders (TDRs), were later deployed on a number of species of fur seals and some sea lions to study the effects of variation in body size and environment on the foraging patterns of lactating females. However, because the instruments were rather large and because they were attached with harnesses, they likely had some influence on the recorded durations of dives because of the effects of drag on swimming that they imposed, particularly for fur seals. Other simple instruments used capillary tubes with pressure sensors attached to record the maximum depth of a single dive or the maximum depth achieved during a period of diving.

Figure 1 *A sonic tag glued to the pelage of an adult male Weddell seal for monitoring its underwater movements in McMurdo Sound, Antarctica. Photo by B. S. Stewart.*

Mechanical instruments were replaced in the late 1980s with much smaller electronic instruments, armored to keep seawater out under extreme hydrostatic pressures. These instruments could collect and store substantially more data on depth and duration of dives and also had less impact on behavior. Indeed, today most of these instruments weigh less than 50 g and can be glued (Fig. 2) to the hair or fur of pinnipeds for long-term (up to a year) monitoring, attached to the dorsal fin of small cetaceans (Fig. 3), attached to the skin surface with subdermal anchors (Fig. 4) or deeply embedded into the blubber of large whales, or attached with suction cups to the skin of cetaceans for shorter term (up to several days) study. Because these instruments may now also collect data other than just water depth as a function of time (e.g., swim speed, ambient light level, compass bearing, seawater temperature, salinity), they are called time-data recorders. These instruments are generally controlled by small microprocessors that can be pro-

Figure 2 *A satellite-linked radio transmitter (PTT) attached to the head of a southern elephant seal at Marion Island. Photo by B. S. Stewart.*

grammed to record measures of various parameters at particular intervals that are then stored in electronic memory for several months or more. Thus, detailed records (e.g., at 1-sec intervals) of a marine mammal's position in the water column, in addition to other environmental and behavioral data, can be collected continuously for months or more.

Even more recently, technological developments and improvements have involved remote sensing of diving patterns and geographic movements of marine mammals using radio transmitters that communicate with earth-orbiting satellites, most notably the two polar orbiting satellites of the ARGOS

Figure 3 *A satellite-linked radio transmitter (PTT) attached to the dorsal fin of a short-beaked common dolphin. Photo by B. S. Stewart.*

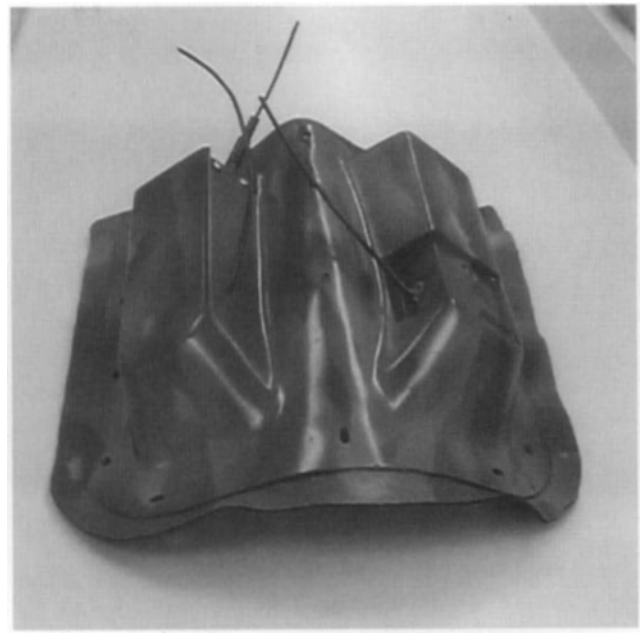

Figure 4 *A saddle package with a satellite-linked data recorder and transmitters custom built for attachment to the skin surface of a California gray whale. Photo by B. S. Stewart.*

Data Collection and Location (DCLS) system. These transmitters are known as platform transmitter terminals (PTTs). They allow animals to be located several times each day. They also allow small amounts of behavioral and environmental data to be transmitted through the DCLS. Further continuing improvement and miniaturization of film and digital video equipment are allowing the underwater diving, social, and hunting behaviors of marine mammals to be visually documented.

Most of what is now known and summarized below on the diving behaviors of marine mammals is based on two-dimensional (depth versus time) data from electronic TDRs, which are occasionally supplemented by geographic locations of the animals at the sea surface. Almost nothing is known of the movements of these animals in three-dimensional ocean space beneath the sea surface. Nevertheless, the seductiveness of representations of a single spatial vector (depth) versus time as a trace in a two-dimensional, linear spatial format led some researchers to infer the geographical form of dives in three-dimensional space. Moreover, some researchers further assigned physiological and behavioral function to those inferred spatial forms. However, the validity of such inferences and conclusions of function is untested, although they are interesting hypotheses for further rigorous inspection.

A substantial amount of information was collected on diving patterns of a number of pinniped species in the 1990s compared to relatively little progress in the study of cetacean diving patterns. The primary reason for the difference in quantity and quality of data between these taxa is principally due to the greater difficulty of keeping instruments attached to cetaceans compared to the long-term attachment of instruments, up to one year, to pinnipeds by gluing them to their hair.

Regardless, the dive patterns of virtually all species were limited to particular times of the year and even to particular classes of individuals (e.g., lactating female pinnipeds). Nearly year-round monitoring of northern elephant seals (*Mirounga angustirostris*) has been the exception. Consequently, any discussion of diving patterns is conditioned on these important constraints. Moreover, whether hunting or feeding occurs whenever animals are submerged and diving has not been confirmed. The incorporation of additional environmental and physiological sensors to TDRs and PTTs will undoubtedly help refine studies of diving patterns to more rigorously evaluate spatial form and function of subsurface movements and to enhance the summaries of dive patterns presented here.

II. Pinnipeds

A. Otariids

California sea lion females (*Zalophus californianus*) dive mostly to depths of around 75 m for about 4 min during summer and then deeper and longer the rest of the year (maximum depth of 536 m and longest dive of 12 min). When at sea for several days at a time and up to 1 to 2 weeks at some seasons, California sea lions dive virtually continually and rest at the surface for only about 3% of the time.

Juvenile Steller (northern) sea lions (*Eumetopias jubatus*) dive to average depths of 21 m (maximum 200 m). Most dives last less than 1 min. They are generally shallower at night and deeper in spring and summer than in winter. Adult females dive deeper than juveniles. Dives are deeper in winter than in autumn.

Southern sea lions (*Otaria flavescens*) dive mostly at night, apparently to the sea bed, where they hunt at depths down to 250 m. While at sea near the Falkland Islands, these sea lions dive virtually continually. Near Patagonia, over half of the time that lactating females are at sea they are diving. Their dives are mostly to depths of 19 to 62 m (maximum of 97 to 175 m) and for 2 to 3 min (maximum of 4.4 to 7.7 min). Diving is continuous during these bouts, and time spent at the surface between successive dives is brief, around 1 min.

Lactating New Zealand (Hooker's) sea lions (*Phocarctos hookeri*) also dive almost continually when at sea, averaging about 7.5 dives per hour, varying little with time of day. Dive depths average about 123 m (maximum of 474 m) and last between 4 and 6 min (maximum of 11.3 min). Most dives are evidently to the sea bed to forage on demersal and epibenthic fish, invertebrates, and cephalopods.

A few lactating Australian sea lion (*Neophoca cinerea*) females were reported to repeatedly forage on the sea botton (ca. 150 m deep) on the continental shelf of South Australia within 30 km of the coast.

Northern fur seals (*Callorhinus ursinus*) may be at sea continuously for several months or more from autumn through spring, but their diving behavior has not been studied then. Most data come from lactating female fur seals that are foraging near ROOKERIES in the Bering Sea in summer. Then they forage in bouts that mostly occur at night. Seals mostly make shallow dives to depths of 11 to 13 m, lasting around 1 to 1.5 min. These dives tend to be at night when seals are in pelagic habitats.

Depths and durations of dives of Galapagos fur seals (*Arctocephalus galapagoensis*) increase as they get older. Six-month-old seals dive to depths of around 6 m for up to 50 sec and dives occur at all hours. One-year-old seals reach depths of 47 m and durations average 2.5 min. Most of those dives occur at night. When 18 months old, seals are at sea mostly at night, diving continually for periods lasting around 3 min and reaching depths of 61 m.

Lactating Juan Fernandez fur seal (*Arctocephalus philippii*) females dive mostly at night to depths of 50 to 90 m, although most dives are shallower than 10 m. They last, on average, 1.7 to 2.0 min (longest 3.46 min).

Lactating female New Zealand fur seals (*Arctocephalus forsteri*) dive as deep as 274 m, and their longest dives have been measured at around 11 min. Median dive depths are around 5 to 10 m. They occur in bouts with the longest bouts at night. The deepest dives occur around dawn and dusk. Dives are shallowest (30 m) and shortest (1.4 min) in summer and get progressively deeper and longer through autumn (54 m, 2.4 min) and winter (74 m, 2.9 min).

Most dives of female Australian fur seals (*Arctocephalus pusillus doriferus*) are to the sea bed on the continental shelf at depths of 65 to 85 m. The median depth of one foraging male fur seal was 14 m and the median duration of dives was 2.5 min. The deepest and longest dives of that male were 102 m and 6.8 min, respectively, and the seal spent about one-third of its time at sea diving and foraging, with little variation in activity with time of day.

Lactating female subantarctic fur seals (*Arctocephalus tropicalis*) at Amsterdam Island dive predominantly at night. These foraging dives get progressively deeper and longer from summer (10 to 20 m and about 1 min long) through winter (20 to 50 m and about 1.5 min long). The deepest dive recorded is 208 m and the longest is 6.5 min.

Lactating female Antarctic fur seals (*Arctocephalus gazella*) dive mostly at night when they are at sea for periods of 3 to 8 days at a time in summer. These nighttime dives are shallower (about 30 m or less) than dives made during the day (40 to 75 m), closely matching the vertical distribution of krill. Maximum depths and durations of dives have been measured at 82 to 181 m and 2.8 to 10 min, respectively, for individual females. Seals apparently adjust their diving behavior to maximize the proportion of time that they spend at depth. Young pups dive mostly to depths of about 14 m, depending on their body size, for mean durations of 20 sec. Their diving abilities continue to develop during their first couple of months of life, and by the time they are weaned at around 4 months of age, they are able to dive to the same depths and for about the same amount of time as adult females.

B. Odobenids

The diving patterns of the walrus (*Odobenus rosmarus*) are not well studied. It is known, however, that its dives may last 20 min or more, although most may be less than 10 min and exceed 100 m. The longest dive yet recorded lasted about 25 min and the deepest was to 133 m. Most dives are likely shallower than about 80 m, as its benthic prey of mollusks are generally found in relatively shallow coastal or continental shelf

habitats. Near northeast Greenland, walruses may be submerged about 81% of the time when they are at sea and are presumably diving and foraging most of that time.

C. Phocids

Phocid seals generally are at sea continually for weeks to months and appear to dive, and perhaps forage, virtually constantly.

Elephant seals are perhaps the best studied of marine mammal divers. The dives of weaned southern elephant seal pups (*Mirounga leonina*) are to about 100 m for about 6 min and they dive virtually continuously when at sea for several months. Heavier pups dive deeper (to ca. 130 m) and longer (ca. 7 min) than smaller pups (88 m and 5 min). Dives of juvenile southern elephant seals last around 15.5 min (maximum of 39 min) to depths averaging 416 m (deepest 1270 m) and they spend about 90% of their several months at sea diving. Intervals between dives are brief, rarely lasting more than 2 min. Adult southern elephant seal dives average 400 to 600 m and 19 to 33 min (deepest 1444 m and 113 min) and also occur continuously while they are at sea for up to 7 to 8 months.

Northern elephant seals also dive continually when at sea for several months or more with only brief periods at the surface (1 to 3 min) between dives. Dives of adults are to modal depths of 350 to 400 m and 700 to 800 m (maximum of 1567 m) and average 20 to 30 min (maximum of 77 min). Depths and durations of dives differ between adult males and females depending on season and geographic location. Generally, these seals feed on pelagic fish and squid, although some seals may also dive to and feed near the sea floor near the coastlines of continents and islands.

Dives of Hawaiian monk seals (*Monachus schauinslandi*) are between 3 and 6 min long and mostly shallow, between 10 and 40 m deep, where the seals forage near the sea bed on epibenthic fish, cephalopods, and other invertebrates. Adults may occasionally dive to greater depths of up to 550 m when foraging outside of the shallow atoll lagoons of the northwestern Hawaiian Islands.

Weddell seals (*Leptonychotes weddellii*) may forage for much, if not most, of the year beneath the unbroken fast ice and the more open pelagic pack ice zones of the Antarctic. Diving and foraging occur in bouts of about 40 to 50 consecutive dives over a several hour period, usually to depths of 50 to 500 m. Dives of young pups are relatively shallow and brief but get progressively deeper and longer as pups age. They plateau when the pups are weaned when about 6 to 8 weeks old. The dives of 1 year olds are somewhat shallower, to around 118 m, compared to adult females (163 m). The deepest recorded is about 750 m and the longest over 73 minutes. Dives are shallower (350 to 450 m) in spring (October to December) than in summer (January; 50 to 200 m), evidently reflecting a shift in preferred hunting depths.

Among the Antarctic pack ice seals, Ross seals (*Ommatophoca rossii*) are also relatively deep divers. One female that was monitored near the Antarctic Peninsula in summer dove exclusively at night, mostly to depths of 110 m (maximum of 212 m) and for about 6.4 min (longest 9.8 min). Diving was continual while the seal was in the water with about 1 min between dives. The deepest dives (175 to 200 m) occurred near twilight and the shallowest (ca. 75 to 100 m) at midnight.

In summer, crabeater seals (*Lobodon carcinophaga*) dive primarily at night and haul out on pack ice during the day, although some diving bouts may last up to 44 hr without interruption. Most dives are 4 to 5 min long to depths of 20 to 30 m, with maximum depths and durations of 430 m and 11 min, respectively. Dives near twilight are deepest and those near midnight shallowest.

Baikal seals (*Pusa sibirica*) apparently dive continually from September through May, when the freshwater Lake Baikal is frozen over, and haul out only infrequently then. Most dives are 10 to 50 m deep in the middle of Lake Baikal where the water depth is around 1000 to 1600 m. Occasionally seals descend to more than 300 m. Dives last between 2 and 6 min but some have been measured at more than 40 min.

Dives of another closely related freshwater seal, the Saimaa seal (*Pusa hispida saimanensis*) of Lake Saimaa in eastern Finland, last about 6 min in spring and increase to about 10 to 11 min by autumn. In summer and autumn, long series of sequential dives lasting more than 10 min each may occur over 3 hr or more. The longest dive recorded is about 23 min, when the seal may actually have been resting on the bottom rather than feeding.

Modal dive depths for breeding age, male ringed seals (*P. hispida hispida*) are 10 to 45 m and for subadult males and postpartum females 100 to 145 m. Durations of dives for adult males are around 4 min and around 7.5 min for adult females.

Harbor seal (*Phoca vitulina*) diving behaviors have been studied in a number of areas throughout their range in the North Pacific and North Atlantic Oceans. Dives in the Wadden Sea (northeast Atlantic) average from 1 to 3 min (maximum of 31 min) with little variation between night and daytime behavior. When in the water, about 85% of their time is spent diving. In the western Atlantic, foraging dives of adult males are mostly deeper than 20 m but are shallower during the mating period, when they are defending aquatic territories or searching for females to mate with instead of foraging. Dives of lactating females are to 12 to 40 m and occur in bouts lasting several hours, mostly during the day. In southern California, dives are as deep as 446 m. Most, however, are to modal depths of 10, 70, or 100 m with an occasional mode at around 280.

Bearded seal (*Erignathus barbatus*) adult females near the coast of Spitzbergen, Norway, dive mostly at night to depths of around 20 m (deepest at 288 m) and for 2 to 4 min (longest 19 min). Nursing pups may dive to around 10 m (maximum of 84 m) for about 1 min (maximum of 5.5 min). Pups spend about 40% of the time that they are in the water diving. Depths and durations of dives increase as the pups age.

Most dives of lactating female gray seals (*Halichoerus grypus*) are to the sea floor and last about 1.5 to 3 min (maximum of 9 min). Most foraging dives of juvenile gray seals in the Baltic Sea are to depths of 20 to 40 m.

Lactating female harp seals (*Pagophilus groenlandicus*) dive about 40 to 50% of the time that they are at sea. Dives average about 3 min (maximum of 13 min) to depths of up to 90 m.

Hooded seals (*Cystophora cristata*) repeatedly dive to depths of 1000 m or more and for 52 min or longer. Most feeding dives appear to be to depths of 100 to 600 m.

III. Cetaceans

A. Odontocetes

Limited data for odontocete cetaceans so far indicate that short-beaked common dolphins (*Delphinus delphis*) may forage at depths of up to 260 m for 8 min or more, although most dives are around 90 m deep, last about 3 min, and are mostly at night. Pantropical spotted dolphins (*Stenella attenuata*) dive to at least 170 m; most of their dives are to 50 to 100 m for 2 to 4 min and most feeding appears to occur at night. Atlantic bottlenose dolphins (*Tursiops truncatus*) near Grand Bahama Island off southeastern Florida often dive to the ocean bottom (7–13 m depth) and burrow into the sediment ("crater-feeding") to catch fish dwelling or hiding there. Long-finned pilot whales (*Globicephalas melas*) dive to over 500 to 600 m for up to 16 min. Northern bottlenose whales (*Hyperoodon ampullatus*) regularly dive to the sea bed at depths of 800 to 1500 m for more than 30 min per dive and occasionally for 2 hr.

Harbor porpoises (*Phocoena phocoena*) near Japan have dived almost continuously when observed for short periods. Maximum dive depths are around 70 to 100 m, although about 70% of dives may be less than 20 m. These porpoises descend to and ascend from depth at greater rates when diving deep than when the dives are shallow. In waters near Denmark, porpoises dive as deeply as 84 m and for up to 7 min from spring through late autumn.

Female white whales (*Delphinapterus leucas*) dive more often between 2300 and 0500 hr than during the day, although males may dive at the same rate at all hours. Dive rates and time spent at the surface decline whereas dives deepen and lengthen from early through late autumn. Most dives are deep (400 to 700 m), with the deepest recorded at 872 m, and last about 13 min on average (maximum of 23 minutes). Dive duration increases with body size.

Narwhals (*Monodon monoceros*) regularly dive to more than 500 m and occasionally deeper than 1000 m, but most dives are to depths of 8 to 52 m and last less than 5 min, although as long as 20 min on occasion. The rate of diving varies between adult males and females. When diving shallow, narwhals descend and ascend relatively slowly (<0.05 m/sec) compared with deeper, longer dives (1 to 2 m/sec) where substantially more time is spent at maximum depth.

Killer whales (*Orcinus orca*) along the northern coast of North Island, New Zealand, dive to the ocean bottom (ca. 12 m depth or less) after stingrays and perhaps burrow into the sediment to catch them.

Sperm whales (*Physeter macrocephalus*) dive to depths of up to 2000 m for 60 min or more. Near Kaikoura, New Zealand, the average duration of dives is about 41 min with about 9 min spent at the surface between dives. Both durations and surface intervals are longer in summer than in winter. Males spend little time at the surface compared to females. Average dive durations have been measured at 36 min near Sri Lanka and about 55 min near the Azores. Sperm whales in the Caribbean were reported to make dives averaging 22 to 32 min during the day (longest 79 min) and 32 to 39 min at night (longest 63 min).

B. Mysticetes

As yet there is no evidence for a taxonomic relationship between body size and maximum dive depths for mysticete cetaceans, although preliminary correlations have been reported between maximum dive durations and body size.

While in shallow coastal lagoons during the spring breeding season, gray whales (*Eschrichtius robustus*) dive for about 1 to 5 min (maximum of 28 min) to average depths of 4 to 10 m (maximum recorded of 20.7 m). It is not clear what the function of these dives may be other than perhaps subsurface resting, as breeding whales are presumed to fast. In the Bering Sea in summer, when whales are feeding, dives average about 3 min.

Fin whales (*Balaenoptera physalus*) in the Ligurian Sea dive repeatedly to depths around 180 m (maximum 474 m) for around 10 min (longest 20 min) while they prey on deep-dwelling krill. Elsewhere, fin whale dives have been reported to last about 5 min near Iceland and about 3 min in the North Atlantic and near Long Island, New York, in summer.

When chased by commercial whalers, dives of blue whales (*Balaenoptera musculus*) lasted up to 50 min. Blue whales off central and southern California otherwise spend about 94% of their time submerged. Dives lasting longer than 1 min are 4.2 to 7.2 min, on average (longest 18 min), and to around 105 m (deepest 150 to 200 m). Dives of pygmy blue whales (*B. m. brevicauda*) have been measured to average 9.9 min (longest 26.9 min).

Humpback whales (*Megaptera novaeangliae*) in Frederick Sound, Alaska, make rather brief (most less than 3 min) and shallow (60 m or less) dives, although some may exceed 120 m on occasion.

When on summer feeding grounds in the Beaufort sea, dives of bowhead whales (*Balaena mysticetus*) last 3.4 to 12.1 min and some are to the relatively shallow sea bed. Dives of calves are very short compared to adults and they also spend more time at the surface between dives. Most dives of juveniles last about 1 min (longest 52 min) to depths of around 20 min. Longer dives, up to 80 min, have been observed for bowhead whales that were harpooned and being chased by whalers. Dives lasting longer than 1 min ("sounding dives") average between 7 and 14 min. Dives made while whales are migrating through heavy pack ice are deeper and longer than those made while in open water. Lactating females dive less often and for shorter periods than other adult whales.

Dives of North Atlantic right whales (*Eubalaena glacialis*) near Cape Cod, Massachussetts, last around 2.1 min.

IV. Other Marine Mammals

Manatees (*Trichechus manatus*, *T. inunguis*, and *T. senegalensis*) feed on floating and submerged vegetation in shallow nearshore habitats so it is unlikely that their dives often exceed 25 to 30 m. Direct observations of free-ranging animals have shown that most dives are less than 5 min, although a few have been timed at more than 20 min. These longer dives may have periods of rest at the bottom rather than feeding activity. Dugongs (*Dugong dugon*) also feed on submerged vegetation, most often in coastal and offshore seagrass beds either on the sea bottom to depths of 20 m or in surface canopies. The longest foraging dives observed are around 6 min, but most have been reported to last only between 2 and 4 min.

Sea otters dive and forage mostly in shallow nearshore waters. Dives may be in bouts lasting several hours during the day and

night, interrupted by periods at the surface to groom, process food, or rest. Juvenile males often dive in deeper water, for longer periods, and further from shore than juvenile and adult females. Details on diving sequences, depths, durations, and other parameters are just beginning to emerge from the recent deployment of TDRs in southeast Alaska and in the Gulf of Alaska.

Polar bears (*Ursus maritimus*) are powerful swimmers and probably make some dives while moving among ice floes, the fast-ice edge, or coastlines, but nothing is known of the details of such diving performance. They prey mostly on ringed seals and whale carcasses on the surface of the ice or along shorelines and also on white whales and narwhals that they may attack and kill at the sea surface and then drag out of the water to consume.

Diving Physiology

GERALD L. KOOYMAN
Scripps Institution of Oceanography, La Jolla, California

ver since humankind has lived by and gone down to the sea, we have been awestruck by the creatures that make it their home. First we feared them, later we ate them, and now we try to emulate them with humble attempts to set "world" diving records. At present the record for a descent-assisted dive at 133 m during a breath hold is a little over 2 min. Most marine mammals exceed that depth within the first few months of life. Premier divers such as elephant seals (*Mirounga* spp.) and sperm whales (*Physeter macrocephalus*) will occasionally dive to depths beyond a kilometer (Table 1). The spectacular abilities of marine birds and mammals to dive deep and for long periods of time are a source of interest and curiosity for marine scientists and amateurs alike.

When marine mammals descend below the sea's surface they leave behind the thin skin of the earth's atmosphere with one of its essential ingredients to all vertebrate life—oxygen. They begin a journey that is incredible in diverse ways. The magnitude of incredulity varies according to the species, but for all, even the most humble of marine mammals, such as the sea otter (*Enhydra lutris*), much if not most of the experience is beyond our imagination. Unlike flying, in which our technology now enables us to fly faster, higher, and further than any bird, bat, or pterosaur ever has or did, marine mammals, particularly those that dive to great depths, explore and exploit a realm that overwhelms much of our technology and which enables us to gain only fleeting glimpses of what their environment is like. Recently we have enlisted the animals themselves to help us discover more about this cold, dark world without oxygen, where awesome hydrostatic pressures always prevail. However, "crittercams" will only give us fleeting glimpses, under very special conditions, with those few species that lend themselves to the attachment of these bulky cameras. Life in the deep blue remains a mystery. So too do the means that enable diving mammals to exploit this habitat.

TABLE I
Distribution and Quantity of Oxygen Stores, Maximum and Routine Diving Depths, and Durations for Some Marine Mammals

Species	Body mass (kg)	Total store (ml/kg)	% Lung	% Blood	% Muscle	Routine depth (m)	Maximum depth (m)	Routine duration (min)	Maximum duration (min)
Human	70	20	24	57	15	5	133	0.25	6
Weddell seal	400	87	5	66	29	200	700	15	93
Elephant seal	400	97	4	71	25	500	1500	25	120
California sea lion	100	40	21	45	34	40	275	2.5	10
Bottlenose dolphin	200	36	34	27	39		535		
Sperm whale	10000	77	10	58	34	500	2035	40	75

This article discusses some of what is known about adaptations to breath holding and overcoming the crushing effects of pressure. These adaptations are among the most unique among vertebrates. Even after our primordial fish ancestors overcame great obstacles to adapt to the terrestrial environment, and eventually to spread throughout all land habitats of the world, the sea continued to be a rich habitat that would bring great success to those species that exploited it. Some air-breathing vertebrates are doing just that. In fact, this has occurred several times in the history of vertebrates as they reinvaded the sea. The marine reptiles of the Mesozoic were diverse, abundant, and no doubt very capable divers. They had at least one major advantage over marine mammals: a small brain. The brains of mammals require a substantial share of the oxygen being supplied to the body, and it is an obligate need with very little reserve for those times when supply is interrupted. Within 3 min after blood flow and oxygen transport to the human brain are interrupted, there is irreversible damage. This sensitivity of large, complex brains to a grave need for oxygen makes it seem a contradiction that animals who routinely breath hold many times every day are all so smart. Proportionately in terms of brain size relative to body size, several cetacean species have some of the largest brains of mammals. Despite this "handicap," marine mammals have been an extremely successful group that are found in all the world's oceans, in extremely large numbers, and have the biomass of some species matching that of any of the formerly abundant terrestrial mammals of the world.

What is the secret of their success? Some routinely dive to depths of several hundred meters, and a few species may occasionally descend from 1 to 3 km (Table I). Although these depths may seem just a superficial range compared to the ocean limit of 11 km, with an average depth of 3.5 km, the range used by most marine mammals is in the zone of greatest oceanic life. Nevertheless, this region of cold, dark waters requires special adaptations enabling the animal to endure low temperatures and to find prey in the "dark." Marine mammal diving skill provides a dramatic contrast to human capacities. On average, we can dive to a few meters for about 30 sec. The super athletes who make a career of setting records, such as the record breath-hold dive of 133 m, require mechanical aids of weights, pulleys, and drop lines. To extend our depth beyond these few meters, humans have gone to costly extremes in mechanical devices. Most deep submersibles are usually limited to several hundred meters depth, but ALVIN, the workhorse of the scientific submersibles, can go as deep as 4500 m.

Adaptations of marine mammals to the marine environment are diverse in order for them to become successful marine predators. They involve many systems in and out of the body, ranging from external body shape to overcome the high density and viscosity of water to the sensory systems necessary to find their way and to detect prey and predator. Space will allow for discussion of only a few of the numerous adaptations necessary for a successful marine mammal. The following paragraphs discuss adaptations to hypoxia and pressure. These paragraphs address pelagic, offshore deep divers in which the adaptations are the most extreme.

I. Adaptations to Hypoxia

A. Oxygen Stores and Their Distribution

An increased total body O_2 store is considered an essential factor in the breath-hold capacity of diving mammals. The oxygen consumed by body metabolism during a breath hold is stored in three compartments: the respiratory system, the blood, and the body musculature. The theoretical maximum amount of oxygen available in each compartment is a function of several criteria. The respiratory oxygen store is dependent on lung volume and the concentration of oxygen in the lung at the start of a breath hold. The blood and muscle oxygen stores are dependent on blood volume and muscle mass and on the concentration of the oxygen-binding proteins of hemoglobin in blood and myoglobin in muscle. From the measurements of myoglobin concentration in the muscles of many species of divers, it is clear that one of the most consistent hallmarks of oxygen storage in all marine mammals that dive to depth is an elevated myoglobin concentration. This trait is more characteristic of deep divers than any changes in blood volume, hemoglobin concentration, or respiratory volumes. However, increased blood volume and hemoglobin concentration often contribute to elevated oxygen storage.

As the distributions of oxygen stores vary among species, so do the ranges of the total oxygen store (Table I). In humans the

total store is 20 ml O_2kg^{-1} body mass, which is about a fifth of the nearly 100 ml O_2kg^{-1} body mass in elephant seals (*Mirounga* spp.). Using the seal as our basic model, it is noted that most of its oxygen is in blood and muscle. The large amount relative to terrestrial animals, using the human average as a standard, is a result of a blood volume 3 times, a hemoglobin concentration 1.5 times, and a myoglobin concentration approximately 10 times the human value. In seals the lung is a minor source of oxygen, as it is in most other marine mammals. It is less than 5% of the total, in part because seals exhale to 50% of their total lung capacity just before diving. Furthermore, at depth the lung is collapsed and does not exchange gas.

B. Cardiovascular Responses

The cardiovascular response to breath holding falls into at least two categories of whether the dive is extended or of routine duration for that species. Measurements of cardiovascular and metabolic responses under these circumstances are very limited for any species and most measurements are from seals. Diving mammals are arrhythmic breathers with pauses between series of breaths. The resting maintenance heart rate is probably most closely reflected in the rate during the respiratory pause or apnea. Using the heart rate during apnea as a basis of comparison for heart rates during a routine dive, heart rates during the dive are lower than the rate of a resting apneusis, and this occurs despite the fact that the mammal is swimming. When an extended dive is performed, the heart rate is even lower than that during routine diving. Because no measurements of blood flow distribution have been directly measured during dives of marine mammals, it is by extrapolation from indirect measures of other organ functions that allude to what may be occurring. During routine dives it is likely that gastric, renal, and hepatic functions are reduced a small amount, but no more than what can be compensated for by higher than normal performance during the short breathing intervals at the surface. Muscle may utilize a small part of the circulating blood oxygen, but it probably relies on its internal store of oxygen bound to myoglobin for much of the aerobic metabolic needs.

Extended dives, those that are three to five times the routine dives, are uncommon. They are most likely to occur because of some urgent need, such as a Weddell seal (*Leptonychotes weddellii*) searching for a new hole under sea ice or an elephant seal hiding at depth to escape notice from a passing pod of killer whales (*Orcinus orca*) near the surface. The cardiovascular response in these extreme cases may be a limitation of blood flow to obligate aerobic tissues, the most conspicuous of which is the brain. Having no internal store of oxygen, and a need to be at full functional capacity, a constant supply of oxygen and other metabolites provided by the blood, as well as transport of waste products of metabolism from the brain, means that constant blood flow is essential. There is a lesser need for transport of oxygen to the heart because of a reduced work load (the slower heart rate) and a small store of internal oxygen. The blood flow to muscle is reduced to a trickle as it draws from the large oxygen store within the muscle and the internal store of glycogen for the production of the high-energy compounds of adenosine triphosphate (ATP). The high concentration of myoglobin in *all* mammals that dive to depths greater than about 100 m indicates that myoglobin is a key adaptation for diving. Blood flow would be a liability as the affinity of myoglobin for oxygen is much higher than the affinity of hemoglobin for oxygen. Consequently, any flow to muscle that had utilized much of its oxygen store would strip oxygen from the circulating blood and deprive more vital organs, such as the brain, from oxygen. A reduced blood flow to muscle also decreases cardiac output needs and, hence, the work of the heart and its oxygen consumption. Thus, the degree of muscle blood flow reduction during long and short dives is key to understanding the management of oxygen stores. Unfortunately, little is known about this crucial topic. Unlike other organs, muscle is widely distributed in the body, and the vascularity is diffuse. Consequently, it is an intractable problem which has not lent itself to study.

Muscle also has a great capacity for anaerobic metabolism and tolerance for high concentrations of the metabolic end product of lactic acid, which is stored in the form of lactate. Nevertheless, muscle must continue to function for locomotion either continuously, as a Weddell seal swims below the sea ice, or intermittently, as in an elephant seal as it drifts in the depths, but in the end must call upon muscle to provide the locomotion to return to the surface. In contrast, the splanchnic organs may shut down or greatly reduce function until the diving mammal returns to the surface.

C. Metabolic Responses

The cessation of metabolic function in the splanchnic organs reduces metabolic rate substantially, as these organs functioning at normal rates account for nearly 50% of the total resting metabolism of the animal. In addition, the heart beats more slowly and performs less work, which may also be the case for striated muscle. In the cold environment at depth, some tissues may also be cooling, which would result in an additional savings in energy consumption. The final result is to lower the overall metabolic rate to below the resting level during these short and metastable conditions.

D. Anaerobic Metabolism

Dominating the many factors that affect how long an animal may breath hold is the amount of oxygen available and its rate of utilization. Through oxygen-supported metabolic pathways, 18 times more high-energy ATP is produced from glucose than through anaerobic processes. Furthermore, carbon dioxide and water, the end products of oxygen-supported catabolism, are less polluting to the cells and circulation than those of anaerobic catabolism. Finally, nerve cells, especially within the brain, are completely dependent on aerobic metabolism. Therefore, the duration of time an animal may breath hold is most strongly affected by the availability of oxygen, with subsidiary support from anaerobic glycolysis and creatine phosphate catabolism. Although an animal may extend its dive considerably by relying on anaerobic glycolysis, the subsequent recovery is in turn extensive because of the time required to process lactic acid and restore the acid base balance of the cells and circulatory system. For routine dives that occur in sequence over many hours, aerobic metabolism is the only practical option. Oxygen-supported metabolic pathways are also the

only means of producing ATP that is derived from catabolism of fat and protein.

E. Aerobic Diving Limit

The only diving mammal in which there has been a detailed correlation of the diving duration and the postdive blood lactate concentration is the Weddell seal (Fig. 1). The source of the lactate has been shown to be from muscle, in which it accumulates rapidly as muscle oxygen is depleted. After the seal surfaces, there is increased blood flow to muscle and much of the lactate is flushed into the circulation and gradually disappears over several minutes. If the seal should dive again before all of the blood lactate is processed, it will continue to decline over the course of the dive unless that dive exceeds what has been termed the aerobic diving limit (ADL). The ADL is defined as the diving duration beyond which there is a net increase in lactate production. This rise in lactate concentration first occurs primarily in muscle and eventually diffuses from the organ into the circulation where it can be measured easily. It has been proposed that this threshold be called the diving lactate threshold (DLT) to avoid confusion about the numerous ways that the ADL has been derived since the first measurements were made on Weddell seals. From those measurements it was also shown that with some reasonable accuracy the ADL could be obtained from the quotient of the O_2 store divided by the metabolic rate, the calculated ADL (cADL). Because this limit predicts basic information about the foraging behavior of diving animals, as well as clarifying physiological responses and models to breath holding, it has been calculated for many diving species. Some of the most intriguing calculations have been made for the elephant seal, a continuous diver that appears to allow no surface time for recovery from dives exceeding the cADL. There are several possibilities that could resolve this puzzle. A recent computer simulation of oxygen store depletion provides a physiological model of aerobic diving that may clarify this problem and provide direction for further studies.

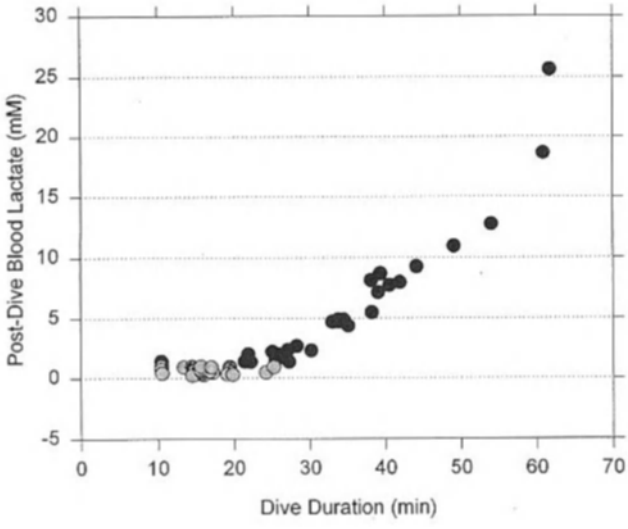

Figure 1 *Peak concentration of lactate in arterial blood after dives of different duration in adult Weddell seals. The inflection represents transitions from completely aerobic dives and is considered the aerobic diving limit or diving lactate threshold. Gray circles reflect blood values of dives in which there is no net production of lactate, and black circles are those in which there was a net production.*

This comprehensive, numerical model uses as its data source the Weddell seal because there is extensive information on this species. The calculations in the model are based on or derived from available data on cardiac output, O_2 depletion rates of blood and muscle, blood flow patterns in various organs, and the diving metabolic rates that may occur in the Weddell seal. The model demonstrates how the matching or mismatching of oxygen transport and regional oxygen consumption can affect the ADL. This theoretical treatment of the ADL goes a long way in understanding how oxygen must be managed during a dive and, in particular, explains how 31% of the body O_2 store remains unconsumed under the most optimal cardiac output conditions. The model also shows that only 49% of the muscle oxygen provision comes from the internal store during the longest possible aerobic dive. In regard to recovery from an extended dive, the oxygen replenishment rate is much more rapid than the reconversion of lactate to glycogen.

Assuming that the model can be applied to other aquatic species, it may help explain the enigma of the serial dives in the elephant seal that exceed previous cADLs. However, the model does not take into account the influence of creatine phosphate to support the few dives that may appear to exceed the ADL, and for which some have invoked some unusual hypometabolic responses. Because the creatine phosphate concentration is 15–20 mmol kg^{-1} in mammals, this is enough to have a significant effect on the magnitude of the ADL and the production of energy without oxygen, but before measurable amounts of lactate are produced.

II. Adaptations to Pressure

Once a marine mammal descends below the surface, it not only must deal with the lack of oxygen but also with the effects of pressure. This is one of the most imposing physical variables to which vertebrates must adjust. We become especially sensitive to pressure during the most modest dive to depth because our airspaces, such as the middle ear and facial sinuses, make us acutely aware of any difference between the ambient pressure and our internal pressure. More subtle is the effect of pressure on the lung. For humans the lung is an important oxygen store, but in deep-diving mammals the lung is not an important oxygen store. Over a long period of evolution the main function of the vertebrate lung became the exchange of gases between blood and air. During the descent to depth, this function is diminished in deep-diving marine mammals. As the transfer of gases between the lung and blood slackens or ceases, the rise in nitrogen partial pressure within the lung is not matched in the blood. The lack of gas exchange also results in the avoidance of nitrogen narcosis and oxygen toxicity. Even with this adaptation there is still the pure physical effect of hydrostatic pressure on the nervous system. In terrestrial mammals, pressure causes overstimulation or uncoordinated nerve conduction and dysfunction called high-pressure nervous syndrome (HPNS). How

do marine mammals manage to avoid these problems that are manifested in their terrestrial relatives?

The pressure within all airspaces must closely match that of the ambient pressure or the diving animal will suffer damage to the membranes and blood vessels lining the space and a breakdown in normal function. There are at least three major airspaces within most mammals that are liabilities for diving. First are the facial sinuses. Any experienced diver or airline passenger is aware that flying or diving during or soon after having a head cold is a bad idea. The blockage that may ensue during rapid pressure changes can cause extreme pain and serious damage to tissues and blood vessels lining the walls of these cavities. Marine mammals do not have this problem because they have no facial sinuses. Thus, one problem is dealt with by the absence of the airspace.

Similar to all other mammals there is a cavity that forms the middle ear. This is a rigid structure that has little or no compressibility. A pressure differential is prevented, at least for seals and sea lions, because of a complex vascular sinus lining the wall of the middle ear cavity. As the pressure within the middle ear cavity begins to fall below that of the vascular tree, the blood sinuses volume increases. This is a result of the close match between ambient pressure and blood pressure transferred from one fluid (sea water) to another (blood). Another problem is resolved by the reduction of an airspace by hydraulic compression through the vascular system.

Third, the largest airspace of all, and potentially the most problematic, is the lung. Volume pressure curves of the chest wall and lung of the ribbon seal, *Histriophoca fasciata,* show that both the chest and the lung are nearly limitless in the degree of compression collapse that they can tolerate. This must be so for other diving mammals as well, and in less detailed studies it has been shown that there is exceptional compressibility in other seals, sea lions, and dolphins. Dolphins and other toothed whales show the most extreme modifications within the lung among marine mammals, or any other mammal. Most notable is the reinforcement of peripheral airways, the loss of respiratory bronchioles, and the presence of a series of bronchial sphincters. Sea lions also have robust cartilaginous airway reinforcement extending to the alveolar sac, but there are no bronchial sphincters. In seals there is no cartilage in the terminal airway, but the walls are thickened by connective tissue and smooth muscle, which reduces their compliance to less than that of the alveoli. Hence, during compression the more compliant alveoli collapse first and the gases within these alveoli are squeezed into the upper airway spaces.

These airways enable a graded collapse of the lung to occur during a dive to depth. The result is that most of the lung air is forced into the upper airways where gas exchange with the blood ceases. It has been shown that blood PN_2 in seals only rises slightly, no matter how deep the dive. During simulated and actual dives to depth, the P_aN_2 of the northern elephant seal, *Mirounga angustirostris,* peaked at 300 kPa and equilibrated to 200 kPa where it was approximately the same as venous PN_2 (Fig. 2). This was independent of the ambient pressure from 37 to 138 m (1480 kPa). Similar values were obtained for Weddell seals diving voluntarily to depths as great as 230 m (2400 kPa). These small increases in P_aN_2 indicate that lung

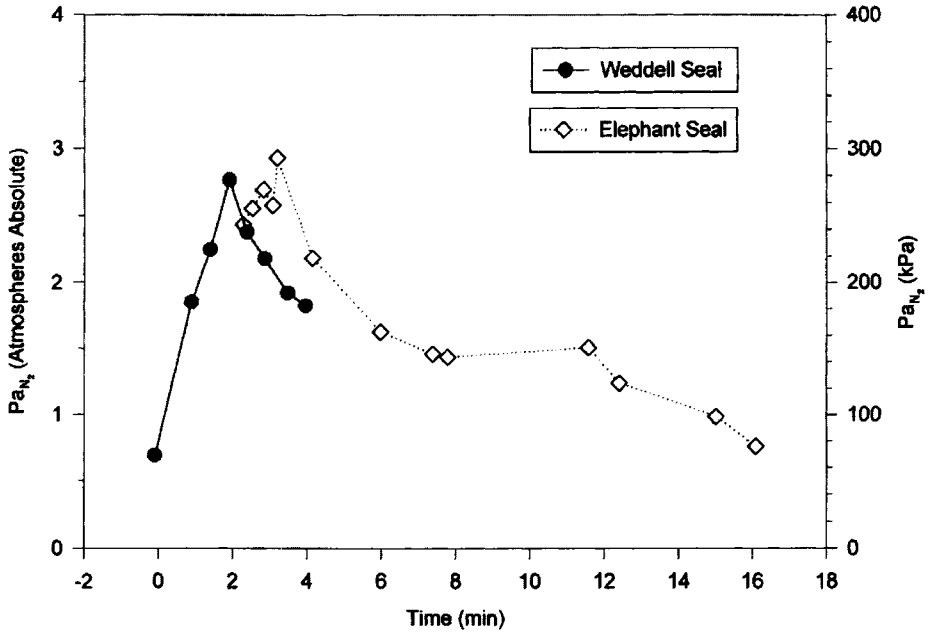

Figure 2 *Arterial N_2 tensions in an elephant seal and a Weddell seal. The elephant seal submersion was simulated in a water-filled hydraulic compression chamber to pressures equivalent to a seawater depth of 272 m. Compression began at zero; at 11 min pressure was released and at 14 min the submersion ended. The Weddell seal made a free dive to 89 m under Antarctic ice. Maximum depth was reached at 5 min, and the dive ended after 8 min.*

collapse in both species occurred between 20 and 50 m. The early occurrence of lung collapse in seals makes the lung almost useless as an O_2 store, but it limits N_2 absorption during the dive. These N_2 values are below the minimum PN_2 of 330 kPa found to be necessary for bubble formation in cats, and it is assumed that a similar threshold for bubble formation prevails in marine mammals. An additional benefit of early lung collapse is that it eliminates the likelihood of nitrogen narcosis. This condition is often experienced by SCUBA divers descending to depths greater than 30 m. At these depths the tissue nitrogen level is at least 399 kPa, greater than the P_aN_2 measured in seals. A final thought is the intriguing condition of elephant seals at sea when they spend 90% of their time underwater and at depths greater than 100 m. At these times the lung does not do what it was originally evolved to do, i.e., to exchange gas with the blood and with the atmosphere. Instead it is collapsed to a solid organ, and the alveoli become unavailable for gas exchange.

Finally, in humans and other nonaquatic animals descending to depths of more than 100 m and at rates of 100 m min^{-1}, the mechanical compression on nervous tissue can cause HPNS. The symptoms are modest to severe tremors throughout the body that can become so severe as to be incapacitating. The range of depths and the rate of descent are modest compared to that of some deep-diving marine mammals. Surely a well-adapted mammal does not experience HPNS, which leads to the compelling question of what the difference is between the neural makeup of a marine mammal that protects it from experiencing HPNS and that of a terrestrial mammal that is susceptible to HPNS. We must conclude that the structure of the nervous system is modified in a unique way for a life at high pressure.

III. Epilogue: Mysteries of the Deep

Our understanding of the physiology of diving in marine mammals is still elementary. These animals have adapted to some of the most extreme conditions on the planet. What we can learn from them about hypoxia and pressure is of much intellectual interest as well as of clinical significance. In addition to the brief summary presented, there is a host of other adaptations not mentioned and in some cases not studied. Some of these are blood and muscle interactions under extreme hypoxia, and acoustical and visual sensing under the extreme conditions of depth where pressure is intense, the cold is penetrating, and light from the surface is at times nil. Many organisms have adapted to a life under these various conditions, but marine mammals commute to the depths, and where they excel is in their adaptability to rapid changes in these extremes as they move from the conditions at the interface of air and water to those of several hundred meters to even a few kilometers beneath the surface.

Dolphin

SEE *Delphinids, Overview*

Dugong

Dugong dugon

HELENE MARSH
James Cook University, Townsville, Queensland, Australia

The dugong (*Dugong dugon*) looks rather like a cross between a rotund dolphin and a walrus. Its body, flippers, and fluke resemble those of a dolphin without a dorsal fin. Its head looks somewhat like that of a walrus without the long tusks. Growing to a length of up to about 3 m, the dugong is the only extant plant-eating mammal that spends all its life in the sea. The other sea cows (or sirenians), the three species of manatee, all use fresh water to varying degrees.

I. Diagnostic Characteristics

Dugongs can be difficult to distinguish from dolphins in the wild, especially as they often occur in muddy water. They surface very discreetly, often with only their nostrils showing above the water. Dugongs tend to move more slowly than dolphins.

Adults are gray in color but appear brown from the air or from a boat. Older "scarback" individuals may have a large area of unpigmented skin on the back above the pectoral fins. There is no dorsal fin. The dugong's head is distinctive with the mouth opening ventrally beneath a broad, flat muzzle. The tusks of mature males and some old females erupt on either side of

the head. The eyes are small and not prominent. Externally the ears consist of only of small openings, one on either side of the head. The flippers are short and, unlike those of the West Indian and West African manatees, lack nails. There are two mammary glands, each opening via a single teat situated in the "armpit" or axilla. The mammaries are somewhat reminiscent of the breasts of human females, which probably explains the legendary links between mermaids and sirenians. Hindlimbs are absent. Unlike manatees, which have a paddle-shaped tail, the tail of the dugong is triangular like that of a whale (Fig. 1).

II. Distribution and Abundance

The dugong has a large range that spans over 37 countries and includes tropical and subtropical coastal and island waters from east Africa to Vanuatu, between about 26° and 27° north and south of the equator. The dugong's historic distribution was broadly coincident with the tropical Indo-Pacific distribution of its seagrass food plants. It is believed that throughout most of this region outside Australia, the dugong is currently represented by relict populations separated by large areas where it is close to extinction or extinct. The degree to which dugong numbers have dwindled, and their range fragmented, is not known.

Over most of its range, the dugong is known only from incidental sightings, accidental drownings, and the anecdotal reports of fishermen. However, within Australia, extensive aerial surveys have resulted in a more comprehensive knowledge of dugong distribution. A significant proportion of the world's dugongs is found in northern Australian waters from Moreton Bay in the east to Shark Bay in the west. Dedicated aerial surveys of dugong populations in Australian waters indicate that dugongs are the most abundant marine mammal in the inshore waters of northern Australia. Although some areas of suitable habitat have not been surveyed, the population estimates sum to about 85,000 dugongs. This estimate is likely to be an underestimate as the correction for the number of animals that are not available to observers due to water turbidity is probably conservative.

III. Food and Foraging

Dugongs are seagrass specialists, uprooting whole plants when they are accessible, leaving long serpentine furrows bare of seagrass in seagrass meadows. When the whole plant cannot be uprooted, dugongs feed only on the leaves. Dugongs may also selectively forage for the rhizomes of some seagrasses. Dugongs prefer "weedy" or "pioneer" species of seagrass, especially species of the genera *Halophila* and *Halodule*. These seagrasses are low in fiber, high in available nutrients, and easily digested. Experiments simulating dugong grazing indicate that feeding dugongs alter both the species composition and the nutrient qualities of seagrass communities. Dugongs are like farmers cultivating their crops. If dugongs become locally extinct, those seagrass meadows are likely to deteriorate as dugong habitat.

IV. Habitat

Dugongs frequent coastal waters. Major concentrations of dugongs tend to occur in wide shallow protected bays, wide shallow mangrove channels, and in the lee of large inshore islands where there are sizable seagrass beds. Dugongs are also regularly observed in deeper water further offshore in areas where the continental shelf is wide, shallow, and protected. This distribution reflects that of deepwater seagrasses. Dugong feeding scars have been observed at depths of up to 33 m in seagrass beds off northeastern Queensland.

V. Behavior

Knowledge of the social behavior of dugongs is rudimentary. The habits and habitats of dugongs make them difficult to observe, and the lack of distinct size classes or obvious sexual dimorphism limits the data obtained. The only definite long-lasting social unit is the cow and her calf. Most dugongs are sighted in groups of one or two animals. Large aggregations of up to several hundred animals are regularly seen at some locations. Despite this gregariousness, little is known of the structure and function of dugong herds. One of the functions of herds seems to be cultivation grazing, which maintains the seagrass meadow at the stage favored by dugongs as discussed earlier.

As with many other mammals, the mating behavior of dugongs seems to vary with location. Mating herds have been observed at several locations along the Queensland and Northern Territory coasts. In these herds, splashing and fighting precede mating. The presumed female swims, turns, twists, and thrashes as she attempts to escape from her persistent

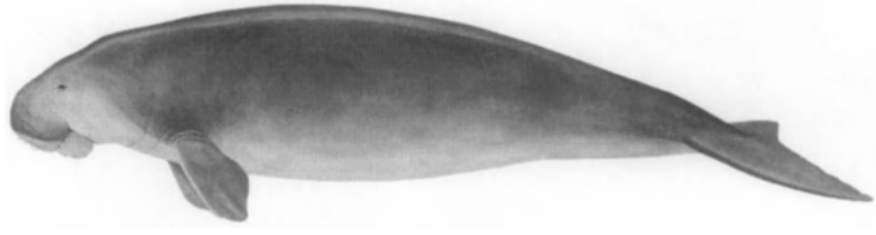

Figure 1 *Gentle vegetarians, dugongs often frequent muddy nearshore and estuarian waters that make it hard to positively identify them. Slow moving and lacking any hint of a dorsal fin, dugongs can be confused with dolphins, especially at a distance. Pieter A. Folkens/Higher Porpoise DG.*

entourage. Members of this entourage engage in bouts of violent fighting before attempting to mount the female in a form of pack rape (Fig. 2).

In contrast, in South Cove in Shark Bay in Western Australia, presumed male dugongs defend mutually exclusive territories in which unique behaviors are displayed in order to attract females. It is not known whether this behavior occurs elsewhere in the dugong's range.

More than 60 dugongs that have been tracked using satellite transmitters. Most movements have been localized to the vicinity of seagrass beds and are dictated by the tide. At the high-latitude limits of their range, dugongs make seasonal movements to warmer waters. In winter in Moreton Bay near Brisbane in eastern Australia, many dugongs regularly make round trips of 15–40 km between their foraging grounds inside the bay and oceanic waters, which average up to 5°C warmer. Some dugongs undertake long-distance movements. In tropical Australia, several dugongs have been recorded making trips of more than 100 and up to 600 km over a few days. Many of these movements have been return trips.

VI. Life History

Dugongs are long-lived with a low reproductive rate, long generation time, and a high investment in each offspring. Like the teeth of other marine mammals, dugong tusks accumulate "growth layer groups" that are used to estimate age, rather like the growth rings of a tree. The oldest dugong whose tusks have been examined for age determination was estimated to be 73 years old when she died. Females do not bear their first calf until they are at least 10 and up to 17 years old. Gestation is approximately 13 months. The usual litter size is one. The calf suckles for 18 months or so, and the period between successive births is very variable; estimates range from 3 to 7 years. Dugongs start eating seagrasses soon after birth and grow rapidly during the suckling period. Population simulations indicate that a dugong population is unlikely to be able to increase more than 5% per year. This makes the dugong highly susceptible to overexploitation by humans.

VII. Interactions with Humans

Dugongs are vulnerable to human impacts because of their life history and their dependence on seagrasses that are restricted to coastal habitats, which are often under pressure from human activities. The sustainable harvest is likely to be in the order 2% of the female population per year. This rate will be lower in areas where their reproductive rate has been shortened by food shortage. Dugongs may be short of food for several reasons, including habitat loss, seagrass dieback, decline in the nutrient quality of available seagrass, or a reduction in the time available for feeding due to boat traffic.

Experience from various parts of northern Australia suggests that episodic losses of hundreds of square kilometres of seagrass are associated with extreme weather events such as some cyclones and floods. For example, ~900 km^2 of seagrass was lost in Hervey Bay in 1992–1993, possibly because of high turbidities resulting from flooding of local rivers and runoff turbulence from a cyclone. Such events can cause extensive damage to seagrass communities through severe wave action, shifting sand, adverse changes in salinity, and light reduction.

Accidental entangling in gill and mesh nets set by commercial fishers is considered a major, but largely unquantified, cause of dugong mortality in many countries. Shark nets set for bather protection have been another source of dugong mortality in Queensland, Australia. Between 1962 and 1999, shark nets set on swimming beaches in Queensland netted some 800 dugongs. In most dugong habitats in Queensland, baited hooks have replaced shark nets. The rate of decline in the catch per beach in the shark nets over this 40-year period averaged about 8% per year. If the shark net catches are a reliable index of the overall decline in the dugong population from all causes, the population of dugongs along the urban coast of Queensland is only a small fraction of that in the 1960s.

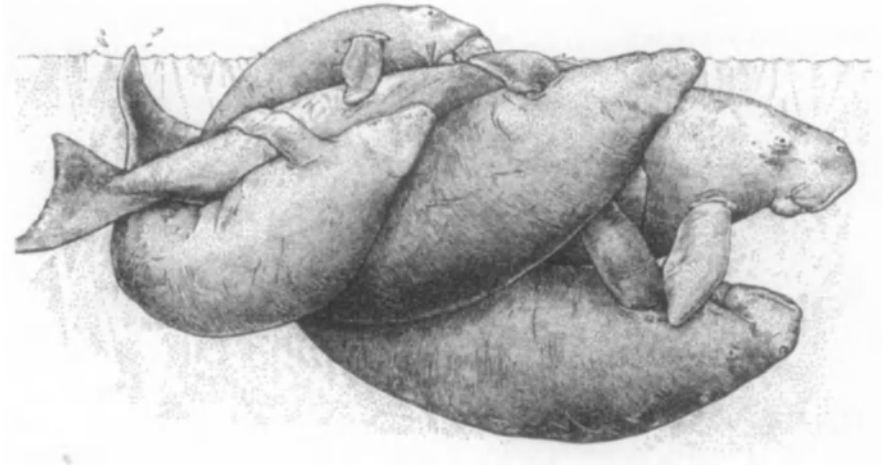

Figure 2 *Part of a mating herd of dugongs. Several males are attempting to embrace the female and mate with her. Drawing by Lucy Smith. Reproduced from Bryden* et al. *(1998), with permission.*

In response to concerns about declines in dugong abundance on much of the urban coast of Queensland, the Australian and Queensland governments agreed to several measures including a resolution not to issue permits for traditional hunting in this region. A two-tier system of dugong protection areas (DPAs) has been established in the Great Barrier Reef region in which gill and mesh netting is greatly restricted or banned (seven zone A DPAs totaling 2407 km^2) or subject to lesser modifications designed to reduce the probability of a dugong drowning after entangling in a commercial net (eight zone B DPAs totaling 2243 km^2). An additional DPA of 1703 km^2 in which gill and mesh netting practices have been modified was established in Hervey Bay, immediately south of the region.

Dugong meat tastes like beef or pork, and dugong hunting for food and oil was once widespread throughout the dugong's range. Today the dugong is legally protected in most countries. Members of Aboriginal and Torres Strait Islander communities in northern Australia and villagers in Western Province in Papua New Guinea are still permitted to hunt. Australia's indigenous peoples consider dugong hunting to be an important expression of their cultural identity. Dugong oil extracted by boiling the parts of the dugong not used for food, such as the head, is used as a panacea for aches, pains, and many illnesses. A dugong yields about 35% of its body weight in usable meat and fat and on average ~18 liters of oil.

It is increasingly recognized that arrangements to ensure that indigenous hunting of dugongs is sustainable will require the active participation of relevant indigenous communities. The Turtle and Dugong Hunting Management Strategy developed by the Hope Vale community on Cape York is northeastern Australia in association with the Great Barrier Reef Marine Park Authority is a useful model for community-based management of dugong hunting.

VIII. Conclusions

The dugong is a long-lived, slow-breeding animal with a low potential rate of population increase even under ideal conditions. It has a highly specialized diet, feeding selectively on pioneer species of seagrasses. Thus the dugong is dependent on habitats that are under pressure from coastal development.

The World Conservation Union (IUCN) classifies the dugong as vulnerable to extinction at a global scale on the basis of anecdotal evidence of declines in its abundance throughout most of its range. In recent years, there has been an encouraging and widespread increase in interest in dugong biology and management. Nonetheless, the difficulties of managing adverse influences on dugongs in highly populated developing countries emphasize the importance of the remote regions of tropical Australia to dugong conservation.

Eared Seals

Otariidae

Roger L. Gentry
National Marine Fisheries Service, Silver Spring, Maryland

The Otariidae, or "eared seals," evolved around the rim of the North Pacific Ocean 11–12 million years ago and subsequently spread into the Southern Hemisphere. About three million years ago, sea lions diverged from the fur seals that preceded them. The two are distinguishable by their pelage. Sea lions have a single coat of hair whereas fur seals have stiff outer guard hairs emerging from a dense, thick layer of fine underfur, which is waterproof, thereby providing thermoregulation.

Otariids comprise 16 species (Table I). All breeding sites they use are between 60° S and 55° N latitude. Eight species breed in temperate latitudes, two in subpolar, and two in equatorial regions. The sea lions use only temperate or equatorial regions, but fur seals use all three. No species of otariids mate on ice, but at least two encounter snow during breeding and pup rearing. Four species mate on the shores of deserts where the climate is ameliorated by fog or cool ocean winds. Only two species of fur seals and three species of sea lions still inhabit the North Pacific waters where otariids evolved. Otariids never occupied the North Atlantic Ocean, perhaps because the Central American seaway was closed when the family dispersed into the Southern Hemisphere.

Otariids use both island and mainland sites, but at present, island sites predominate worldwide. Islands offer a combination of freedom from terrestrial predators (including humans), cooling winds for THERMOREGULATION, and closer access to offshore prey concentrations than most mainland sites provide. The preferred substrate for mating is rock or sand, rarely soil or mud. All species mate on open ground, except some small populations of Hooker's sea lions (see Table I for scientific names), which use forested sites.

I. Unique Traits

Otariids are truly amphibious in that they feed at sea but mate and rear their young on land. Therefore, their anatomy strikes a balance between functioning in air and under water.

Unlike other pinnipeds or cetaceans, otariids have an external ear flap (hence their scientific and common names), an air-filled external auditory canal, and a middle ear structure very similar to a terrestrial ear. Otariids hear best in the frequency range of 2–12 kHz. In contrast, dolphins and porpoises that rely on a sophisticated echolocation system to feed hear best from 8 to 90 kHz or higher. This difference suggests that otariids either do not echolocate or do so in a rudimentary way.

Laboratory tests have demonstrated that sea lions have excellent visual acuity at low-light levels. Large eyes, an all-rod retina, and a well-developed reflective layer (*tapeta lucidum*) account for this ability. These features suggest that eared seals feed visually in the dark (at night, in deep water, or both). However, they maintain good visual acuity in air in bright light by being able to close down their pupil to a pinhole. Well-developed, highly-enervated vibrissae may provide tactile cues that combine with visual cues for feeding in the dark.

Locomotion also points out the balance between their terrestrial and aquatic lives. Unlike phocids, otariids can rotate their rear flippers forward and walk or run using all four limbs. They can outrun a human over slippery rocks. Using their chin and their long, strong front flippers, they can climb steeply sloping surfaces, which means they can take advantage of broken, rocky terrain for BREEDING SITES. They swim using the front flippers powered by well-developed pectoral muscles, while the rear flippers trail behind and are used only in turning and stopping. Otariids are quick, graceful swimmers that can leap free of the water and "porpoise" to breathe while swimming fast. They can execute a forward somersault while surfing.

Laboratory tests have also shown that otariids have well-developed cognitive abilities. They can perform complex learning tasks and have excellent memories, abilities that are perhaps related to their role as high-level consumers which depend on patchy prey to survive.

Otariids must reduce heat loss to cold ocean waters, but simultaneously have the ability to lose body heat while on land

TABLE I
Otariids

Common name	*Scientific name*	*Location*	*Approximate numbers*	*Trend*
Northern fur seal	*Callorhinus ursinus*	Subpolar	1,400,000	Stable
Antarctic fur seal	*Arctocephalus gazella*	Subpolar	3,000.000	Increasing
Sub-antarctic fur seal	*A. tropicalis*	High temperate	>310,000	Increasing
Juan Fernandez fur seal	*A. philippii*	Temperate	18,000	Increasing
Guadalupe fur seal	*A. townsendi*	Temperate	>7,000	Increasing
Cape fur seal	*A. pusillus pusillus*	Temperate	1,700.000	Increasing
Australian fur seal	*A. pusillus doriferus*	Temperate	<60,000	Stable
South American fur seal	*A. australis*	Temperate	<285,000	Increasing
New Zealand fur seal	*A. forsteri*	Temperate	135,000	Increasing
Galapagos fur seal	*A. galapogoensis*	Equatorial	40,000	Fluctuating
Galapagos sea lion	*Zalophus wollebaeki*	Equatorial	40.000	Fluctuating
California sea lion	*Z. californianus*	Temperate	<188,000	Increasing
Japanese sea lion	*Z. japonicus*	Temperate	Extinct	
Steller sea lion	*Eumetopias jubatus*	High temp.	>76.000	Decreasing
Hooker's sea lion	*Phocarctos hookeri*	Temperate	13.000	Stable
Australian sea lion	*Neophoca cinerea*	Temperate	12,000	Stable
Southern sea lion	*Otaria flavescens*	Temperate	275.000	Decreasing

in the sun. A BLUBBER layer (abetted by the underfur in fur seals) reduces heat loss to water. To promote heat loss on land, otariids use shade, immersion in tide pools or spray, flipper waving, or panting. At least one species urinates on its rear flippers for evaporative cooling. Only the flippers are naked, so evaporative cooling from sweat is ineffective. A few animals drink seawater, but usually only at the beginning of fasting at the start of the breeding season. As in VISION and HEARING, the primary adaptations for thermoregulation and water balance seem to be for life at sea, with secondary adaptations for life on land.

II. Diet

Otariids tend to be generalist feeders, taking a wide variety of prey. For example, the northern fur seal takes at least 63 species of prey over its full range. Fur seals and sea lions tend to feed on dissimilar prey. Fur seals often feed in deep water beyond the continental shelf break on small squid or fish, especially myctophids (lantern fish). The Antarctic fur seal takes krill as well as fish, and the New Zealand fur seal supplements fish with rock lobster. Sea lions tend to feed on or near the continental shelf and to take larger or more mature stages of prey than are used by fur seals (e.g., adult halibut). Hooker's and Australian sea lions specialize in squid and octopus, which are hunted on the bottom and under rocks. Several species of sea lions are known to eat the young of other seals, one species exhibits cannibalism, and several are known to eat penguins or other birds. For an as yet unexplained reason, otariids (especially sea lions) intentionally swallow fist-sized rocks.

III. Maternal Strategy

Otariids differ from phocids in that the females of all species continue to feed while they are lactating. Otariid mothers capture prey and within a few days time transfer the energy it contains to their young on shore in the form of milk fat. They make a series of brief, regular nursing visits to shore from birth to weaning, an interval that varies with latitude. In contrast, most phocid mothers gather energy from prey for several months, lay it down as extensive blubber reserves, and then deliver it to their young in a single, prolonged nursing bout that may last a few weeks at most.

Feeding during lactation has widespread implications for otariid natural history. Eared seal mothers are restricted in how long they may be absent for foraging by the limited fasting abilities of their newborn pups. To meet this restriction, mothers must find abundant prey of a given type close enough to the colony that they can commute between the two and still experience a net energetic gain for themselves and their young. The number of sites that meet these conditions and that have proper terrain, cooling winds, absence of predators, and other factors are relatively few. Otariids tend to gather in large numbers (up to hundreds of thousands) on the few sites in the world that meet these specific needs and to form dense aggregations there. Therefore, largely because of maternal commuting, otariids tend to breed in a few large, dense colonies that are most often on islands. Most phocids do not commute for foraging and therefore tend to breed dispersed as pairs or in small numbers on a large number of dispersed sites. Among phocids, only elephant seals (*Mirounga* spp.) form colonies that superficially resemble those of otariids (few sites, large dense groups).

The details of otariid maternal strategies vary considerably according to the local foraging environment. As a generalization, the duration of the maternal feeding trip, duration of nursing visits, and fat content of the milk all increase with increasing distance to feeding locations. However, the amount of milk fat and its delivery schedule are both constrained by the need to wean the young at a particular age. At high latitudes this age is 4 months, which allows mother and young time to migrate to lower latitudes before winter begins. At temperate latitudes the age is 9–12 months, which allows females to bear young annually without having to support two simultaneously. The two species at the equator are not limited by season, but by the rate at which mothers can bring their pups to the size needed for independent foraging. In good years, Galapagos fur seal mothers may achieve this in 12 months. However, when periodic El Niño events disrupt the food supply, they may not achieve it until age 3 years.

IV. Reproductive Adaptations

Otariids and phocids both possess a postpartum estrus. The uterus is Y shaped with two "horns," one of which holds the full-term fetus while the other prepares to receive the new blastocyst soon after birth. In all but one species of otariid, females enter estrus and mate during the 4- to 11-day perinatal nursing period. (The exception is the California sea lion, which mates about 23 days postpartum, well beyond its perinatal nursing period.) Because the perinatal period may be the females' longest single shore visit of the year, estrus at that time gives adult males the longest uninterrupted chance to mate with them. The process is quite efficient; pregnancy rates may exceed 93% for some age groups of females.

Dense gatherings have produced the most striking feature of the otariids, namely SEXUAL DIMORPHISM in body size and appearance (Fig. 1). In each species the adult male is 2 to 4.5 times the size of the female. Looking across species, there is more dissimilarity in the appearance of males as a group than there is among females as a group. These differences in body size and appearance probably result from the dissimilar selection pressures that the two sexes are under. Unlike females, in which fitness is measured by the quality of the single young they bear, male fitness is measured by the number of offspring produced. This means that males attempt to obtain the largest possible number of mates but females do not. Increased size not only gives males an advantage in fights related to obtaining mates, it also allows them to fast longer and thus remain among estrous females longer than males of smaller size. Male otariids weigh from 200 to 1000 kg and can fast for 12 weeks, although a fast of 4 to 6 weeks is more common.

V. Mating System

In all species, males defend space on the land sites that females use for giving birth and nursing their young. In two species (California sea lions and Juan Fernandez fur seals) males also partition some of the aquatic areas where females gather. Defending space gives males exclusive reproductive access to all females on that site. Failure to obtain space among females means having low reproductive success because of the characteristics of estrus (see later). In very few cases do males defend the actual females on a site rather than the boundaries around the site they use.

Defended space in otariids should be referred to as territories, not as leks. The reason is that, except possibly in the California sea lion, otariid females do not actively choose their mates as in a lek system. Instead, females choose their parturition site and then mate with any nearby male when estrus occurs. Females may use the exact same parturition site for 10 years or more, whereas the males that defend these sites change every breeding season or two.

All otariids are polygynous; average adult sex ratios of up to 10 females per male are common. Although the sex ratio at birth is near unity, males have higher mortality rates during maturation than females, and some males that reach adulthood are excluded from mating by the territorial system, which leaves more mating females than males. The average adult sex ratio is difficult to determine because a variable number of females will be at sea on any given day.

Sexual receptivity in female otariids is usually terminated by the physical act of coitus. For that reason, receptivity may last only minutes per year, and most females (85 to 90%) copulate only once. No second estrus is known to occur later in the year, even for females that fail to mate immediately postpartum. The advantage to females of a single copulation is that they can dispense with mating and quickly resume feeding to support their young. The advantage to males is that they can inseminate more females with fewer copulations in a shorter period of time. Most virgin females mate on the same grounds as more mature females, but at the end of the breeding season. For these reasons, males that do not acquire territory on traditional pieces of ground at predictable times of year find many fewer mates than males that do.

Female otariids have an open society that features a loose, size-related dominance system. Larger, older, more experienced females generally have more access to favored rest sites, water, or shade than younger, smaller females. However, no evidence has been found for hierarchies of *individuals*. Also, no evidence has been found for any social bond between adult females, including those between mothers and their previous female offspring. The society is open in the sense that females can enter and leave it frequently without loss of social status. It thus fits with, and may have resulted from, the need of females to forage specific to the needs of their nursing offspring.

Females maintain close spacing while on shore. All sea lions plus the South African fur seal are thigmotactic (seek full body contact with others); spacing in the other species varies seasonally and with the radiant load (less contact on hot days). Despite their close spacing on shore, females are simultaneously aggressive toward each other. Fights that draw blood are uncommon, but females threaten each other frequently in various ways.

The offspring of otariids are precocial. Some can swim on the day of birth but most defer swimming for a month or more. Sexual dimorphism is evident at birth. In one species (northern fur seal) it exists as early in embryonic development as the sexes can be distinguished. During the lactation period, otariid pups tend to form dense aggregations and to avoid contact with adult males, which may bite and kill any pup that approaches them. Pups engage in play bouts that feature many of the components of adult aggressive behavior, sexual behavior, and prey handling in mixed order. These patterns appear to be innate in that pups born in captivity display behavior that they cannot have witnessed. Sneak suckling, especially in starvelings, occurs probably in all otariids. In some species (Steller sea lion), some females that lose their pups may actually foster a foreign pup.

Weaning is difficult to observe and document. It has been studied well in only two species (northern and Antarctic fur seals). In both species, most pups leave shore before their mothers, thereby weaning themselves at 4 months, just prior to migrating. In nonmigratory species, varying degrees of mother–young conflict exist at weaning, depending on environmental conditions, age at weaning, and presence of younger offspring.

Outside the breeding season, when no adult males are present, weaned juveniles may reside among the females and young. Juvenile females may remain there during the breeding season, but juvenile males are usually excluded from breeding areas and may gather on nearby all-male landing areas. In some areas of the world, several species of seals may mix on these landing areas. Juvenile males spend much time play fighting and occasionally make brief running forays into breeding areas or wait offshore to intercept females departing on foraging trips. Copulations sometimes occur in these circumstances.

VI. Foraging Behavior

Otariids usually only dive deeply when foraging. This summary is based on dive records for females, which have been studied more thoroughly than males. Most otariids feed in the water column, sometimes over very deep water. Dive depths measured in the field reflect the vertical distribution of the prey more than the physiological limits of the divers. These depths are usually less than 450 m, and dives to more than 200 m are uncommon. Dive durations are usually less than 12 min, and dives of more than 5–7 min are uncommon. Most dives of otariids (more than 85% for individuals) are aerobic, i.e., the duration of most dives does not exceed the estimated oxygen that animals take down stored in hemoglobin or myoglobin. Diving occurs at all hours, but nighttime diving predominates. The dive depth may change with time of day, suggesting that the otariid is following the daily migration of prey toward the surface at dusk and toward deep water at dawn. There is as yet no evidence of cooperative feeding by otariids (such as group attacks by killer whales), but coordinated group diving has been observed.

VII. Population Trends

Starting in the 16th century, otariids were harvested for furs, hides, blubber, various organs, or, in the case of Steller sea lions, vibrissae (for cleaning opium pipes). By the end of the 19th century, sealers had obliterated many stocks and reduced many species to near extinction. Stocks recovered throughout the 20th century in varying degrees. After a long lag time, the Antarctic fur seal recovered at a rate of 10% per year, the highest known for any otariid population. Recovery for most species was nearer 5–7%. The Japanese sea lion is probably extinct. Some populations (Hooker's sea lion, Australian sea lion, see Table I) are small but apparently stable, whereas others are small but growing (Guadalupe and Juan Fernandez fur seals). Two species (Galapagos fur seal and sea lion) experience intermittent declines and recoveries related to El Niño events. The northern fur seal has been declining at various rates from 1956 to the present. The only otariid species presently of concern to managers is the Steller sea lion, which is rapidly declining for as yet unknown reasons. Worldwide, fur seal populations tend to be increasing faster than sea lion populations and outnumber them by an order of magnitude (nearly 7 million fur seals worldwide compared to just over 600,000 sea lions; Table I). The diet and place of foraging differ between the two groups and may explain these differences. It could be the habit of feeding beyond the continental shelf, like a fur seal, that has accounted for the present rapid growth of the California sea lion population.

Earless Seals

Phocidae

MIKE O. HAMMILL
Department of Fisheries and Oceans, Mont Joli, Canada

I. Systematics

The family Phocidae contains the earless or "true" seals. They are distinguished from sea lions and fur seals (family Otariidae) by the absence of external visible ear pinnae, internal testes, a generally larger size, and the inability to draw their hindlimbs forward under their body when on land. This latter character, the absence of tusks, and a notched tongue also distinguish them from the family Odobenidae or walruses.

There had been considerable debate as to whether pinnipeds were diphyletic or monophyletic in origin. The diphyletic view proposed that odobenids and otariids were related to the bears (Ursidae) and that phocids were more closely linked to otters, weasels, and skunks (Mustelidae). However, a reevaluation of morphological evidence and the application of molecular techniques support the monophyletic hypothesis, with pinnipeds descending from arctoid carnivores, a group that includes the bears.

The Phocidae can be divided into two subfamilies: the Monachinae (*Monachus* spp.), with $2n=34$ chromosomes, consisting of the southern phocids, the southern and northern elephant seals (*Mirounga* spp.), and the monk seals; and the Phocinae, or northern seals, with $2n=34$ chromosomes in bearded (*Erignathus barbatus*) and hooded (*Cystophora cristata*) seals and $2n=32$ chromosomes in the remaining seven species (Table I). The separation between these two groups has been confirmed in molecular studies, but the relationships among members within the subfamilies are uncertain. More recent work indicates that the gray seal (*Halichoerus grypus*) may not be sufficiently separated from the ringed seal to warrant its own genus, and a closer relationship between ribbon and harp seals than of either to the *Phoca* group. This suggests that the harp seal should retain its old name: *Pagophilus groenlandicus*. Support has also been found for grouping the ribbon, harp, and hooded together, but the use of karyotypic data as a diagnostic landmark in the phylogenetic analysis may be sufficient to maintain the separation (Table I).

II. Life History

Phocids are found throughout all of the world's major oceans except for the Indian Ocean. Twelve species breed on ice and six species breed on land, including the Caribbean monk seal, which is probably extinct. The gray seal breeds on both land and on ice (Fig. 1). Among the ice-breeding seals, eight species breed primarily on pack ice. Four species breed on land-fast ice. Phocids in the Northern Hemisphere have also colonized freshwater areas; these include the harbor seal (*Phoca vitulina mellonae*) in freshwater lakes of northern Quebec, the ringed seal (*Pusa hispida lagodensis* and *Pusa hispida saimensis*) in Lakes Lagoda and Saimaa in Russia and Finland, respectively, and the Baikal seal (*Pusa sibirica*) in Lake Baikal in Siberia. Ringed seals also frequent Nettelling Lake on Baffin Island in northern Canada.

Pinnipeds are adapted to marine foraging but must haul out on land or ice for parturition and successful rearing of offspring. Marine adaptations include a thick blubber layer for insulation, modifications in limbs and body shape to improve hydrodynamics and agility, and anatomical and physiological changes to improve diving performance. Compared to otariids, phocids generally spend more time at sea, swim more slowly, and dive to deeper depths and for longer periods. Southern elephant seals (*Mirounga leonina*) may dive to 1200 m and remain below the surface for up to 120 min. Other deep-diving phocids include northern elephant seals (*M. angustirostris*) (1500 m), Weddell seals (*Leptonychotes weddellii*) (700 m), and hooded seals (1000 m). Phocids have adopted what is sometimes referred to as a "slow-lane" strategy to reduce energy use during diving. This is achieved through a combination of (1) apnea with exhalation upon initiation of diving to minimize buoyancy and pressure-related problems; (2) an enhanced oxygen-carrying capacity, which is accomplished by a greater blood volume, an increase in red cell mass (haematocrit) within the blood cell volume, a greater hemoglobin concentration in the red blood cells, and possibly a higher content of oxygen-carrying myoglobin in the muscles; and (3) a generally larger body size to maximize oxygen-carrying abilities while minimizing mass-specific energy demands while diving.

The improvements in swimming ability have occurred at the expense of mobility on land or ice, which in turn increases vulnerability to terrestrial predators. Phocids whelp on the ice, isolated islands, or inaccessible beaches, which makes it more difficult for terrestrial predators to approach seals undetected. Some ice-breeding species, e.g., the Baikal seal and the ringed seals, limit further their accessibility to predators such as humans, bears (*Ursus maritimus*), arctic foxes (*Alopex lagopus*), and birds (e.g., *Corvus* sp., *Larus* sp.) by using small caves or lairs under the snow. These lairs also provide shelter from cold ambient temperatures. Current global-warming trends will likely result in the reduction of suitable ice habitat for many phocids, particularly in the more temperate regions of their distribution. This will impact not only seal populations, but also predators that rely on seals as food.

III. Reproduction

Sexual maturity is delayed in phocids. Some females are sexually mature at the age of 3+ years, but the mean age of sexual maturity is normally around 4–6 years, although it may vary with the population size and availability of resources. In northwest Atlantic harp seals the mean age of sexual maturity among females may vary from 5.8 and 4.6 years. These changes have mirrored changes in population size due to exploitation. As the population has increased, the mean age of sexual maturity has also increased. It is currently around 5.4 years. Normally about 80% of the adult females are pregnant, but some interannual variability in adult reproductive rates can occur. Extremely low (~60%) adult reproductive rates have been

TABLE 1
Members of the Family Phocidae, General Distribution, and Breeding Habitat

Common name	*Latin name*	*Subspecies*	*Distribution*	*Breeding habitat*
		Northern Hemisphere		
Gray seal	*Halichoerus grypus*		North Atlantic	Land, ice breeder
Harp seal	*Pagophilus groenlandicus*		North Atlantic	Pack-ice breeder
Harbor seal	*Phoca vitulina*	*P.v. vitulina* *P.v. concolor* *P.v. stejnegeri* *P.v. richardsi* *P.v. mellonae*	Atlantic, Pacific Oceans, Arctic regions	Land breeder
Spotted seal	*Phoca largha*		North Pacific, Chukchi Sea	Pack-ice breeder
Caspian seal	*Pusa caspica*		Caspian Sea	Fast-ice breeder
Ringed seal	*Pusa hispida*	*P.h. hispida* *P.h. botnica* *P.h. ochotensis* *P.h. krascheninikovi* *P.h. saimensis* *P.h. ladogensis*	Arctic regions, Baltic Sea	Fast-ice breeder
Hooded seal	*Cystophora cristata*		North Atlantic	Pack-ice breeder
Bearded seal	*Erignathus barbatus*	*E.b. barbatus* *E.b. nauticus*	Arctic	Pack-ice breeder
Baikal seal	*Pusa sibirica*		Lake Baikal, Siberia	Fast-ice breeder
Northern elephant seal	*Mirounga angustirostris*		North Pacific	Land breeder
Ribbon seal	*Histriophoca fasciata*		North Pacific (Chukchi, Bering, and Okhotsk Seas)	Pack-ice breeder

documented in some years among ringed seals in the Beaufort Sea and Hudson Bay areas of northern Canada. These changes may be related to changes in ice conditions and the availability of food resources.

Males become sexually mature around the same time or slightly later than females, but recently mature males appear to be incapable of defending access to females until 2 or more years after they are sexually mature. Sexually monomorphic species have the longest life expectancies; e.g., ringed seals aged 45 years old have been reported. The life expectancy of sexually dimorphic species is much shorter, particularly among males. In elephant seals, which show perhaps the most extreme level of SEXUAL DIMORPHISM, males are sexually mature at about 5 years of age, but they seldom achieve any rank within the colony until the age of 8. The greatest reproductive success occurs between the ages of 9–12 years, and males die by the age of 14.

The female phocid reproductive cycle is characterized by parturition, a short lactation period (4–50 days), copulation near the end of lactation, embryonic diapause (~3 months), and active fetal growth (~9 months). In most temperate species, implantation occurs during late summer–early autumn when light levels are decreasing, and pupping occurs during the spring, when light levels are increasing. However, an irregular pattern is seen among gray seals. Gray seals in the United Kingdom give birth during the fall, and implantation occurs during the spring. Implantation of the embryo occurs after the moult, when female energy reserves are at a minimum.

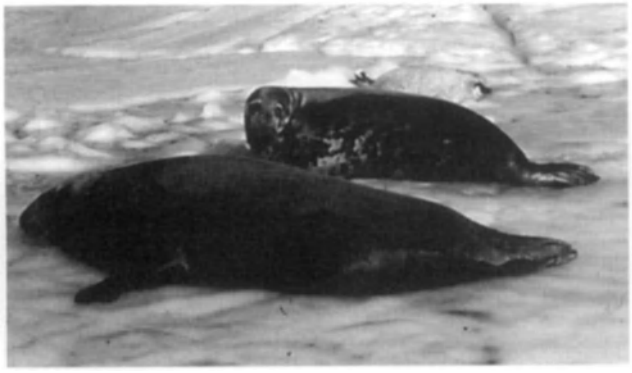

Figure 1 *Gray seals on the ice in Northumberland Strait, Canada. The male is in the foreground, the female in the middle, and the white pup in the background.*

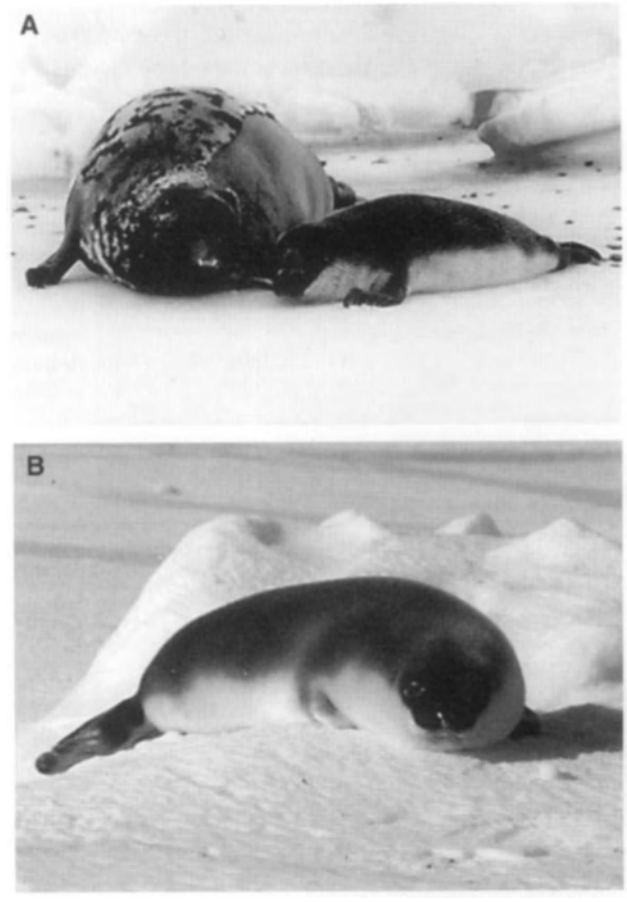

Figure 2 *Newborn hooded seal pup with its mother weighing about 20 kg (A) and a weaned pup 4 days old weighing 44 kg (B). Behind the newborn, note the small balls ("silver dollars") of fetal hair on the ice that were ejected with the placenta at birth.*

Embryonic diapause provides females a mean of terminating reproduction if conditions are poor before her investment becomes too costly. It also leads to synchronization of reproductive activity.

The characteristic phocid lactation strategy consists of building up energy reserves throughout the year, fasting during lactation, and lactating for a short period. The utilization of fat reserves to satisfy their own energy requirements and the costs of providing milk for her pup has favored selection for large body size because energy stores scale to $Mass^{1.0-1.19}$, whereas metabolic requirements scale to $Mass^{0.75}$. Thus an increased body size increases energy-storing capabilities at a greater rate than increasing mass-specific energy requirements. This has led to a larger body size in phocid females than among otariid females (phocid females: mean = 229 kg, median = 141 kg; otariid females: mean = 80 kg, median = 55 kg). The need to build up energy reserves over the year probably adds about 12% to the daily energy requirements of a female phocid, but it also allows the spatial and temporal separation of FEEDING and reproduction.

To minimize the metabolic overhead associated with lactation, phocids have shortened the lactation period to 4–50 days instead of the months seen in otariids and odobenids. This is achieved by remaining beside the pup, providing more opportunities for the pup to suckle, and producing a very fat-rich milk, which increases the energy transfer per volume of milk consumed. In elephant seals, the fat content is very low at the beginning of lactation (~10%), but increases to about 50% fat by midlactation. In harp, gray, and Weddell seals, the milk fat content increases from around 40% to between 50 and 65% fat by midlactation, whereas in hooded seals there is relatively little change in fat content of the milk (55–68%) over the short 4-day lactation period (Fig. 2).

Stability of the whelping habitat and vulnerability to predation appear to be two important factors that have influenced the duration of lactation within the phocid group. Pups on unstable, drifting pack ice nurse for only 4 days in the hooded seal to as much as 30 days among the crabeater and Ross seals (mean = 18 days). In contrast, the longest lactation periods are found among the fast-ice-breeding Weddell, Baikal, and ringed seals (mean = 57 days). The lengthy lactation period among the very small ringed and Baikal seals may be related to their small size and their relative inability to store and deliver energy quickly to their offspring (Fig. 3). The Weddell seal, which weighs around 450 kg, is almost four times heavier than the diminutive ringed seal. The lengthy nursing period of Weddell seal pups may keep the young away from the fast-ice edges where their exposure to aquatic predators such as leopard seals and killer whales would be greater. The duration of lactation among land-breeding phocids is intermediate to that of the fast-ice and pack-ice animals, with an average of 32 days.

The "fasting strategy" is certainly characteristic of lactation in the largest phocids such as the elephant seals and in the hooded seal. Facultative feeding occurs among female Weddell, bearded, harp, and gray seals, whereas feeding appears to be obligatory among the smaller phocids (≤ 100 kg), such as harbor and ringed seals. Feeding may be necessary because females are unable to store sufficient energy to satisfy their own energy requirements, plus energy required for lactation. The need to continue foraging during lactation means that females

Figure 3 *Female ringed seal with her pup on fast ice in Svalbard, Norway.*

must leave their pups in a safe area while they forage or the pup must accompany the female. In both instances, the spatial separation between whelping sites and foraging areas is limited. In the ringed seal, females scrape out lairs beneath the snow to haul out in. Females leave their pups to feed under the ice but remain close enough to help the pup move to an alternate lair if a predator approaches. Among harbor seals, foraging acivity is restricted during the early stages of lactation. In large groups, as lactation advances, some females leave their pups unattended while they forage. In areas where only small groups are seen, the pups may follow the females over extensive distances of as much as 30 km away from the original haul-out site.

Fewer studies have examined male energy expenditures during breeding, due in part to the difficulties associated with handling large, dangerous, and aggressive animals or their inaccessibility in the case of males that spend much of their time in water. Daily energy expenditures of males during the breeding season are much lower than those of females because they do not incur the costs of milk production. However, once females wean their pups they resume feeding. This contrasts with males, who continue fasting to maximize their access to successively receptive females as the breeding season advances. Elephant, gray, and hooded seals appear to terminate breeding activity when fat levels have declined to levels similar to those observed in females. This suggests that the overall reproductive effort is similar between the two sexes.

At birth, phocid neonates are larger than otariid neonates. When female body size is taken into account, phocid and otariid mass at birth represents about 10% of their mother's mass. The pups are quite lean at birth, with a fat content of 5–8%. Notable exceptions are hooded, harbor, and bearded seals, which are larger relative to other species, with a mass at birth equal to about 12–13% of the maternal mass. Harbor, hooded, and bearded seal pups also differ from otariid and other phocid pups by the presence of a thin blubber layer at birth. Fat content represents 11–14% of the total body mass in harbor and hooded seal pups at birth. Phocid pups gain weight rapidly, achieving a weaning mass two to five times their birth mass in a period of 4–50 days, but mass at weaning is relatively constant across species, being equivalent to 25–30% of the mother's mass. Among hooded, harp, and gray seal pups, 65–75% of the milk energy is deposited, primarily as fat. Elephant, hooded, harp, ringed, and gray seal pups are 40–50% fat at weaning, whereas species with very active pups, such as Weddell, bearded, and harbor seals, may contain only 34–37% fat at weaning. The rate of mass gain is inversely related to the duration of the lactation period when expressed relative to the female's metabolic mass. The lowest rates of relative mass gain are seen among Hawaiian monk seals, bearded, harbor, and ringed seals, species where the pups are very active and begin entering the water early during lactation. Ice-breeding neonate phocids, such as harp, ringed, ribbon, Caspian, Baikal, and largha seals, are born with a white, relatively long fur called lanugo (Fig. 3). The white color may provide some protective camouflage on the white snow from predators. However, the lanugo may be more effective in its role as an insulator, particularly to the very young pup who has not yet developed a thick layer of BLUBBER for insulation. The structure and color of this fur permits short-wave energy received from the sun to be transmitted through the fur, where it is absorbed by the dark skin. It also traps heat energy radiated from the animal's skin and thus acts like a greenhouse, heating up the air trapped within the fur, but limiting heat loss to the outside air. Among species where the young enter the water very soon after birth (e.g., harbor, bearded, and hooded seals), the young are born with a thin layer of blubber, and the lanugo is shed or moulted within the uterus. This is because blubber acts as a much better insulator in water than fur. Among harbor seals, 5–30% of the pups are born with a white lanugo, depending on the region, but this is quickly replaced by a grayish pelage similar to that of adults. In bearded seals, shedding of the lanugo begins *in utero*, but is completed after birth. In hooded seals, the fetal fur is expelled in small clumps on the ice with the placenta; these are referred to as silver dollars by commercial sealers. At birth the pups are covered by blue (dorsal) and silver (ventral) fur that is much thicker and longer than the adult fur, and at this stage the pups are known as bluebacks (Fig. 2). Hooded seal pups differ from harbor and bearded seals in that they do not enter the water until they are weaned. However, in this species lactation lasts for only 4 days. The remaining species that whelp on the ice in the Northern Hemisphere tend to give birth to pups with a white lanugo, which may afford some

protection against surface predators. Gray seals have their pups on both the land and on the ice, but the pups are born with a white lanugo (Fig. 1). Neonates of southern ice-breeding seals, such as Weddell, crabeater (*Lobodon carcinophaga*), leopard (*Hydrurga leptonyx*), and Ross seals (*Ommatophoca rossii*), are born with a gray, brown, or grayish-brown pelage. Southern ice-breeding phocids are not exposed to surface predators other than humans and hence the white lanugo may not be required. Elephant and monk seal pups are born on land with a black pelage.

Pup mortality during the lactation period is normally quite low. Among land-breeding species, trampling and wounds caused by interactions between adults may encourage infection, which may result in death of the pup. This problem is more aggravated in crowded colonies where the number of interactions would increase. In Arctic ice-breeding species, predation by bears, foxes, and birds such as ravens (*Corvus* sp.) and gulls (*Larus* sp.) in the case of ringed seal pups is an important source of pup mortality, although the effects of PREDATION are reduced by the use of lairs. Ringed seal pups are also quite active and are capable swimmers at a very young age. However, swimming incurs a high metabolic cost due to the minimum blubber thickness. Repeated disturbance may affect growth and survival. Surface predators are not present in the southern polar regions, but leopard seals and killer whales are important marine predators. In the pack ice, pups may drown or be crushed as a result of storms causing the breakup and rafting of the ice.

IV. Mating Systems

The study of mating systems among phocids has relied heavily on behavioral observations of animals in the breeding areas. Male reproductive success has been evaluated by a male's ability to monopolize females or by the number of copulations observed. However, DNA techniques have suggested that the evaluation of reproductive success may be more complex, with the existence of alternative mating strategies within a population. In captive harbor seals, behavioral observations during courtship were not reliable indices of paternity, whereas in one population of gray seals, large males sired significantly fewer pups than would otherwise have been indicated from their observed mating opportunities. Females tended to produce several pups fathered by the same male, who in many cases was not the large attendant male.

Phocids breeding on land prefer islands or isolated beaches, where threats from predation are reduced. The combination of habitat limitations and synchronization of reproductive activity encourages the aggregation of females. Males are not involved in caring for the pup. Therefore the best strategy for males is to copulate with as many females as possible, whereas the strategy of females is to successfully rear her pup. Males will attempt to prevent other males from having access to females. In phocids, this may involve defending a geographical area, but if the female moves, the male will follow to defend a new space around the female. The number of females that can be defended is limited by habitat features and the skills of defending males. Large, open beaches are more difficult for a male to control than more topographically irregular sites, where geographic barriers will aid established males in limiting the approach of intruding males. Reproductive success will also be affected by the fighting and signaling ability of males and how long they can remain beside females without leaving to feed. In male hooded seals, a series of displays involving the inflatable nasal sac and nasal septum are often associated with the approach of other males (Fig. 4). Not all approaches result in combat, suggesting that some signaling occurs. The gradual evolution toward large size observed in females, which permitted the separation of reproduction and feeding, would also have operated on males as well. Larger males could spend more time ashore fasting. Larger males would also be favored over small males in combat, although experience and individual skill development would also be contributing factors. The greatest degree of polygyny seen among phocids is exhibited by the elephant seals, who may defend harems containing upward of 100 females. Southern elephant seal males may weigh up to 3700 kg, whereas northern elephant seal males may reach 2300 kg. In both species the males are typically five to six times larger than the females. Males arrive on the whelping area just before the females and the most successful males remain on the beaches fasting until the last females leave about 3 months later.

In other species the development of polygyny is more variable. Gray seals copulate on land and occasionally in water. Males at 350 kg are about 50% larger than females. In some areas in the British Isles, they control access to up to 8 females, whereas in the open beaches and ice-breeding areas in Canada, males are only able to control access to 1 to 3 females. Less is known about the structure of mating systems of phocids that copulate primarily in water. The development of polygyny is limited by the three-dimensional nature of the marine environment. Among hooded seals, the marked sexual dimorphism observed in many terrestrial mating species is also observed. Male hooded seals weigh up to 440 kg, whereas females reach about 290 kg. The hooded seal male begins to defend one female about midway through the short 4-day lactation period (Fig. 4). Once the pup is weaned, he accompanies the female into the water, mates with her, and then returns to the ice and will attempt to establish himself beside another female. Because pupping occurs over a 2- to 3-week period, males have opportunities for multiple matings during that period. Mating success of a male is affected by his ability to defend access to females against other males and by the amount of time he can spend on the ice before his energy reserves are depleted. Among the remaining phocids that copulate in the water, little difference in body size is seen between males and females; in some cases, such as bearded and Weddell seals, the females appear to be slightly larger. In these cases, smaller size may favor underwater agility. The mating system of harp seals has been referred to as promiscuous, but little information is available. Males do haul out, but no displays or fighting are observed on the ice. Extensive vocal activity within harp seal whelping patches has been recorded, and groups of males are observed often patrolling leads, vocalizing and diving. It is possible that male harp seals are displaying to females, suggesting more of a lek-type system, but there is insufficient data to comment further. Among ringed seals, the presence of predators in the fast ice, such as bears, foxes, and humans, selects against aggregation, whereas the need to con-

Figure 4 *Two male hooded seals fighting on pack ice in the Gulf of St. Lawrence, Canada. Note the inflatable sac on the male on the left.*

tinue feeding during lactation, in an area generally considered to have low productivity, would also be a contributing factor. In this species, some underwater vocal activity has been recorded, but unlike the underwater vocalizations of the widely dispersed bearded seal that can be heard over distances of 25 km, the underwater vocalizations of the ringed seal are relatively weak, limiting their use as a signal to potential mates. However, the males emit a strong odor during the breeding season due to the enlargement and increased secretion activity of sebaceous and apocrine glands in the muzzle region. The strong odor may serve as a signal to inform both females and other males that a breathing hole is used or belongs to a particular male. In harbor seals, the females move with their pups between haul-out sites and foraging areas. Males are unable to defend females or sites against other males. As the time that females will become receptive approaches, males reduce the size of the range that they occupy, but remain in the water, making repeated short dives that are associated with underwater vocal displays. Some males establish themselves near haul-out sites and some near foraging areas used by females, whereas others appear to establish themselves on transit routes between haul-out sites and foraging areas. It has been suggested that a "lekking" type of mating system occurs in this species. In the Antarctic Weddell seal, males appear to defend underwater territories around breathing holes and cracks.

V. Foraging

Many early studies relied on stomach content material from hunted animals, fecal collections, and entrapments in fishing gear to provide information on diving and foraging activity. During the last decade, major technological advances have provided researchers with satellite transmitters, time-depth recorders, stomach temperature probes, and video recorders to study diving and foraging activity.

Phocids feed on a wide variety of prey, including invertebrates, such as amphipods, mysids, squid, and krill, and vertebrate prey, such as fish. Birds have been recorded in the diet of some species such as the leopard seal and harp seal. Leopard seals also prey on other seal species, and cannibalism has been reported in gray seals. DIET composition may change seasonally, geographically, and with age. Newly weaned pups of ringed and harp seals begin foraging on zooplankton in their initial attempts to forage independently and then become more piscivorous as their skills develop. Phocids feed primarily on smaller prey that can be consumed whole, but large prey may be taken. Under certain conditions where prey are very abundant or accessible, e.g., when fish are caught in nets, seals may consume only pieces from fish.

Little is known about factors affecting prey choice. Research has indicated that feeding preferences in harp and harbor seals occur for particular types and sizes of prey that may be independent of local abundance. Harp seals digest capelin more efficiently than most other prey, and throughout their range capelin forms an important component of their diet, whereas other species such as commercially important Atlantic cod (*Gadus morhua*) form only a very minor component in the overall diet. While foraging, phocids must balance their intake of oxygen and the distribution of oxygen for locomotion, body maintenance, and processing of food (specific dynamic action or heat increment of feeding). Their approach to balancing these sometimes conflicting needs will influence their foraging strategy. A seal may process (digest) food while actively swimming and foraging. If it uses only aerobic metabolism, then the consumption of oxygen required to process the food will reduce the amount of time spent diving and collecting food. If

the seal attempts to maintain the duration of diving, then the switch to anaerobic conditions will force the animal to rest at the surface until lactic acid levels are reduced. A second strategy is to forage and then spend time resting at the surface, hauled out on the ice or on land until food processing is completed. However, resting at the surface increases vulnerability to surface predators such as sharks or killer whales, whereas returning to shore or ice involves time lost due to transit and may limit the distances that foraging can occur away from haul-out sites. A third strategy involves foraging and then if successful, reducing locomotory costs by drifting during the surfacing phase of the dive, allowing food processing to occur. Many phocids may utilize the first two strategies. Weddell, ringed, harp, and hood seals are often seen hauled out on the ice and occasionally on land. Harbor and gray seals may forage in offshore areas, but rarely spend more than a few days away from haul-out sites. The third strategy appears to be utilized by elephant seals, who spend almost 8–9 months of the year at sea.

Foraging activity has been examined in detail in elephant seals. In northern elephant seals, females are dispersed over a broad geographic area across the northeastern Pacific from the coast to as far west as 150°W, but tend to remain between 44° and 52°N. Foraging occurs both offshore and during transit between inshore and offshore areas. Diurnal changes in diving depths are observed, indicating that they are foraging on vertically migrating prey in the pelagic and mesopelagic environment. Their principal prey are mesopelagic squid and fish. Males utilize a different foraging strategy by foraging little while en route to particular foraging areas along continental margins off the stage of Washington to as far north as the Aleutian Islands. Once on site, repeated, uniform flat-bottomed dives predominate diving, with little diurnal variability, suggesting intensive foraging activity, possibly on benthic prey such as energy-rich elasmobranchs and cyclostomes (sharks, skates, ratfish, hagfish). While at sea, both species dive continuously, spending almost 90% of their total time at sea submerged, leading to the suggestion that they should be called surfacers instead of divers. At the opposite end of the size spectrum, a very different strategy is seen among harbor seals. Although capable of diving to depths of 500 m, harbor seals rarely dive deeper than 65 m and, in some studies, an average of 65% of diving activity occurs at depths of less than 4 m. Visual and telemetry data indicate that harbor seals in some areas spend most of their time very close to the coast in shallow water areas. Foraging distances rarely exceed 50 km away from haul-out sites. Little difference is seen between males and females in dive depths and foraging distances away from haul-out sites outside of the breeding season.

Echolocation

WHITLOW W. L. AU
University of Hawaii, Kaneohe

Echolocation is the process in which an animal obtains an assessment of its environment by emitting sounds and listening to echoes as the sound waves reflect off different objects in the environment. In a very general sense any animal that can emit sounds may be able to hear echoes from large obstacles (i.e., humans yelling in a canyon); however, this type of process is not considered echolocation. The term echolocation is reserved for a specialized acoustic adaptation by animals who utilize this capability on a regular basis to forage for prey, navigate, and avoid predators. Therefore, echolocating dolphins are often searching for entities that are considerably smaller than themselves and must make fine discrimination of these objects. Over the eon of time, this specialized adaptation has been continually refined under evolutionary pressures.

Echolocation in bats was suspected as early as 1912, but it was not until 1938 when G. Pierce and D. Griffin (1938) provided evidence of bats emitting ultrasonic pulses using an ultrasonic detector that the concept began to gain acceptance. Echolocation in dolphins was suspected around 1947 as was evidenced in the personal notes of A. McBride, the first curator of Marine Studio (later Marineland) in Florida (McBride, 1956). However, it was not until 1960 that Kenneth Norris and colleagues performed the first unequivocal demonstration of echolocation in dolphins by placing rubber suction cups over the eyes of an Atlantic bottlenose dolphin (*Tursiops truncatus*) and observing that the animal was

able to swim and avoid various obstacles. Ultrasonic pulses were also detected as the blindfolded dolphin swam and avoided obstacles, including pipes suspended vertically to form a maze.

Since the Norris demonstration, considerable progress has been made in our understanding of the echolocation capabilities of dolphins. Most of the research has been done with the Atlantic bottlenose dolphin, the most common dolphin in captivity. Research in dolphin echolocation can be divided into the following areas: (1) sound production mechanism and propagation in the dolphin's head, (2) sound reception and auditory capabilities, (3) sound transmission and the characteristics of echolocation signals, (4) target detection capabilities, (5) target discrimination capabilities, (6) auditory nervous system function and capabilities, and (7) signal processing modeling. This article addresses each of the first six areas, providing the most recent findings in most cases along with some fundamental capabilities.

I. Sound Production Mechanism and Propagation in the Dolphin's Head

The head of a dolphin shown in Fig. 1 is a very complex structure with unique air sacs and special sound-conducting

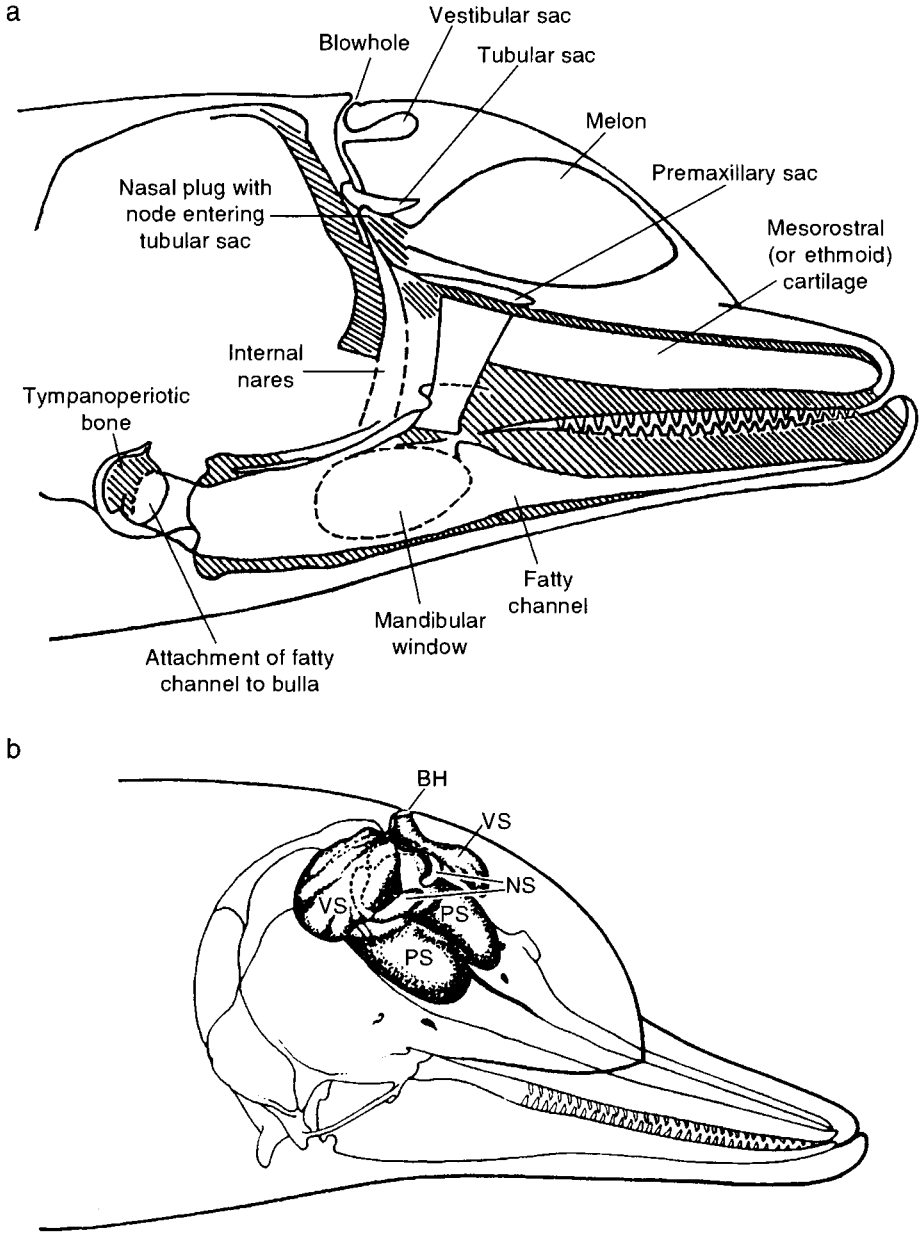

Figure 1 *(a) Schematic of a dolphin's head (adapted from Norris, 1968) and (b) three-dimensional diagram of the air sacs in a dolphin's head. PS, premaxillary sac; VS, vestibular sac; NS, nasofrontal (tubular) sac; AS, accessory sac. Adapted from Purves and Pilleri (1983).*

fats. Once of the most perplexing issues that has eluded researchers since the discovery of echolocation has been the location and mechanism of sound production in dolphins. In the mid-1980s, Ted Cranford began using modern X-ray computer tomography (CT) and magnetic resonance imaging techniques to study the internal structure within a dolphin's head. These noninvasive techniques allowed Cranford to study the relative position, shape, and density of various structures in the dolphin's head and helped him to conclude that the monkey lip–dorsal bursae (MLDB) region of the dolphin nasal complex was the location of the sound generator. Eventually, Cranford and colleagues were able to obtain high-speed video in 1997, of the phonic lips (previously referred to as the monkey lips) with simultaneous hydrophone observations of echolocation signals. There are two sets of phonic lips, associated with the two nares in the dolphin's nasal complex. Cranford and colleagues have obtained additional high-speed video observation of movements in both sets of phonic lips during the production of echolocation signals and whistles.

The numerical simulation of sound propagation in the head of a dolphin by James Aroyan, then a Ph.D. student at the University of California Santa Cruz, has provided considerable understanding of the role of the air sacs, skull, and melon in the propagation of sounds in a dolphin's head. One of the interesting problems Aroyan considered was that of a plane wave propagating toward the head of a dolphin (as depicted in Fig. 2a) to determine where sounds would focus in the dolphin's head in a similar manner to the process used by geologists to determine the epicenter of an earthquake. He numerically solved the three-dimensional wave equation (also shown in Fig. 2) using a finite-difference technique and a super computer. The density and sound velocity structure of the dolphin's head were estimated from the CT scan results of Ted Cranford. The grid points represent a pictorial illustration of how the head of a dolphin may be mathematically subdivided so that the solution of the wave equation is numerically determined at each grid point. The results for the geometry depicted in Fig. 2a are shown in Fig. 2b, with focal regions at the two auditory bullas and at the MLDB region of the nasal system, supporting Cranford's earlier suspicion of the MLDB being the site of the sound generator for echolocation sounds.

Aroyan then placed a hypothetical sound source at the MLDB region and numerically solved the three-dimensional wave equation as the sound propagated through the dolphin's head into the water. He found that the skull, the various air sacs, and the nonhomogeneous melon all played important roles in forming the beam in which sounds are transmitted into the free field. The specific characteristics of this beam are discussed in Section III. He also showed that if a hypothetical sound source was placed at the larynx, the resulting beam in the free field was not compatible to the actual beam measured

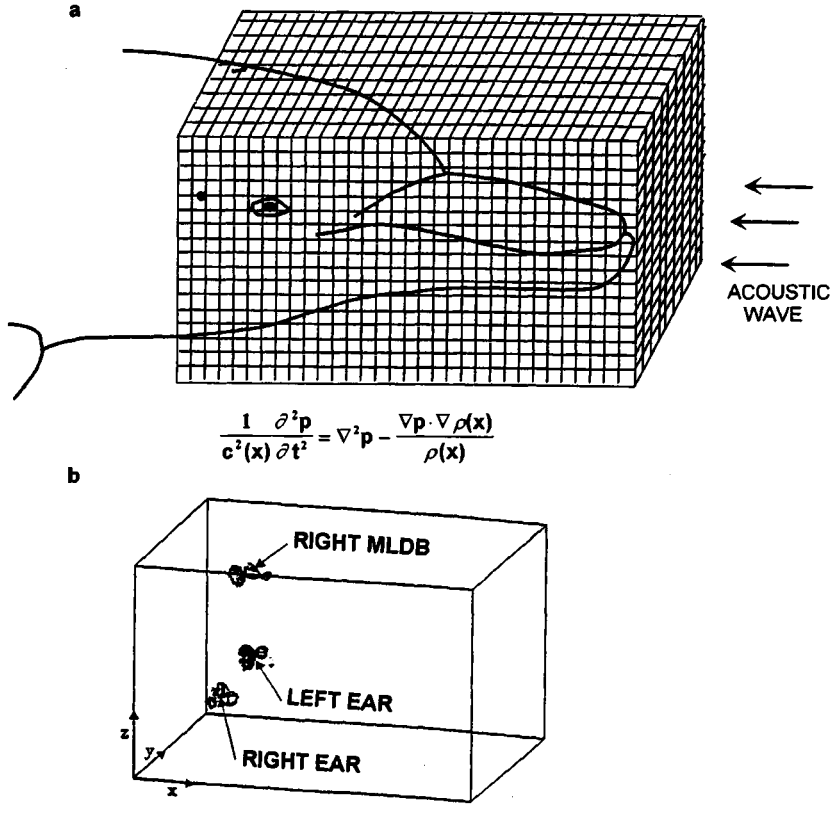

Figure 2 *(a) Configuration of numerical simulation of sound propagation in the head of a dolphin to determine acoustic focal regions and (b) results of numerical simulation for the geometry depicted. After Aroyan (1996).*

for dolphins, therefore essentially eliminating the larynx as a possible site for a sound generator.

II. Sound Reception and Auditory Capabilities

A. Sound Reception Site

Dolphins do not have pinnae and their external auditory meatus is but a pinhole with vestigial fibrous tissues connecting the surface to the tympanic structure. Kenneth Norris was the first to postulate that sound enters the dolphin's auditory system through the thin posterior portion of the mandible (see Fig. 1a) and is transmitted via a fat-filled canal to the tympano-periotic bone, which contains the middle and inner ears. Two electrophysiological measurements, one by Theodore Bullock and colleagues, were conducted that provided evidence to support Norris' theory. However, the acoustic conditions for both experiments were less than ideal: the subjects were confined to small holding tanks and their heads were held near the surface to keep the electrodes from shorting out by the water. The acoustic propagation for such a situation can be extremely variable, with the sound pressure level changing drastically because of multipath propagation, on the order of 10 to 20 dB.

Bertel Møhl and colleagues took a slightly different electrophysiological approach by measuring the brain stem-evoked potential of a bottlenose dolphin that was trained to beach itself on a rubberized mat. A special suction cup hydrophone having a water interface between the piezoelectric element and the skin of the dolphin was positioned at different locations on the dolphin's head. By performing the measurement in air, the point at which sound from the piezoelectric element enters into the dolphin could be firmly established. Acoustic energy will only propagate toward the dolphin's skin, and energy propagating in any other direction will be reflected back at the boundary of the suction cup. Møhl and colleagues positioned the suction cup hydrophone at different locations around the dolphin's head, and at each location, the amount of attenuation needed to obtain the evoked potential threshold was determined. Their results are shown in Fig. 3, where the circles indicate the different positions of the suction cup and the number within each circle represents the amount of attenuation needed to achieve threshold. Therefore, a larger number is indicative of a more sensitive region of sound reception. The dashed line indicates the area of the pan bone or mandibular window shown in Fig. 1a. These results indicated that the area just forward of the pan bone area of the dolphin's lower jaw is the most sensitive area of sound reception, which seems to be inconsistent with Norris' pan bone theory. However, the numerical simulations of acoustic propagation by Aroyan suggest that sounds that enter the dolphin's lower jaw just forward of the pan bone actually propagate below the skin surface to the pan bone and enter into the lower jaw through the pan bone.

B. Hearing Sensitivity

The hearing sensitivity of a dolphin was first measured accurately in 1967 by Dr. Scott Johnson in a pioneering experiment. Johnson found that the upper limit of hearing of an Atlantic bottlenose dolphin was 150 kHz. Since Johnson's research, audiograms have been determined for the harbor porpoise (*Phocoena phocoena*), Amazon River dolphin (*Inia geoffrensis*), beluga whale (*Delphinapterus leucas*), false killer whale (*Pseudorca crassidens*), Chinese river dolphin (*Lipotes vexillifer*), Risso's dolphin (*Grampus griseus*), Tucuxi (*Sotalia fluviatilus*), and killer whale (*Orcinus orca*). The audiograms for these odontocetes are shown in Fig. 4.

One of the most remarkable features of these audiograms is the high upper frequency limit of hearing extending beyond 100 kHz. This is rather remarkable when the wide range of sizes of the animals depicted in Fig. 4 is considered. The largest animal represented in Fig. 4 is the killer whale, which weighed about 3600 kg and was about 5 m in length compared to the smallest animal, the harbor porpoise, which typically weighs about 33 kg and is about 1.3 m in length. The typical rule of thumb in mammalian hearing is that larger animals tend to

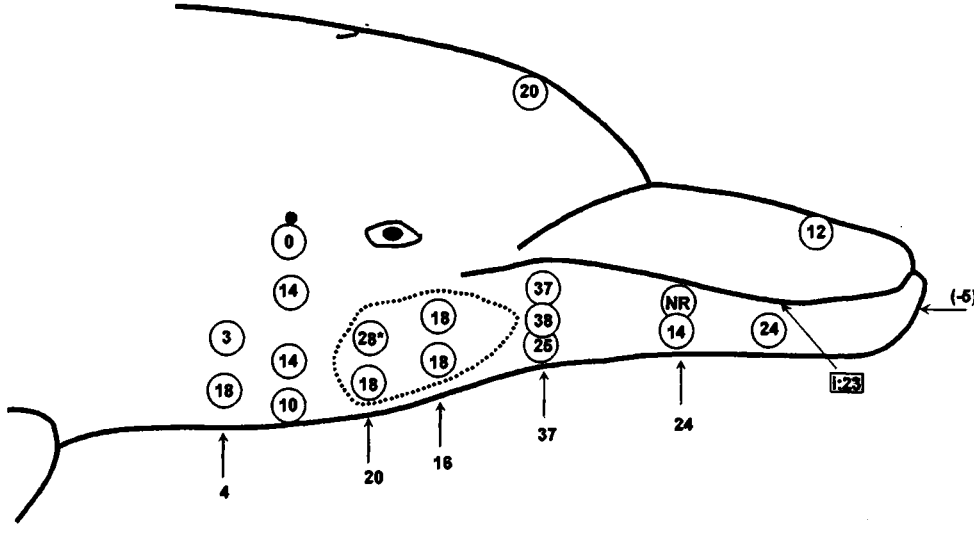

Figure 3 *Relative reception sensitivity of hearing at different locations around a dolphin's head. The higher the number, the more sensitive the region. Adapted from Møhl* et al. *(1999).*

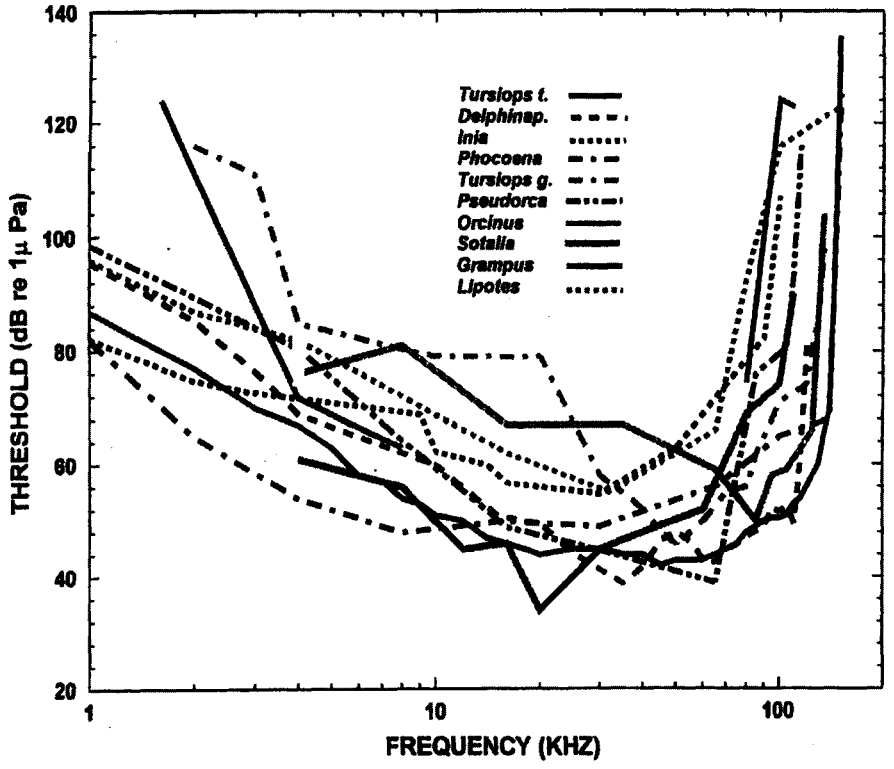

Figure 4 *Audiograms for 10 species of odontocetes.*

have limited high-frequency hearing capabilities. A killer whale is considerably larger than the smallest dolphin, yet its upper limit of hearing is approximately 120 kHz, and may therefore represent an exception to the norm. Another interesting feature of Fig. 4 is the fact that the maximum sensitivity for the different odontocetes has a very similar value, within 10 dB.

Although dolphins do not have pinnaes, the auditory system of the dolphins is directional. Sounds are received best when the source is directly in front of an animal. The receiving beam pattern of a *T. truncatus* in both horizontal and vertical planes is shown in Fig. 5. Several features of the beam patterns are worth pointing out. First, the beam becomes wider as the frequency decreases. Planar transducers also behave in a similar fashion with their beam becoming narrower as the frequency increases. Second, the major axis of the beam in the vertical plane is pointed upward with respect to the teeth line by about 5–10°. Third, the major axis in the horizontal plane is pointing directly in front of the animal parallel to the longitudinal axis of the dolphin. The receiving beam pattern can also be discussed in terms of the spatial variation in the hearing sensitivity of the dolphin. Therefore, the dolphin has the best high-frequency hearing sensitivity when sounds approach from the front and poorer sensitivity as the sound sources move to other locations about the animal's head.

III. Sound Transmission and the Characteristics of Echolocation Signals

There is a distinct difference in the echolocation signals used by odontocetes that produce whistle signals and those that do not whistle. Whistling dolphins project short, almost exponentially decaying signals with durations of 40 to 70 μsec and bandwidths of tens of kHz. Nonwhistling dolphins and porpoises project signals with much durations of 120 to 200 μsec and with narrow bandwidths that are typically less than 10 kHz. An example of a typical echolocation signal produced by an Atlantic bottlenose dolphin is shown in Fig. 6, along with a typical echolocation signal produced by a harbor porpoise (a nonwhistling animal). Whether riverine dolphins produce whistles is still an open question: however, these dolphins emit signals that are of the broadband, short duration variety. Most odontocete species produce whistles, and only a few, such as the harbor porpoise, Commerson's dolphin (*Cephalorhynchus commersonii*), Hector's dolphin (*C. hectori*), Dall's porpoise (*Phocoenoides dalli*), and pygmy sperm whale (*Kogia breviceps*), are known to not.

The amplitudes of the echolocation signals also are very different between whistling and nonwhistling odontocetes. Whistling dolphins, such as *T. truncatus*, *P. crassidens*, and *D. leucas*, can project echolocation signals with peak-to-peak amplitudes as high as 225 dB re 1 μPa. The center frequency of the signals used by whistling dolphins is affected by the level of the outgoing signal. The center frequency of clicks varies almost linearly with the peak-to-peak amplitude. Nonwhistling dolphins and porpoises, such as *P. phocoena* and *Phocoenoides dalli*, emit signals that normally do not exceed 170 dB re 1 μPa. Peak-to-peak source level measurements for *P. phocoena* by Au and colleagues in 1999, while the animal was performing a target detection task, indicated an average peak-to-peak source level of only 160 dB, which is considerably smaller than the 210–225 dB used by *T. truncatus*,

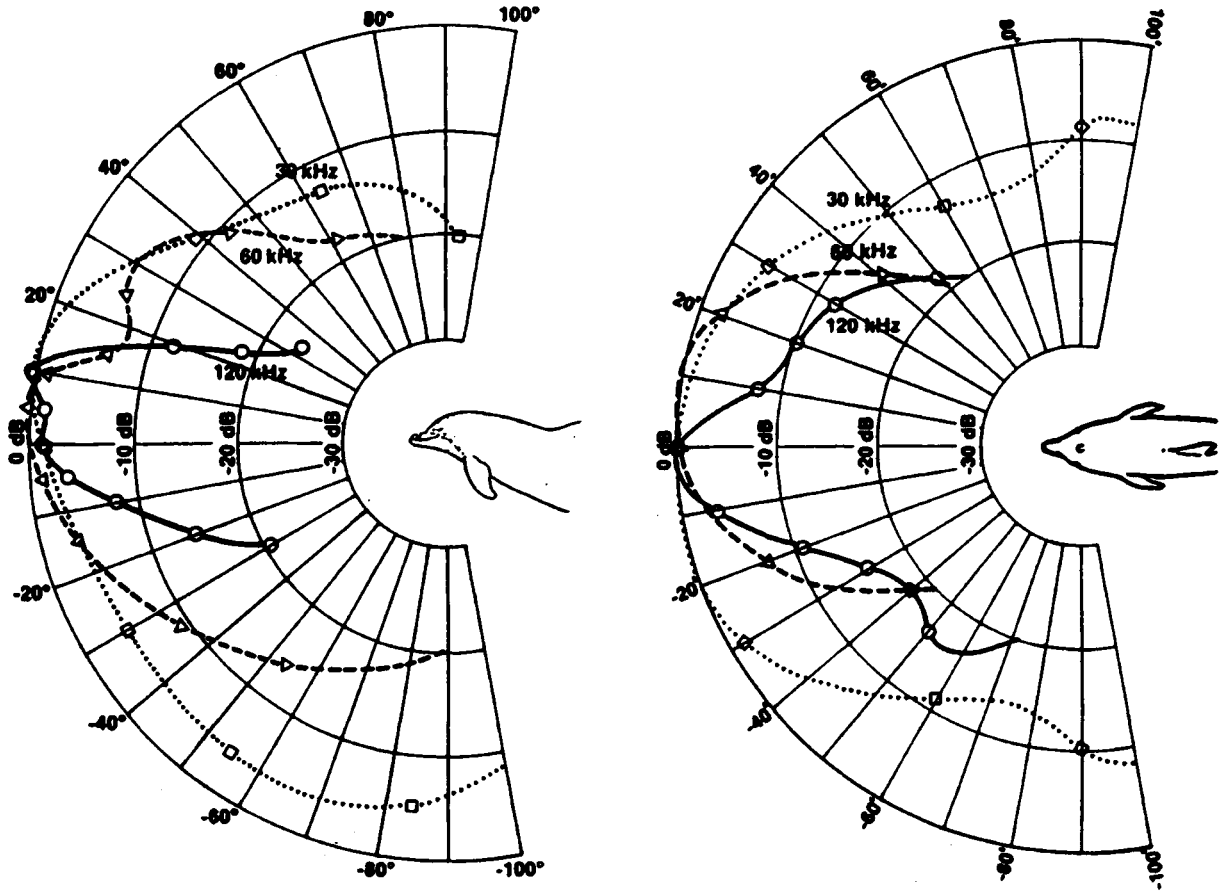

Figure 5 *The receiving beam patterns in the horizontal and vertical planes for different frequencies. Adapted from Au (1993).*

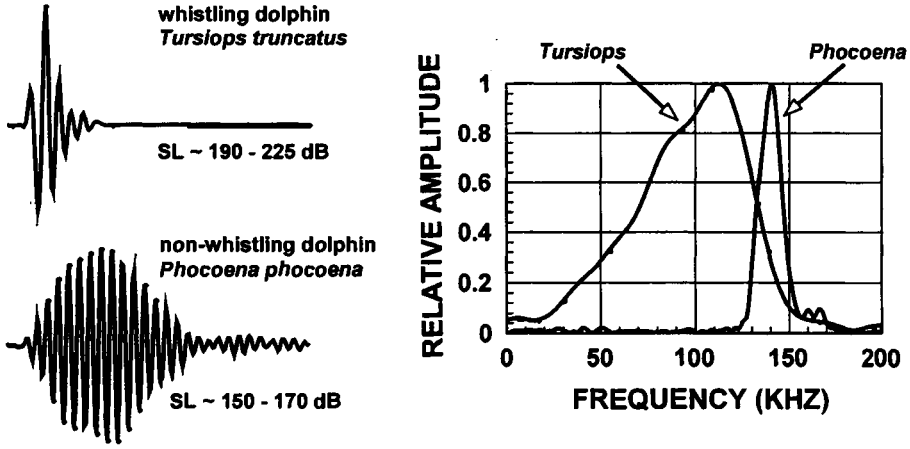

Figure 6 *Typical echolocation signal emitted by* T. truncatus *(a whistling dolphin) and* P. phocoena *(a nonwhistling porpoise). The source level (SL) is the peak-to-peak sound pressure level referenced to 1 μPa at 1 m.*

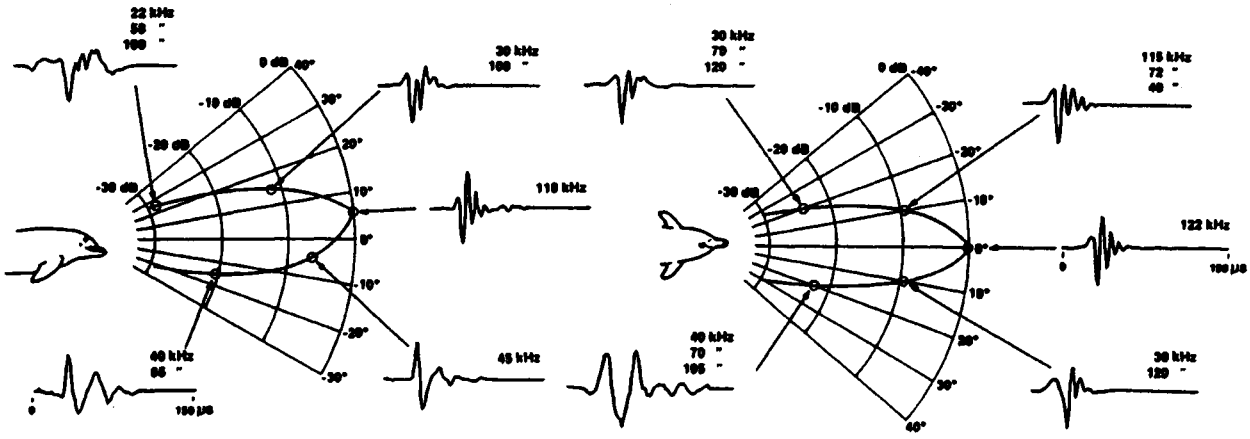

Figure 7 *The transmission beam pattern in horizontal and vertical planes. The signals shown with each beam pattern are all the same signal captured simultaneously by five hydrophones located about the dolphin's head. After Au (1993).*

P. crassidens, and *D. leucas.* The center frequency of the *P. phocoena* signal, which is typically between 120 and 145 kHz, does not depend on the level of the projected sonar signals.

Echolocation signals are projected from a dolphin's head in a beam. An example of the transmitting beam pattern for a *T. truncatus* in both horizontal and vertical planes is shown in Fig. 7. The signal shown at different angles about the animal's head is the same signal captured by an array of hydrophones. Note that only the signal traveling along the major axis of the beam is undistorted. This phenomenon occurs in horizontal and vertical planes. The numbers above each signal are the maxima in the frequency spectra of the signals, in order of descending amplitude. The further away from the major axis of the beam, the more the signal is changed. This property of the beam makes it very difficult to measure echolocation signals in the wild. Occasionally, dolphins in the wild may actually swim directly toward a hydrophone so that relatively true measurements can be made.

Beam pattern measurements have also been conducted for *D. leucas, P. crassidens,* and *P. phocoena.* The signals from all of these animals, with the exception of *P. phocoena,* exhibit changes in frequency content when the measuring hydrophone is located away from the major axis. However, in the case of *P. phocoena,* the signals detected by hydrophones located away from the major axis are not distorted, as can be seen in Fig. 8. Distortion does not occur because the signal has a relatively narrow bandwidth.

IV. Target Detection Capabilities

One of the most fundamental properties of a sonar system is its maximum detection range. A simple way to determine the

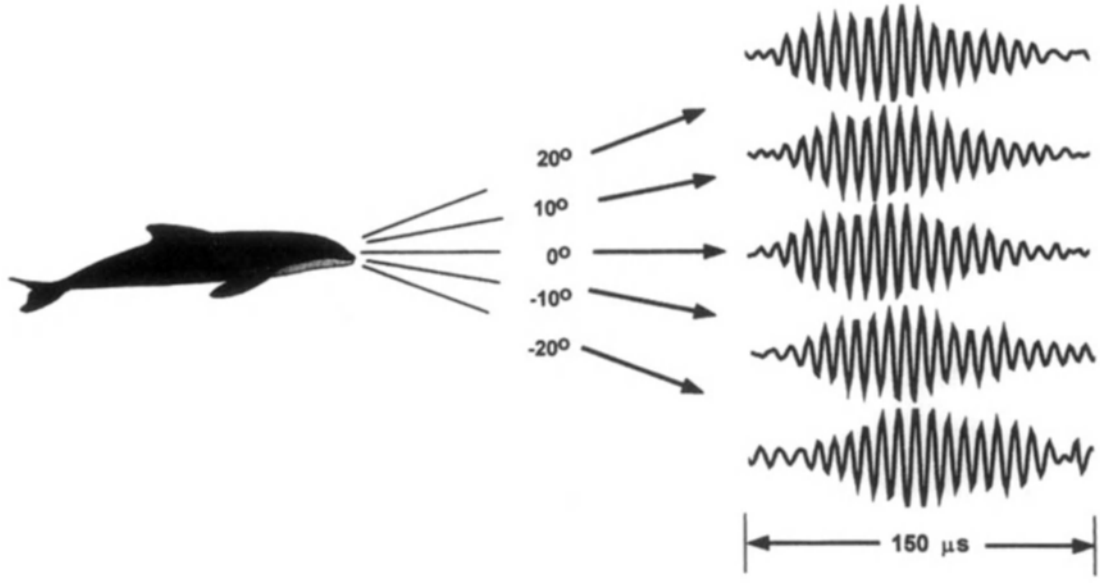

Figure 8 *The waveform of an echolocation signal detected by hydrophones spaced about the head of a* P. phocoena. *After Au* et al. *(1999).*

maximum target detection range of a sonar is to gradually move a specific target away from the sonar until the target can no longer be detected. Au (1993) used a 7.62-diameter water-filled stainless-steel sphere as the target to determine the maximum detection range of *T. truncatus*. The target was moved progressively away from an echolocating dolphin until the animal could no longer detect its presence. Stringent psychophysical techniques were used and many sessions were conducted in order to stabilize performance and to determine the probability of detection as a function of range. Kastelein and colleagues (1999) used the same type of target (7.62-cm diameter water-filled stainless-steel sphere) as Au and colleagues to determine the sonar detection capability of *P. phocoena*. The results of both experiments are shown in Fig. 9.

The 50% correct detection threshold for the bottlenose dolphin occurred at a range of 113 m. The 50% correct detection threshold for the harbor porpoise was approximately 26 m. An experiment by Au and Snyder took place in Kaneohe Bay, Hawaii, a bay that has a high level of snapping shrimp sounds or noise. Therefore, the bottlenose dolphin was masked by the background noise level. The harbor porpoise target detection experiment was performed at a location in the Netherlands, where the ambient background noise, between 100 and 150 kHz was essentially at sea state 0. Therefore, the harbor porpoise was not masked by background noise and yet its detection threshold was considerably shorter than *Tursiops*'. The difference in the two-way propagation losses for 113 and 26 m is 36 dB. The bottlenose dolphin typically produces clicks that are 50–60 dB greater than that of the harbor porpoise. Therefore, the large difference in the levels of projected signals can account for most, but not all, of the very large difference in the detection threshold ranges of both animals. If the target detection experiment with *T. truncatus* were conducted in a body of water with a low ambient background noise, the dolphin's target detection range would be much longer and, in that case, the difference in the two-way transmission would probably match the difference between the source levels used by the two different species.

V. Target Discrimination Capabilities

There have been many target discrimination experiments involving echolocating dolphins. Unfortunately, in many of these experiments the reflection characteristics of the targets were not measured or were measured with tone-burst signals instead of with a simulated dolphin-like signal. The experiment involving wall thickness discrimination by an echolocating dolphin is one that provided appropriate echo characteristics of the targets (Au, 1993). In this experiment, the dolphin was presented with two hollow aluminum targets separated by 20° at a range of 8 m. The standard target had a wall thickness of 0.63 cm, and the comparison targets had wall thicknesses that were different than the standard by ± 0.8, ± 0.4, ± 0.3, and ± 0.2 mm. All the targets had a length of 12.7 cm. On any given trial, the standard and comparison were introduced into the water separated by ± 20° about the center axis. The dolphin was required to swim into a hoop and echolocate the targets when a screen was lowered out of the way and then touch a paddle that was on the same side of the center line as the standard target. Two sets of targets were available so that the position of the standard could be switched on any given trial.

The results of the wall thickness experiment are shown in Fig. 10. The dolphin performed very well with correct responses in the mid-90 percentile. The animal's correct response performance became progressively worse as the difference in wall thickness decreased. The 75% correct performance threshold was 0.27 mm for the case in which the comparison targets were thinner than the standard target and 0.23 mm when the comparison targets were thicker than the standard.

Echoes from the standard target and the −0.3 mm comparison target are shown in Fig. 11. There are several cues that the animal might have used in order to perform this discrimination. One cue is the difference in the time delay between the first and the second echo component for both the standard and the comparison target. If this cue was used, it suggests that the dolphin could discriminate differences of about 0.5–0.6 μsec.

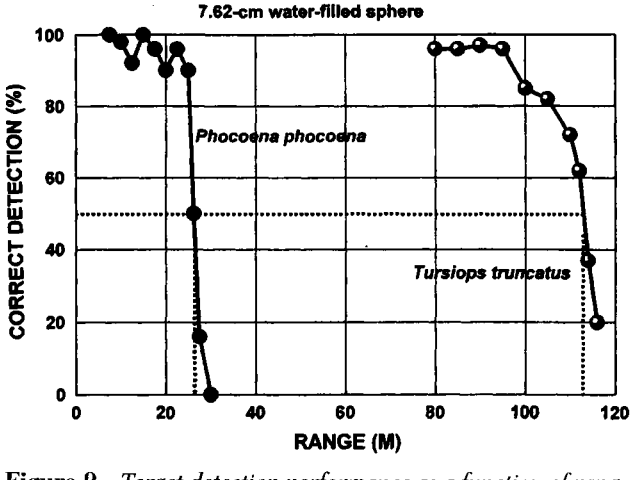

Figure 9 *Target detection performance as a function of range for* T. truncatus *and* P. phocoena. *After Au (1993) and Kastelein (1999).*

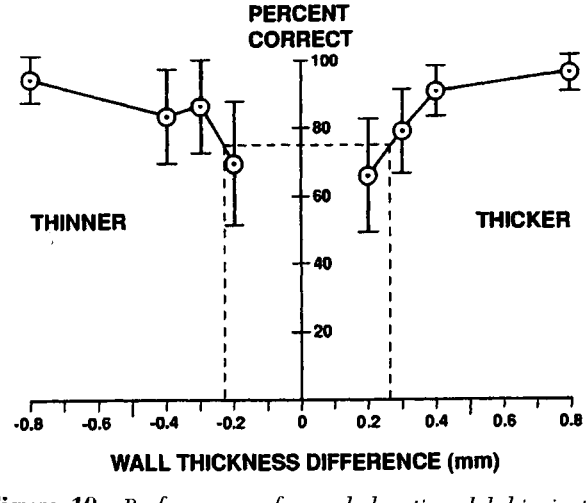

Figure 10 *Performance of an echolocating dolphin in the wall thickness discrimination experiment. Adapted from Au (1993).*

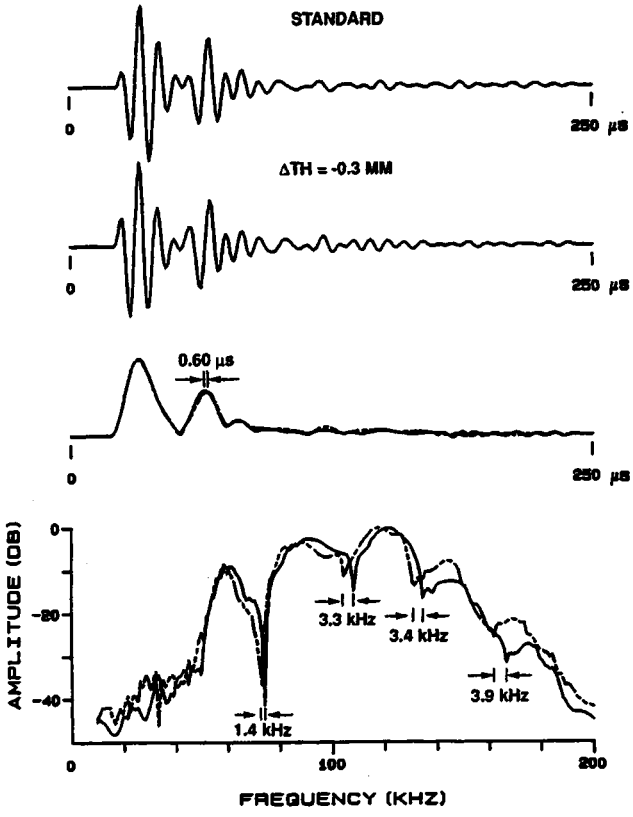

Figure 11 *Echoes from the standard and the −0.3 mm targets. The top two traces are the echo waveforms, the middle trace is the envelope of the echo waveforms overlayed upon each other, and the bottom curve is the spectra of the echoes. Adapted from Au (1993).*

Another cue could be the difference in the time-separation pitch (TSP). When humans are presented with two correlated broadband acoustic signal separated by time T, a time-separation pitch equal to $1/T$ can be perceived. TSP stimulii also have a frequency spectrum that is rippled. The third possible cue is the difference in the frequency spectra of the echoes. The frequency spectrum of the echo from the −0.3 mm comparison target is shifted between 2 and 3 kHz from the spectrum of the standard target. If the dolphin was using this cue, it suggests that the animal was able to perceive a frequency difference of 2–3 kHz in the broadband echoes.

VI. Auditory Nervous System Response

The fact that echolocating dolphins can produce signals with peak frequencies between 100 and 135 kHz implies a relatively fast nervous system response because the time between periods of sound transmission and the auditory response can be short, on the order 7 to 10 μsec. The speed of the auditory response can be determined by performing an electrophysiological experiment in which the time difference between the projection of the stimulus and the onset of the brain stem response is measured. This time difference is typically referred to as the latency of response. A comparison of the latency for a variety of mammals is shown in Fig. 12. In order to fully appreciate Fig. 12, it is important to understand that the brain stem-evoked potential consists of several waves (indicated by Roman numerals) that arrive at the measuring electrodes at slightly different times. From Fig. 12, it is obvious that dolphins have an extremely fast auditory nervous response, even faster than that of a rat. The acoustic stimulus must travel into the inner ear where the cochlea nerves discharge and send the electrical pulses to higher auditory centers and eventually to the brain stem. What is very astonishing is the fact that a rat's head is considerably smaller than that of dolphins, yet dolphins have shorter responses than the rat.

The response time of the auditory system of a dolphin can be estimated by performing an integration-time experiment. Au (1993) performed a target detection experiment using phantom echoes. The phantom echo generator would digitize the outgoing signal, which was detected by a hydrophone 1.5 m in front of the dolphin stationing in a hoop. The digitized signal was stored in the memory of a personal computer, and at the appropriate time delay representing the two-way transit time for a target at 20 m, the "echo," was sent back to the dolphin via a small transducer located 2 m in front of the animal. In the initial phase, a single echo was sent to the dolphin and the dolphin's hearing threshold for the single echo was determined by varying the amplitude of the echo in a staircase fashion. In the second phase, two echoes were separated by a variable spacing that was sent back to the dolphin. The dolphin's threshold was obtained by varying the amplitude of the whole echo in a staircase fashion for various separation times between the two echoes.

The results of the phantom echo experiment are shown in Fig. 13. For an echo consisting of a single click, the threshold is shown on the ordinate of the curve in Fig. 13. Then two echoes were sent back to the animal with a separation time of 50 μsec. The threshold for the two-click echo at 50 μsec was approximately 3 dB lower than for the single click threshold. This was expected because the two-click echo had twice the amount or 3 dB more energy than the single click echo, and

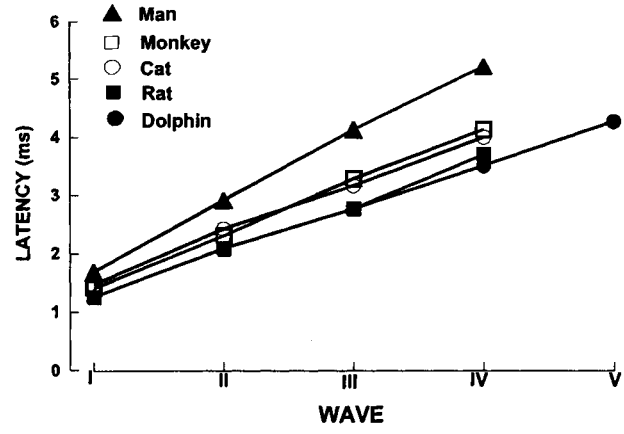

Figure 12 *Brain stem-evoked potential latency for different animals. Adapted from Ridgway (1983).*

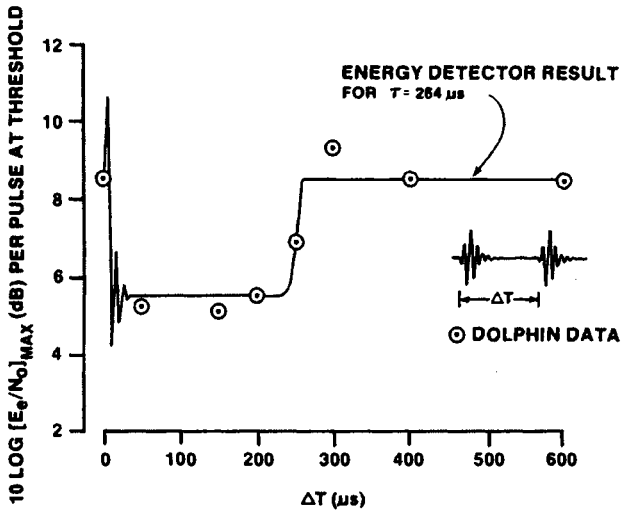

Figure 13 *Results of the phantom echo experiment. After Au (1993).*

the dolphin auditory system, like most mammals, behaves as an energy detector. As the time separation between the two clicks increased to 200 μsec, the dolphin's threshold remained very constant. However, when the time separation increased to 250 μsec and beyond, the dolphin's threshold began to move toward the threshold for a single click echo. The solid line in Fig. 13 represents the output of an energy detector having an integration of 264 μsec. The energy detector response with a 264-μsec integration time best fits the animal results. This integration time is extremely small compared to the integration time of any other mammal.

VII. Conclusions

Dolphins have very keen echolocation capabilities, much keener than any man-made sonar, especially in a shallow water environment. The use of relatively short broadband echolocation signals by whistling dolphins is probably the most important factor in the dolphin's good discrimination capabilities. The broad frequency range of hearing extending over 10 octaves and the good peak sensitivity of 30 to 40 dB re 1 μPa are certainly contributing factors in the dolphin's echolocation capabilities. Another feature of the dolphin's auditory system that contributes to its good echolocation capabilities is the extremely rapid response of its auditory nervous system. The auditory nervous system of the dolphin probably responds faster than that of any other animal if the relative dimensions of the auditory system are taken into account. Finally, dolphins are extremely mobile and can investigate objects at different aspects and angles to maximize the amount of echo information from objects and thus enhance their echolocation capabilities.

Ecology, Overview

BERND WÜRSIG
Texas A&M University, Galveston

Marine mammals have entered just about all ocean habitats, and several mighty rivers and inshore seas as well. Only the deep abyss is foreign to them, but—remarkably—elephant seals (*Mirounga* spp.), sperm whales (*Physeter macrocephalus*), and several other toothed whales can "easily" dive to depths that exceed 1000 m, where it is cold and dark and where the pressure is 100 times and more what we experience on land. Perhaps just as remarkable is the fact that some of these divers, the pinnipeds, are also able to live on land, where they mate, give birth, and molt.

Morphologic, physiologic, and behavioral adaptations to the environments of marine mammals are largely driven by their food, and the habitats of their prey. Although there are various ways that ecological adaptations can be divided, this article does so by several broad-based general habitat types: open ocean, semipelagic, coastal, and riverine feeding and breeding habitats and—for pinnipeds and the polar bear—their obligatory stint on land to breed.

I. Open Ocean

There are two major types of open ocean marine mammals: "surface dwellers" and "deep divers."

A. Surface Dwellers

Most of the open ocean, or pelagic, smaller toothed whales and dolphins spend their entire lives within about 200 m of the surface. The near-surface environment is low in primary and secondary productivity except in latitudes higher than about 50° north and south of the equator. Therefore, these pelagic cetaceans travel great distances in search of food, often in large herds of hundreds to thousands. The large herds may be for better detection of prey, possible cooperative prey herding, and enhanced detection of predators such as deep water sharks and the larger cousins of dolphins, killer whales (*Orcinus orca*). All of these capabilities may be enhanced by several species traveling together, in so-called multispecies aggregations. An example in the eastern tropical Pacific (ETP), where a dolphin herd may travel over 1000 km in 1 week, is the co-occurrence of spinner (*Stenella longirostris*), pantropical spotted (*S. attenuata*), and common (*Delphinus* spp.) dolphins. These dolphins are slim-bodied (or "sleek"), built for speed and long-distance endurance. They do not have the thick blood (packed with red blood cells) so characteristic of deep divers. Instead, they feed on sporadically encountered near-surface fishes and squid, or at night on animals that rise to within several hundred meters of the surface in association with the deep scattering layer (DSL). Their occurrence in large schools has another function: the school is the social, breeding, and calf care-giving unit, and these nomadic wanderers tend to be within their "complete" society at all times. Exceptions are when young males, for example, may form separate bachelor herds or bands or when adult males move among breeding herds (as in sperm whales).

While several species of baleen whales migrate through deep water, they tend to feed on rich areas of invertebrates and fishes that are found more often close to shore. However, others habitually feed in open ocean waters. As is the case for the surface-dwelling odontocetes, baleen whales most often feed within about 200 m of the surface, as none of them are exceptionally deep divers. Blue (*Balaenoptera musculus*), fin (*B. physalus*), sei (*B. borealis*), and Bryde's and Eden's whales (*B. brydei* and/or *edeni*) are good examples of oft-pelagic, near-surface feeders. Blue and fin whales tend to feed on euphausiid crustaceans, or KRILL; whereas sei and Bryde's whales feed more commonly on shoals of fishes. All of them lunge through their food rapidly. The right (*Eubalaena* spp.) and bowhead whales (*Balaena mysticetus*) often surface-skim feed in the open ocean of productive high latitudes, whereas gray whales (*Eschrichtius robustus*) feed on ampeliscid (tube-dwelling) amphipods. They do so in waters less than 200 m deep, both near shore and far away from land in the Bering, Chukchi, and Beaufort Seas. Although rorquals are built for speed so that they can lunge into food rapidly, right whales and gray whales tend to the more rotund body shape, or chunky.

Many pinnipeds also feed near the surface and, at times, up to several hundred kilometers from shore. The smaller true seals (such as ringed seals, *Pusa hispida*, for example) and all of the eared seals are not deep divers and therefore stay near the surface in those generally higher latitude waters where they find themselves in the open sea. Near-surface feeding pinnipeds are not likely to be out on truly oceanic seas further than several hundred kilometers from land. Northern fur seals (*Callorhinus ursinus*), however, are often found in deep pelagic waters of the north Pacific.

B. Deep Divers

Many of the larger toothed whales and a few true seals dive "deeply," or below about 500 m. Sperm whales are likely to be the champion divers. They routinely feed at depths around 500 m on fishes and squid, but can also dive to 2,000 m and more in search of the larger truly pelagic squid. Although we know little of the dive capabilities of other deep-diving odontocetes—pilot whales (*Globicephala* spp.), 20 species of beaked whales (family Ziphiidae), dwarf and pygmy sperm whales (family Kogiidae), and the false killer whale (*Pseudorca crassidens*) are good examples—it is likely that all of them are capable of greater than 500-m dives as they feed largely on midsized deep water fishes (often of the family Myctophidae) and squids. Curiously, the largest dolphin-like (or delphinid) cetacean, the killer whale, appears to feed without diving deeply. It is possible, but remains unproved, that some smaller toothed whales can evade killer whales by diving down.

The champion pinniped divers are northern and southern elephant seals (*Mirounga* spp.) as well as the Weddell (*Leptonychotes weddellii*) and probably several other large true seals. They can (but do not often) dive down to 1000 m and beyond. They feed on fishes and squid at these depths, but it has been surmised that at least some deep dives are "resting dives" as the animals conserve energy while their metabolism is largely shut down at depth. Such possible rest (or "sleep") may even help them evade detection by predators such as most active sharks, who are not deep divers, and killer whales. Because elephant seals spend only about 15% of their time at the surface, it is not really correct to call them "divers." Their life is underwater and they are indeed "surfacers" who come up only for life-sustaining air.

All deep divers have adapted physiologically and morphologically for the task. Blood and muscles have changed to hold as much oxygen as possible, and peripheral vasoconstriction and shutting off of nonvital body functions during a dive take place.

II. Semipelagic

Quite a few marine mammals habitually occur in the zone between shallow and deep water, often at the edge of the continental shelf or some other underwater feature. There is high productivity there, caused by upwelling or current systems as sea meets land, and it makes sense that this is a major point of aggregation. Sperm whales off Kaikoura, on the South Island of New Zealand, feed in such a zone near the deep Hikurangi Trench about 10 km out. However, the sperm whales are often within 1–5 km from shore, in productive waters 200 to 600 m in the deep, shore side of the trench. Blue whales of Monterey Bay, California, do so as well, as they take advantage of large stands of krill to enter the area in late summer. Dall's porpoises (*Phocoenoides dalli*) are also found in some abundance in Monterey Bay, not as frequently in very shallow nor very deep waters, but on the edge of the productive Monterey Canyon. Dozens of species and hundreds of geographic examples could be cited as those that occur in such productive "neither nearshore nor open ocean" zones.

Several dolphins are "semipelagic" in another sense. They seek out deep productive waters in areas close to shore so that they can feed in the open sea yet retreat to the shallows, often into bays and inlets or onto expansive shoals during rest. Spinner dolphins of the tropical islands of the Pacific have such a habit. During the day, they rest and socialize within island bays and lagoons, even entering atolls through narrow passes in some areas. It is believed that nearshore rest is to avoid large oceanic swells and trade winds, as well as predation by large oceanic sharks. At night, these dolphins head out to sea, often only 1–5 km from land off these abruptly rising volcanic islands. The dolphins meet the DSL as it comes to within several hundred meters of the surface at night and thus have a food resource available that these only-average divers could not obtain during the day, when the DSL is 600 m or more below. Atlantic spotted dolphins (*Stenella frontalis*) appear to do the same, but have daytime rest over an expansive shallow area: the Grand Banks of the Bahamas, only 6–10 m deep.

Pinniped females that go on foraging dives in between nursing their young on land, such as Galapagos fur seals (*Arctocephalus galapagoensis*), also use the productive shelf and drop-off waters to feed while—in their case—needing to return to land to take care of their young.

III. Coastal

Many marine mammals can be termed "coastal," and because all of the various taxonomic orders and suborders have coastal representatives, one to several examples of each group are given.

The most coastal baleen whale is undoubtedly the gray whale, for it feeds in shallow waters of the Bering Sea, usually but not always near coasts; travels on its immense migration from the Bering Sea to Baja California, Mexico—and back—along the coast; and mates and calves near and in coastal lagoons of the subtropics. It is likely that this rather slow cetacean hugs the coastline for safety (mainly, one surmises, for its young) against shark and killer whale predation. It probably also uses the coast to navigate. It would not be surprising, although present information is not clear on this point, if gray whales use the depth contours, rocky outcroppings of headlands, and other near-coastal features as signs of location as surely as we find our way to and from the supermarket. The coastline also allows them to find clouds of mysids, small aggregating invertebrates, among kelp beds, and to occasionally feed on stands of inbenthic invertebrates while on migration. A second "coastal" animal is the humpback whale (*Megaptera novaeangliae*), for it feeds in bays and inlets, breeds near islands, and only uses deep oceanic waters to get to and from these ends of migration. In the northeast Pacific, humpbacks feed in the fjord-like bays of southern Alaska and breed around the Hawaiian, and Mexican Revillagigedo, islands.

Odontocete cetaceans have many coastal representatives, with the best studied of them being the bottlenose dolphin (*Tursiops truncatus*). While separate populations of this highly adaptable species can exist in deep oceanic waters as well, it is the coastal form that has taken our fancy and makes for one of the better captive animals, presumably because it feels at home in small groups and with confines of cliffs; rocks, bayous, and channels. Bottlenose dolphins variably nose and poke their way among rocks to feed; feed on schooling fishes in the nearshore, at times trapping schools against a beach or cliff; feed on the bottom; and encircle prey as a cooperating group in the open coast sea. Dolphins of the *Cephalorhynchus* genus of southern oceans tend toward coastal living, as do the humpback dolphins of the genus *Sousa*, harbor porpoises (*Phocoena phocoena*), and beluga whales of the arctic (*Delphinapterus leucas*). Interestingly, these animals appear to have some form of fission–fusion society, traveling in subgroups of variable size from day to day. It is likely that they aggregate in small groups for greatest efficiency in hunting and that the social or breeding unit is all of the small groups of an area that get together at some time throughout a year, but never all at once. Most but not all coastal waters are turbid as well, and it may be that echolocation and communicative sounds are particularly well developed in these animals.

Many pinnipeds have coastal representatives, especially for the physically smaller species. California sea lions (*Zalophus californianus*) rest on the shore and feed in the coastal zone, hardly ever venturing further than several kilometers from land. Harbor seals (*Phoca vitulina*) and the two living but highly endangered tropical monk seals (*Monachus* spp.) do so as well.

Sea otters (*Enhydra lutris*), marine otters of Chile (*Lontra felina*), and the sirenians are all coastal shallow-water feeders. Otters feed on invertebrates on the bottom or on kelp-associated fishes. While many populations of sea and marine otters do not frequently haul out on land, they use kelp beds as resting stations and perhaps as a means to hide from sharks and killer whales. The West Indian manatee (*Trichechus manatus*) and the dugong (*Dugong dugon*), the latter largely of the nearshore Indian Ocean, feed on sea grasses and are thereby restricted to the shallows.

IV. Riverine

While the term "marine mammals" is meant for mammals that take all or most of their sustenance from the sea, several species are included that have gone to a largely freshwater environment. Because these have close taxonomic affiliations to several other marine mammals, this inclusion makes sense.

There are several obligate river dolphins: the susu and bhulan (now listed as subspecies within one species, [*Platanista gangetica*]) of the Indian subcontinent; the baiji (*Lipotes vexillifer*) of the Yangtze River of China; and the boto or Amazon river dolphin (*Inia geoffrensis*) that also occurs in the Orinoco basin of South America. These dolphins live their lives in mighty rivers, feeding on invertebrates and fishes, generally in small groups numbering fewer than about six animals. Their eyes have adapted to the less saline environment, and their kidneys do not need to process the salty foods of the ocean. It is likely that they would not survive in salt water. The Amazonian manatee (*Trichechus inunguis*) is also restricted to the extensive freshwater system of the Amazon basin.

In addition to obligate river dolphins and the Amazonian manatee, there are several mammals that are facultative, those who have populations that occur in rivers and those who go in

and out of rivers to the adjacent ocean. Of the first type are finless porpoises (*Neophocaena phocaenoides*) that occur throughout nearshore waters of southern Asia and a bit of the Indian Ocean, but have a thoroughly fresh water population in the Yangtze River. Recent work shows that the freshwater form has eyes, skin, and kidneys that are adaptively different from their ocean-going conspecifics. As well, the diminutive tucuxi dolphin (*Sotalia fluviatilis*) occurs nearshore along much of the tropical Atlantic Central and South American coast, but as separate populations in the Amazon River basin. Of the second type of marine mammals, where some go in and out of rivers as members of the same population, are Irrawaddy dolphins (*Orcaella brevirostris*), bottlenose dolphins, belugas, and West Indian and West African manatees (*Trichechus manatus* and *T. senegalensis*). To date, there are no well-defined morphologic or physiologic differences between those who frequent fresh waters more than others, and it is assumed that this wide salinity tolerance is itself an adaptation that allows exploitation of food resources in ecologically diverse realms. Belugas seem to enter rivers more often during a concentrated period of skin sloughing, or molt; these are the only whales known to molt.

Almost all pinnipeds are generally tied to the sea to feed, but a form of the harbor seal and the Asian Lake Baikal (fresh water) and Caspian Sea (somewhat salty) seals (*Pusa* spp.) occur in land-locked areas. They occur in remnants of areas that were once connected to oceans.

V. Life on Land

Polar bears do considerable feeding on land or ice, pinnipeds all need to come to land to give birth, and sea otters do so variably by population. Off California, sea otters give birth in the water, but are usually surrounded and buoyed by *Macrocystis* sp. giant kelp fronds. While some pinnipeds, such as the walrus (*Odobenus rosmarus*) and Weddell seals, mate in water, most do so on solid land or ice, and all females need to come to solid substrates to give birth and to suckle their young. Indeed, a newborn pinniped (and polar bear) is not yet a marine mammal and would become overexposed rapidly and die if it were to be dunked into water. The natal pelt of most true or phocid seals is a downy fur, or lanugo, that holds insulating hair but is not waterproof; they have brown fat, a type of lipid that breaks down rapidly to generate heat; and they instinctively huddle near mother and each other to stay warm.

Pinnipeds have shortened and greatly changed fore and hind flippers, modified beautifully for swift and precise movement in water. However, they have had to compromise their morphology to keep a bit of it—so very necessary for procreation—available for life on land. It is now known that early cetaceans lived a similarly dual existence, with morphologic, physiologic, and likely behavioral compromises to survive in both realms. It is tempting to speculate whether pinnipeds, given another 20 million years of evolution, can make the same total transition to the sea.

Elephant Seals

Mirounga angustirostris and *M. leonina*

MARK A. HINDELL
University of Tasmania, Hobart, Australia

I. Diagnostic Characters

The northern elephant seal (*Mirounga angustirostris*) and the southern elephant seal (*Mirounga leonina*) are the largest pinnipeds. The most striking characteristic of both species is the pronounced SEXUAL DIMORPHISM, with males weighing 8–10 times more than females. Male southern elephant seals have been recorded to weigh 3700 kg, whereas females only weigh between 400 and 800 kg. This makes the elephant seal the most sexually dimorphic of any mammal (Fig. 1). There are other pronounced secondary sexual differences in morphology, all of which are related to the highly polygynous mating strategy of the species. Most notable of these is the large proboscis of the male that plays a key part in dominance displays with other males.

The evolutionary origins of the species are unclear, with estimates of the divergence from a common ancestor ranging from as little as 10,000 years ago to as far back as the Pleistocene. Morphological differences between the species are, however, quite distinct and they are readily differentiated. The southern species is larger, with northern elephant seals rarely reaching more than 2300 kg. In both species, adult females exhibit a considerable range in body weight and there are no clear differences between them in this feature. Adult males of the northern species have a longer proboscis than the southern species. Northern elephant seals also have a more developed chest shield, a region of the neck, chest, and shoulders of thickened and scared skin associated with fighting. In the northern species, this has a distinctive red coloration. Females lack the proboscis and chest

Figure 1 *Adult male (background), adult female, and newborn pup southern elephant seals. Adult males weigh 8–10 times as much as the females, making them the most sexually dimorphic of all mammals.*

shields, but northern females are distinguished by a noticeably narrower and flatter nose than in the southern species.

II. Distribution

Despite their physical similarities, the two species have very different geographic distributions, with at least 8000 km separating them. Southern elephant seals have a more extensive range, with breeding sites on islands scattered right around the sub-Antarctic (Fig. 2). Very occasionally, pups are even born on the Antarctic mainland. Studies have indicated that when not ashore during the breeding season or for their annual molt, southern elephant seals utilize most of the Southern Ocean ranging from waters north of the Antarctic Polar Front (sometimes called the Antarctic Convergence) to the high Antarctic pack ice. There is some separation of feeding areas between the sexes, with males tending to feed in the more southerly waters associated with the Antarctic continental shelf.

Northern elephant seals have a limited breeding distribution, pupping at approximately 15 colonies between Point Raines in northern California to the Baja California Peninsula in Mexico (Fig. 3). Most of the colonies occur on offshore islands, but a small number occur on the mainland coast. As with southern elephant seals, the northern species disperses widely during the nonbreeding phase of its annual cycle. Many individuals travel northward along the North American coast to feed in the Gulf of Alaska and the Aleutian Islands, which is a round trip of more than 10,000 km. This MIGRATION is even more remarkable as many individuals make it twice per year, returning to their southern breeding grounds to molt. The northern species also exhibits sexual differences in foraging areas, with males tending to use the more northerly areas and females heading in a more northwesterly direction and feeding in deep oceanic waters of the North Pacific Ocean.

III. Human Interactions

Today, both species of elephant seal are relatively free of adverse interactions with humans. Southern elephant seals are only rarely captured in the nets of Southern Ocean fishing fleets, and this has never been reported for the northern species. There are some grounds for concern that some large-scale fisheries may be competing with the seals for preferred prey species, but this is difficult to quantify given the current paucity of information on the diet of both species.

However, both species have a long history of direct exploitation by humans as they were hunted extensively during the 1800s for their blubber, which yielded an unusually high-quality oil. In the case of the northern elephant seal, this hunting was so intense that the populations were reduced to a small group breeding on a single island by 1890. The more widespread and southerly distribution of the southern species meant that the exploitation was less intensive. Nonetheless, the seals were reduced dramatically at all of their major breeding sites. The exploitation of southern elephant seals also continued longer than that of northern elephant seals, with commercial operations continuing until 1919 at Macquarie Island and until 1964 at South Georgia.

IV. Geographic Variation

As a direct consequence of the extensive hunting in the 19th century, northern elephant seals passed through an intense genetic bottleneck, which has seen almost all genetic variation removed from the population. The relatively recent expansion onto several islands has not yet resulted in discernible genetic variation between the breeding groups.

In contrast, southern elephant seals have quite a clear genetic structure, with four distinct stocks: the southern Pacific Ocean, the south Atlantic, the southern Indian Ocean, and a small, but increasing population of Peninsula Valdes in Argentina. The integrity of the subpopulations appears to be maintained by the extremely low interchange rates between populations. Although genetically distinct, animals from the subpopulations are indistinguishable from each other in external features.

V. Population Size and Trends

Northern elephant seals are presently undergoing a rapid population increase and range extension, whereas the southern species is currently experiencing a decline in two of its three major populations.

Population declines in the order of 50% have been recorded in both the southern Indian and the southern Pacific Ocean populations since the 1950s and 1960s, whereas the populations in the South Atlantic are stable, or increasing. The current estimated total population size for southern elephant seals is 640,000. The underlying cause of the declines are presently unclear, but are thought to be related to changes in the distribution and abundance of the seal's prey.

Conversely, northern elephant seal populations are currently increasing at a rate of approximately 6% per annum. This is the latest phase in one of the most remarkable population recoveries of any mammal. The total number of northern elephant seals in 1890 is thought to have been less than 100 individuals after 50 years of intensive and indiscriminate hunting by sealers. The last published estimates of the population put the total population at 127,000 in 1991.

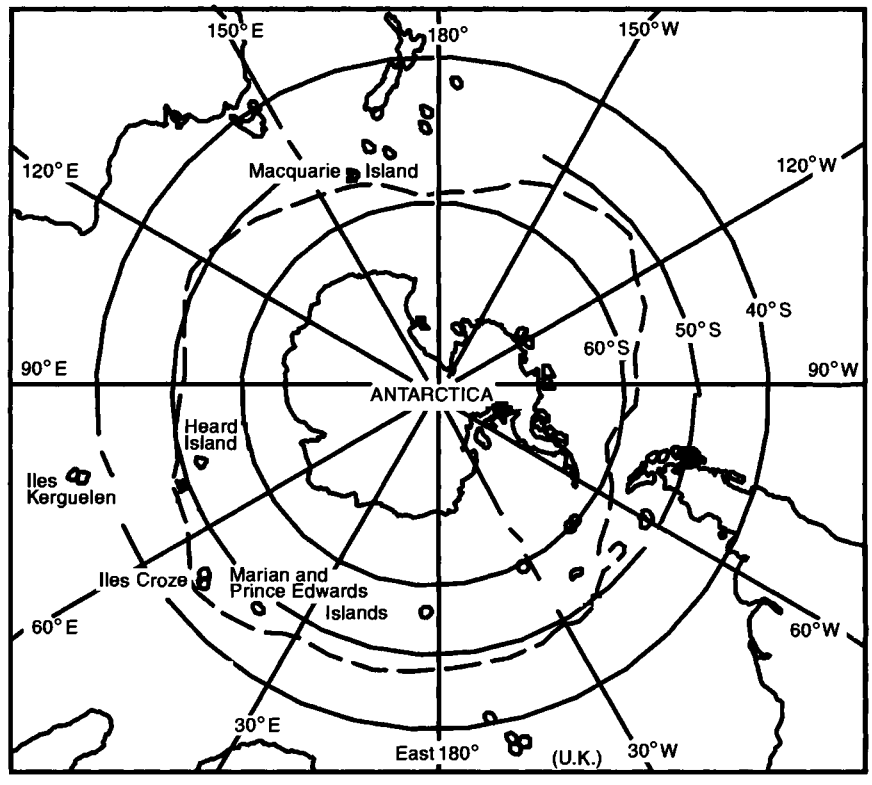

Figure 2 *Map of the Southern Ocean indicating the major southern elephant seal breeding islands.*

VI. Breeding

Both species of elephant seal are highly polygynous, with large, dominant males (alpha males) presiding over large aggregations of females, know as harems. Competition between males for the alpha position is intense and leads to spectacular fights (Fig. 4). Successful males will have almost exclusive access to harems consisting of up to 100 females, and so the reproductive benefits of success are very high. This has led to the evolution of the pronounced secondary sexual characteristics of immense body size and exaggerated proboscis.

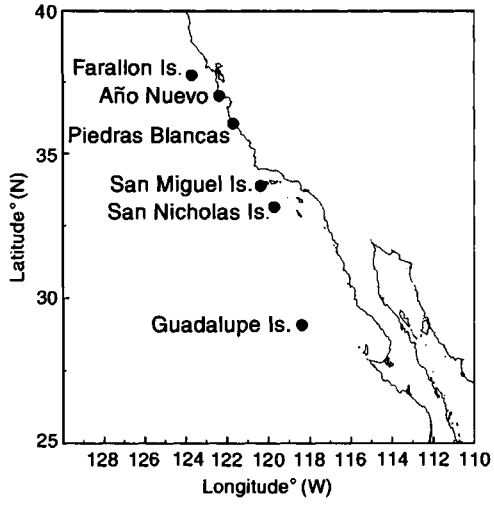

Figure 3 *Map of the West coast of North America indicating the major northern elephant seal breeding sites.*

The annual breeding cycle begins when the largest males haul out on deserted beaches (in August for *M. leonina* and in December for *M. angustirostris*). Pregnant females then haul out in large numbers, aggregating into harems, and giving birth to their single pup 2–5 days after arriving. The females stay with their pup throughout the ensuing lactation period, never feeding and relying on their thick BLUBBER layer to sustain them and to supply the many liters of milk required by the rapidly growing pup. At birth the pups weigh between 30 and 40 kg in both species, but by the time they wean, southern elephant seal pups weigh approximately 120–130 kg and northern elephant pups weigh approximately 140–150 kg. The difference in weaning weight is due to the slight difference in the duration of lactation in the two species, with southern elephant seals weaning at 23–25 days and northern elephant seals at 26–28 days.

Several days before weaning their pups, the females come into estrus and are mated by the dominant males. Although fertilization takes place at this time, the blastocyst does not implant until several months later. This ability, known as delayed implantation, is common to many pinnipeds. Once the pup is weaned, the females depart to sea, leaving the pups to fend for themselves. The pups spend the next 4 to 6 weeks teaching themselves to swim and hunt, during which time they rely

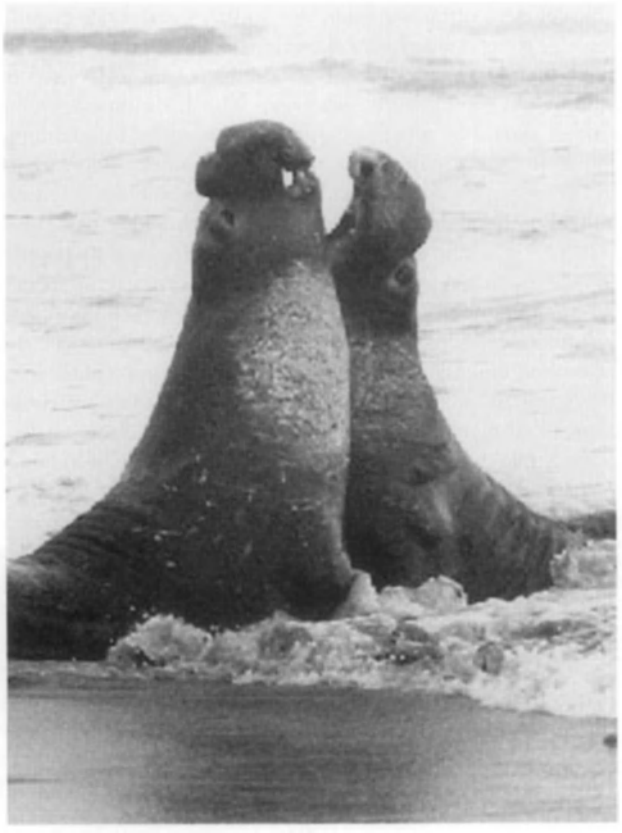

Figure 4 *Two adult male northern elephant seals fighting during the breeding season. Note the enlarged proboscis and predominant chest shields.*

heavily on the large reserves of blubber that they got from their mothers while suckling. When the pups eventually leave their natal beaches they spend the next 6 months at sea. This is a difficult time for the pups and as many as 30% of them die at this time.

VII. Molt

Monachine seals all have an unusual annual molt, which entails the shedding of epidermal tissue in addition to the hair. The rich supplies of blood required at the body surface for the new skin and hair require the animals to leave the water in order to conserve body heat. The seals therefore spend 3–5 weeks fasting ashore during this time, once again relying on stored blubber to supply their energy requirements.

VIII. Behavior at Sea

Elephant seals spend more than 80% of their annual cycle at sea, feeding intensively to build up the blubber stores required to support them during breeding and molting haul outs. The seals prey on deep-water squid and fish and, as a result, have developed the remarkable ability to dive to depths in excess of 1500 m and for as long as 120 min. While these values are the extremes of those recorded, even the average values are impressive. Adult females routinely make dives of 20 min and reach depths of 400–800 m. Paradoxically, although the males generally dive for longer, about 30 min, they often do not go as deep. This is a reflection of their tendency to feed over continental shelves, whereas females use deeper open water. Seals spend as much as 90% of the time submerged, the majority of it hunting for food, but other behaviors, such as traveling from place to place, and apparently even resting, take place at depths of more than 200 m.

Endangered Species and Populations

JOHN E. REYNOLDS III
U.S. Marine Mammal Commission, Bethesda, Maryland

DOUGLAS P. DEMASTER
National Marine Fisheries Service, Seattle, Washington

GREGORY K. SILBER
National Marine Fisheries Service, Silver Spring, Maryland

schricht and Reinhardt (1861) and Scammon (1874) warned well over a century ago that certain species or populations of marine mammals had reached dangerously low levels and that survival of these groups was in peril. Since that time, formal and informal efforts have been made to prevent extinction of marine mammals perceived to be in jeopardy. Some of the efforts have been undertaken by a single nation—witness the Marine Mammal Protection Act (MMPA) of 1973, which protects *all* marine mammals in United States waters. Other efforts, such as the administration of the Convention on International Trade in Endangered species of Wild Fauna and Flora (CITES), have been intended to apply on a global scale. As different groups have attempted to develop

lists of species and populations with pressing conservation needs, at least four criteria are frequently considered: (a) population size and demography, (b) the extent to which human activities adversely affect the species/population either directly or indirectly, (c) the adequacy and protection of habitat deemed necessary for the survival of the group in question, and (d) the extent of markets and trade for products from the population/species to be conserved. Management agencies, in concert with scientists, have begun developing quantitative criteria that will reduce the subjectivity involved in categorizing species as endangered under the U.S. Endangered Species Act (U.S. ESA) (e.g., IUCN, 1996; Gerber and DeMaster, 1999).

This article focuses on groups of marine mammals that seem to truly require protection in order to survive well into the 21st century and beyond. We provide definitions of criteria under which such groups are classified by some of the more powerful and inclusive legislation, conventions, or other approaches, such as CITES, the MMPA, the U.S. ESA, and the International Union for the Conservation of Nature and Natural Resources' (IUCN; now called the World Conservation Union) "Red List of Threatened Animals" (IUCN, 1996). We describe reasons why some marine mammals are in critical condition today, and we look for lessons and trends that may suggest why some groups recover and others do not. We do not assume, however, that all endangered groups of organisms may be able to recover; in some cases, humans have usurped or modified so much important habitat that a group may always be at risk, regardless of what is done in the future. Finally, we suggest approaches that may be fruitful in the fight to preserve species in the future.

This article deliberately uses the word "group" quite often. Although national legislation such as the U.S. ESA would, by its very name, appear to approach conservation at the species level, the actual intent of the U.S. Congress in passing the legislation was that management be carried out at the stock or population level by local or regional resource managers. Management at the species level can lead to loss of biological diversity if local populations are exterminated, even though the species as a whole appears healthy. The importance of management at the stock or population level becomes clear when one considers the status of the Steller sea lion (*Eumetopias jubatus*). In 1990, the species was designated as threatened under the U.S. ESA. By the late 1990s, however, scientists had demonstrated that (a) there were two discrete stocks of the Steller sea lion; (b) the eastern stock was smaller than the stock occupying the western part of the species range but was stable or even possibly increasing in numbers; and (c) the western stock was in precipitous decline, with counts at some sites dropping by 90% or more since the late 1970s. Accordingly, in 1997 the listing under the U.S. ESA was modified so that the western stock was reclassified as endangered, whereas the eastern stock remained listed as threatened (U.S. Marine Mammal Commission, 1999).

The Steller sea lion example illustrates or reinforces some important points. First, good science is essential for effective management. Second, with endangered marine mammals (and other organisms as well), we need to work to better define what "distinct population segments" (or "distinct vertebrate populations," e.g., as defined later according to the U.S. ESA) are, so that management and conservation efforts can be focused on the most critical groups and areas. Third, the management process should be adaptive and flexible in order to accommodate new data. Finally, even though many stocks, populations, and even species may be accorded special protection, a few are truly in desperate need of assistance. Unfortunately, due either to lack of scientific information that identifies separate populations or to other reasons, management still occurs at the species level in some cases. Worse, the general public may have serious misconceptions about modern management practices and have often equated the precarious status of a population (e.g., the North Atlantic right whale, *Eubalaena glacialis*) with the status of all species in a taxonomic group (e.g., baleen whales).

Only one marine mammal species has definitely become extinct since Eschricht and Reinhardt (1861) warned of the possible demise of the bowhead whale in the middle of the 19th century: the Caribbean monk seal, *Monachus tropicalis*. Steller's sea cow (*Hydrodamalis gigas*) had already been driven to extinction by the end of the 18th century, and the Japanese sea lion (*Zalophus japonicus*) has probably gone extinct sometime in the last 50 years (Rice, 1998). However, populations of some other species have also become extinct (e.g., the North Atlantic gray whale, *Eshrictius robustus*), and other stocks and even whole species may not survive long into the 21st century. We must change how we value and manage marine mammals if we intend for them to remain a functioning part of the marine ecosystem.

I. Listings of Specially Protected Marine Mammals

Although globally and regionally there are a number of lists of specially protected species, we provide three widely accepted lists of protected marine mammals. Table I lists endangered and threatened (from the U.S. ESA) and depleted (from the U.S. MMPA) species and stocks. Table II lists marine mammals found in Appendix I and Appendix II of CITES. Table III lists those marine mammals categorized by the IUCN as critically endangered (CR), endangered (EN), and vulnerable (V). We did not herein reproduce the IUCN "Red List of Threatened Animals" for all marine mammal species because of spatial constraints.

Because predicting extinction probabilities is fraught with uncertainty, objectively classifying stocks and populations according to their precise level of vulnerability is very difficult. Although all of the criteria used to classify species at risk are credible, we prefer the use of criteria similar to those reported in the IUCN "Red List of Threatened Animals."

It should be noted that of the 128 extant species of marine mammals, only 3 are presently listed by the IUCN as CR [i.e., Mediterranean monk seal (*Monachus monachus*), vaquita (*Phocoena sinus*), and baiji (*Lipotes vexillifer*)]. However, it should further be noted that 8 species are listed as EN and 16 species as VU, while a classification of lower risk has been assigned to 14 species of marine mammals. Finally, status of 38 species of marine mammals has been determined to have insufficient data for classification.

TABLE I
Marine Mammal Species and Populations Listed as Endangered (E) or Threatened (T) under the U.S. Endangered Species Act and Depleted (D) under the Marine Mammal Protection Act[a]

Common name	*Scientific name*	*Status*	*Range*
Manatees and dugongs			
West Indian manatee	*Trichechus manatus*	E/D	Caribbean Sea and North Atlantic from southeastern United States to Brazil; and Great Antilles Islands
Amazonian manatee	*Trichechus inunguis*	E/D	Amazon River basin of South America
West African manatee	*T. senegalensis*	T/D	West Africa coasts and rivers; Senegal to Angola
Dugong	*Dugong dugon*	E/D	Northern Indian Ocean from Madagascar to Indonesia; Philippines; Australia; southern China; Palau
Otters			
Marine otter	*Lutra felina*	E/D	Western South America; Peru to southern Chile
Southern sea otter	*Enhydra lutris nereis*	T/D	Central California coast
Seals and sea lions			
Hawaiian monk seal	*Monachus schauinslandi*	E/D	Hawaiian Archipelago
Caribbean monk seal	*M. tropicalis*	E/D	Caribbean Sea and Bahamas (probably extinct)
Mediterranean monk seal	*M. monachus*	E/D	Mediterranean Sea; northwest African coast
Guadalupe fur seal	*Arctocephalus townsendi*	T/D	Baja California, Mexico, to southern California
Northern fur seal	*Callorhinus ursinus*	D	North Pacific Rim from California to Japan
Western North Pacific Steller sea lion	*Eumetopias jubatus*	E/D	North Pacific Rim from Japan to Prince William Sound, Alaska (east of 144°W longitude)
Eastern North Pacific Steller sea lion	*E. jubatus*	T/D	North Pacific Rim from Prince William Sound, Alaska, to California (east of 144°W longitude)
Saimaa seal	*Phoca hispida saimensis* (= *Pusa hispida saimensis*)	E/D	Lake Saimaa, Finland
Whales, porpoises, and dolphins			
Baiji	*Lipotes vexillifer*	E/D	Changjiang (Yangtze) River, China
Indus river dolphin	*Platanista minor* (= *P. gangetica minor*)	E/D	Indus River and tributaries, Pakistan
Vaquita	*Phocoena sinus*	E/D	Northern Gulf of California, Mexico
Northern offshore spotted dolphin	*Stenella attenuata*	D	Eastern tropical Pacific Ocean
Eastern spinner dolphin	*S. longirostris orientalis*	D	Eastern tropical Pacific Ocean
Mid-Atlantic coastal bottlenose dolphin	*Tursiops truncatus*	D	Atlantic coastal waters, New York to Florida
Northern right whale	*Eubalaena glacialis* (includes *E. japonica*)	E/D	North Atlantic, North Pacific Oceans; Bering Sea
Southern right whale	*E. australis*	E/D	South Atlantic, South Pacific, Indian, and Southern Oceans
Bowhead whale	*Balaena mysticetus*	E/D	Arctic Ocean and adjacent seas
Humpback whale	*Megaptera novaeangliae*	E/D	Oceanic, all oceans
Blue whale	*Balaenoptera musculus*	E/D	Oceanic, all oceans
Finback or fin whale	*B. physalus*	E/D	Oceanic, all oceans
Western North Pacific gray whale	*Eschrichtius robustus*	E/D	Western North Pacific Ocean
Sei whale	*Balaenoptera borealis*	E/D	Oceanic, all oceans
Sperm whale	*Physeter macrocephalus*	E/D	Oceanic, all oceans

[a]As of December 31, 1999 (from Marine Mammal Commission, 1999). Equivalent species names used by Rice (1998) appear in parentheses.

Not all species in need of protection require that protection equally (see also Clapham *et al.*, 1999). The western North Atlantic stock of the humpback whale (*Megaptera novaeangliae*), which numbers more than 10,000 individuals, scarcely merits the same level of protection as do vaquita (perhaps 500–600 individuals left), northern right whale [probably fewer than 300 individuals in the North Atlantic, and probably low 100s of animals in the North Pacific (now recognized as a separate species, *E. japonica*)], Mediterranean monk seal (around 300 left in the wake of an epizootic in 1997, which killed over half of the members of the largest colony in northwest Africa), and baiji (a few tens of animals in isolated stretches of the Yangtze River).

TABLE II
Marine Mammals Listed under Appendices I and II of CITES[a]

Order	*Species*	*Common name*	*Appendix*
Cetacea	*Balaena mysticetus*	Bowhead	I
	Balaenoptera acutorostrata (includes *B. bonaerensis*)	Minke whale	I
	B. borealis	Sei whale	I
	B. edeni	Bryde's whale	I
	B. musculus	Blue whale	I
	B. physalus	Fin whale	I
	Berardius spp.	Beaked whales	I
	Caperea marginata	Pygmy right whale	I
	Eschrichtius robustus	Gray whale	I
	Eubalaena spp.	Right whales	I
	Hyperoodon spp.	Bottle-nosed whales	I
	Lipotes vexillifer	Chinese river dolphin; white flag dolphin	I
	Megaptera novaeangliae	Humpback whale	I
	Monodon monoceros	Narwhal	II
	Neophocaena phocaenoides	Finless porpoise	I
	Phocoena sinus	Vaquita; Gulf of California harbor porpoise	I
	Physeter catodon (= *P. macrocephalus*)	Sperm whale	I
	Pontoporia blainvillei	La Plata River dolphin	II
	Sotalia spp. (= *S. fluviatilis*)	Humpbacked dolphins	I
	Sousa spp.	Humpbacked dolphins	I
Carnivora			
	Arctocephalus australis	Southern fur seal	II
	A. galapagoensis	Galapagos fur seal	II
	A. philippii	Juan Fernandez fur seal	II
	A. townsendi	Guadalupe fur seal	I
	Enhydra lutris nereis	Southern sea otter	I
	Mirounga leonina	Southern elephant seal	II
	Monachus spp.	Monk seals	I
	Ursus maritimus	Polar bear	II
Sirenia			
	Dugong dugon (except in Australia)	Dugong	I
	D. dugon (Australia)	Dugong	II
	Trichechus inunguis	Amazonian manatee	I
	T. manatus	West Indian manatee	I
	T. senegalensis	West African manatee	II

[a]From Federal Register (1999). Equivalent species names used by Rice (1998) appear in parentheses.

We suggest the following as some of the truly critical species and populations, those for which immediate, effective conservation efforts are needed if they are to survive much longer.

Pinnipeds: Mediterranean monk seal; Saimaa (ringed) seal (*Pusa hispida saimensis*)

Cetaceans: Baiji; Indus river dolphin (*Platanista gangetica minor*); vaquita; North Pacific right whale; North Atlantic right whale; several populations of blue whales (*Balaenoptera musculus*); western North Pacific gray whale; Cook Inlet and St. Lawrence River populations of beluga whales (*Delphinapterus leucas*); bowhead whale (*Balaena mysticetus*) populations in the eastern Arctic

Sirenians: Several populations of dugongs (*Dugong dugon*); several populations of West African and West Indian manatees (*Trichechus senegalensis* and *T. manatus*, respectively)

II. Why Do Marine Mammal Populations Become Endangered?

Relative to any species of plants and animals, marine mammals are susceptible to catastrophic reductions in their numbers for a variety of reasons. One of the reasons for this susceptibility relates to the biology of marine mammals: life history attributes that make them extremely vulnerable to overharvest. In addition, many populations of marine mammals are susceptible to extirpation because the value of marine mammal prod-

	T. senegalensis	West African manatee	V

*Where more than one classification category is given for a particular species, it means that different populations or stocks of that species are threatened at different levels of severity. Similarly, a particular classification does not necessarily mean that a species is threatened rangewide at that level; the classification may reflect the status of only one population or stock. Equivalent species names listed by Rice (1998) appear in parentheses.

ucts has caused them to be hunted for centuries; they are killed or injured incidentally in a number of fisheries and during other human activities (e.g., boat strikes often kill or seriously injure North Atlantic right whales and West Indian manatees); and human activities such as chemical and acoustic pollution and competition for resources have led to dramatic changes in habitat. The combination of a limited ability to recover from overharvesting and various human impacts has led to the precarious status of several species and many stocks.

A. Life History

Life history attributes are biological characteristics of a species that evolved to maximize the fitness of individual male and female members of the species. Life history attributes include such characteristics as the age at sexual maturity, age-specific survivorship, sex- and age-specific rates of growth, reproductive interval, reproduction rate, and longevity. Stated otherwise, life history attributes dictate the potential for population growth. Biologists coarsely contrast two life history strategies among organisms: the so-called *r* strategists and the *K* strategists (see discussions in Pianka, 1970; Reynolds *et al.*, 2000).

The r strategists tend to be small in size, to reach sexual maturity quickly and produce large numbers of offspring (the letter "*r*" denotes intrinsic rate of increase—a feature maximized by *r* strategists), to colonize new areas well, to have short life spans, to have populations that fluctuate a great deal over time, and to have extremely high levels of infant mortality, due in part to low levels of parental care. The *K* strategists (which maintain their populations at or around the carrying capacity of the local environment, i.e., at *K*) have the opposite suite of attributes: delayed sexual maturity, long life span, low reproductive rate, large body size, lots of parental care and social behavior, good survival of infants, and poor colonizing ability.

Most species of plants and animals lie somewhere along the continuum between the purely *r*-selected and the purely *K*-selected species, but the life history attributes of marine mammals, as a group, place them *extremely* close to the end of the spectrum—on the *K*-selected side. Consider the highly endangered North Atlantic right whale, for which longevity is several decades (and may approach or even exceed a century as it does in the related bowhead whale), reproduction is very slow (with an average interval between calves of 3–6 years, tending more toward 6 years in the 1990s), and habitat needs are very specific. When right whale populations were reduced to numbers in the tens or low hundreds by overhunting, it became biologically impossible for right whale numbers to rebound quickly. In addition, when the size of the right whale population became very low, the more *r*-selected species' populations could respond by increasing in number relatively rapidly, causing the level of competition for resources to be higher than what would be predicted for an extremely depleted population of right whales. At the same time, humans are degrading the quality of right whale habitat by introducing boats, fishing gear, pollutants, and noise into areas critical to successful foraging and calving. In *K*-selected species, which generally adapt poorly to changing conditions, effects of humans on the environment may severely compromise recovery.

Thus, based on biology alone, right whale populations are not adapted to rapid recovery from overharvest, but biology is not the only reason. A variety of human-related factors (discussed later) also complicate their recovery. We simply note that for marine mammals, their life history strategies provide points of vulnerability.

B. Human Activities and Their Effects

Historically, humans around the world have taken marine mammals for subsistence and for their commercial value. Scammon (1874) was among the first whalers to point out that hunting had caused extreme depletion of a number of marine mammal species, including the gray whale, the bowhead, and the Guadalupe fur seal (*Arctocephalus townsendi*). Many species of marine mammals have been hunted to the extent that their numbers have been reduced—in some cases dramatically. One should not assume that overharvesting only became a serious problem after the advent of relatively modern hunting methods; in fact, elimination of the right whales in the Bay of Biscay by Basque hunters in the 1600s and Steller's sea cow by Russian fur traders a century later indicates that the problem of significant overharvest is nothing new.

The general public tends to perceive commercial whaling as (a) a thing of the past and (b) an activity that focused on the "great whales." Although commercial harvest of marine mammals reached its zenith (or its nadir, depending on one's perspective) some time ago, in fact, commercial harvest of even the great whales continues today [e.g., by Norway in the North Atlantic for minke whales (*Balaenoptera acutorostrata*)] and the harvest of small cetaceans continues to endanger certain species. Another relatively new perspective has been provided by the Russians, who have made available modern whalers' log books that have shown that records of species-specific landings are not always reliable (Danilov-Danil'yan and Yablokov, 1995). It would not be surprising if other whaling nations also misreported some of their harvest data. Thus, at least some species or populations thought to have been protected for decades in the past were actually protected only on paper.

An additional revelation was that some of the whale meat in Tokyo markets in the 1990s was found to be from protected species, such as the humpback whale, *Megaptera novaeangliae* (Baker and Palumbi, 1994). To some people, this suggests recent, illegal takes, although the Japanese government has responded that the meat has been stored, frozen, for decades. Note, also, that meat from whales taken incidentally during gill-net fishing, for example, could be marketed quite legally under INTERNATIONAL WHALING COMMISSION guidelines.

Habitat alteration by humans may exacerbate problems for marine mammals. In two cases involving endangered marine mammals [the western stock of the Steller sea lion (*Eumetopias jubatus*) and the Hawaiian monk seal (*Monachus schauinslandi*) population around French Frigate Shoals], the harvest by humans of these two marine mammals' preferred prey has been suggested as at least one potential cause of population decline.

Humans modify the coastal and marine environments in subtle and diverse ways, making it difficult to tease apart the various possible impacts to marine mammals. In some cases, those impacts can cause sudden, steep reductions in apparently

healthy populations to the point where they warrant special protection. One especially telling case involves the die-off of common bottlenose dolphins (*Tursiops truncatus*) along the southeastern coast of the United States in 1987–1988. At least 740 animals died, causing the National Marine Fisheries Service to list that "stock" (quotation marks are used because the stock structure of dolphins in that area is still very uncertain) as depleted under the MMPA. Cause of death was first suggested to be ingestion of brevetoxin; later, scientists suggested that high contaminant loads were involved; and later still, other scientists noted the presence of morbillivirus in preserved tissues of dolphins from the die-off. As noted by Reynolds *et al.* (2000), the precise interplay among the natural toxins, anthropogenic toxicants, viral infections, immune dysfunction, opportunistic infections, and death is still unclear.

The dolphin die-off illustrates that human activities may compromise the health and well-being of *both* individuals and populations by making large numbers of animals susceptible to natural pathogens that might not be harmful to robust individuals. In a relatively large population such as coastal bottlenose dolphins, the problem is serious. For species like the Mediterranean monk seal, which suffered a disastrous die-off in 1997 due to as yet undetermined causes (perhaps either saxitoxin poisoning or morbillivirus, or some combination of these or other causes), the problem becomes extremely critical when an already low population size is further reduced over a matter of weeks.

It is relatively easy to count how many animals are killed by hunters or through incidental take. However, it becomes exceedingly difficult, due to both the variety and magnitude of effects and to potential synergisms, to understand the extent to which chemical and noise pollution, harvest of marine mammal prey by humans, and other effects on local environments may compromise, or at least retard, the recovery of depleted populations of marine mammals.

A final point worth making is that, thus far, we have addressed only local or regional effects of humans on habitats. The adverse effects of global climate change (if they are as profound as some believe and predict), superimposed on all the smaller scale changes induced by our species, paint a bleak picture for *K*-selected marine mammals.

III. Recovery and Nonrecovery of Species and Stocks: Lessons and Trends

Scientists and managers do not yet know why some depleted marine mammal populations increase in abundance, whereas others continue to decline or remain static. Perhaps most notable among those groups to have recovered relatively quickly (or at least to have shown recent increases in population size) are the eastern North Pacific stock of gray whale; the western Arctic bowhead whale; the southern right whale (*Eubalaena australis*); most populations of humpback whales; and some pinniped populations in parts of their range, including southern fur seals (*Arctocephalus* spp.), harbor seals (*Phoca vitulina*), and California sea lions (*Zalophus californianus*). In contrast, northern right whale populations, eastern Arctic populations of the bowhead whale, and Hawaiian and Mediterranean monk seals have either continued to decline or failed to increase in abundance in recent years. Some marine mammal species, such as the sea otter (*Enhydra lutris*) and harbor seal, are declining or are stable in parts of their range while increasing in others. As described earlier, the reasons for different patterns of recovery, where known, probably involve a mix of biological attributes (e.g., life history attributes), naturally caused environmental change, and human-related factors; however, the precise interplay of factors that permits or enhances recovery in certain instances (or prevents it in others) remains unclear.

There are a number of examples of divergent recovery trajectories in (a) closely related species, (b) sympatric and ecologically similar but distantly related species, and (c) populations of the same species occurring in different regions. Examples of these divergent recovery patterns are discussed.

As noted, the eastern North Pacific and western North Atlantic right whale populations are at very low levels, possibly numbering fewer than 500 individuals for the two areas combined. The status of the eastern Arctic bowhead whale (a species closely related to right whales) population is also of considerable concern. In contrast, right whale populations in the Southern Hemisphere have increased at rates estimated at 7–8% per year for a number of years. Southern right whale populations off Australia and New Zealand, South Africa, and South America combined now number at least 7500 individuals. Similarly, the western Arctic bowhead whale population has increased steadily at about 3–4% for at least the past decade, despite removals of 44 to 66 animals per year by Alaskan Native aboriginal hunters, and was estimated to number 8000 individuals in 1993.

Each of the just-mentioned right and bowhead whale populations was reduced to very low numbers by commercial whaling in the 19th and early to mid-20th centuries. However, responses to the cessation (at least on paper) of this human activity have been very different. Inasmuch as these are populations of closely related species, it is likely, although certainly not assured, that they are ecological counterparts (in different habitats) and have generally similar life history patterns. Therefore, major differences in life history patterns or large-scale environmental failure are not likely to be the culprits causing the differences in abundance and population growth. Instead, the differences are most likely related to serious injury and mortality and possibly habitat degradation from human activities. In the North Atlantic right whale population, 46 deaths known to have been caused by collisions with ships or ENTANGLEMENT in fishing gear have occurred since the 1970s (the actual number is almost certainly higher because not all carcasses are reported). Because this population was reduced to low levels by whaling and the species is a consummate *K* strategist, it cannot therefore sustain removals by human activities. Other factors may help explain why certain populations have failed to recover and other populations of marine mammals seem to be recovering. Some of these factors are described.

Before we proceed, however, we note our tendency here to use qualitative terms such as "low" and "very low." Such qualitative terms suggest that a population or species may have approached or reached some level that seriously jeopardizes its long-term survival. However, a population reduced to a few tens of individuals has a substantially lower probability of survival

than one in which a few hundred or a thousand individuals survive; for both groups, one could well use descriptive terms such as "very low." Especially in the case of strongly *K*-selected species (such as right whales), survival seems bleak if only tens of animals exist and human-related pressures continue.

Sympatric marine mammal populations of distantly related species can also show divergent population growth rates. The western stock of the Steller sea lion has declined at alarming rates in the past several decades, whereas northern fur seal (*Callorhinus ursinus*) counts in the same region have remained stable for a number of years, albeit at a much lower level than in the past. The causes of the Steller sea lion decline have come under extensive scrutiny—the reasons are not yet completely clear but may in part be related to local competition with a very large commercial fishery in the area. Differences in the lack of growth in the western Steller sea lion stock and those of some sympatric pinniped populations may also be related to ecological shifts (e.g., prey availability) that affect some marine mammals far more than others. In the case of the northern fur seal, the stable but lower than historical population suggests a lower carrying capacity for the species.

In another case, the humpback whale, which occurs sympatrically with right whales in the North Atlantic, is on a positive recovery course (possibly as high as 6–9% per year) relative to the recovery course of the right whales. Although right and humpback whales do not have exactly the same habitat needs and feed at different trophic levels, the recovery of humpback whales suggests an absence of an ecosystem collapse of the North Atlantic marine habitat (as a factor that could impact right whale fecundity) and points further to human impact on the right whale population. Right whales generally occur closer to shore than humpback whales, perhaps exposing the former to greater human impact.

The gray whale provides an interesting example of recovery in one population and a concurrent lack of recovery in a geographically distant population of the same species. The eastern North Pacific gray whale population has grown steadily since the 1970s to levels only slightly less than the lower limit of estimated abundance prior to the initiation of commercial whaling. As a result, this population was removed in 1994 from the list of endangered and threatened wildlife—one of only a handful (but growing number) of endangered species, and the only marine mammal population, to be removed from the list. In contrast, the western North Pacific population of gray whale is very low and remains listed as endangered. Here again, such discrepancies in population growth rates are difficult to interpret. Both populations of gray whales migrate very close to shore and to human population centers along coasts. Presumably, both populations are very similar ecologically and in their life history patterns. The western North Pacific population may be exposed to some heretofore unidentified human activity that adversely affects its growth (such as entanglement in fishing gear, ship strikes, directed and illegal hunting, or pollution or other forms of habitat degradation) or other undetermined selection pressures. Situations analogous to the gray whale scenario exist for other species as well, e.g., sea otters and harbor seals.

A cursory review of the examples just provided suggests that knowledge of the interplay of factors that promote or retard recovery is incomplete. However, where causes of nonrecovery are known, it appears that a common theme involves the adverse effects of human activities.

IV. Improving the Recovery of Species and Stocks

This section makes three key points: (1) it is very unlikely that conservation measures needed to halt the decline of listed species or populations will be effective without understanding the life history of the listed taxon, (2) more information is needed about the effects of human activities on marine mammals, and (3) it is not possible (or at least it becomes dauntingly difficult) to evaluate the effectiveness of recovery efforts or to prioritize the extremely limited funding available for listed species without the establishment of objective criteria for managing and classifying populations under the Endangered Species Act (or other appropriate conventions or legislation).

A. Need for Information on Life Histories of Listed Species

Earlier in this chapter we described listed populations that are still declining (e.g., the western population of Steller sea lion) and listed populations that have remained at very low population levels without showing any signs of recovery (e.g., North Atlantic right whale, vaquita, baiji, the western population of North Pacific gray whale, and both extant species of monk seal). As noted, reasons for the lack of recovery are varied. Therefore, in promoting the recovery of these populations, scientists need, whenever possible, to collect the necessary information on age-specific rates of birth and survival. That is, it is necessary to determine whether recovery is hindered by inadequate reproduction, which could be due to nutritional stress (which, for example, could be caused by COMPETITION WITH COMMERCIAL FISHERIES) or contamination (which, for example, could be related to high levels of pollutants such as organochlorines). Similarly, it is necessary to determine whether there is adequate recruitment into the adult population or high enough levels of adult survival to sustain recovery. For some populations, both reproduction and survival will be found to be inadequate to support a recovery. However, once reliable information on life history parameters is available, it is possible for researchers or managers to step in, implement informed and deliberate strategies, and try to rectify the situation.

For example, levels of recruitment and adult survival in the North Atlantic population of right whale were found to be low because of human-related injury and mortality. In a cooperative effort, the National Oceanic and Atmospheric Administration, U.S. Coast Guard, U.S. Marine Mammal Commission, the International Fund for Animal Welfare, and other agencies and organizations involved in right whale recovery activities worked through the International Maritime Organization to design and implement a system whereby officers of large vessels are required to notify a shore-based station when entering right whale habitat. In return, a message is passed to the ship describing right whale vulnerability to ship strikes and locations of recent whale sightings. This approach seems to be an obvious first step toward a solution.

Similarly, juvenile mortality in Hawaiian monk seals at three of their six breeding colonies has been found to be sufficiently high so as to preclude recovery. Further, it was found that part of this mortality was due to known aggressive male monk seals mobbing and killing adult females and/or pups. In response to this behavior, researchers removed many (but not all) of the adult male monk seals in one area where mobbing was most severe. The result was an immediate and almost total elimination of additional deaths caused by mobbing in that area.

A third example involves the southern sea otter (*E. lutris nereis*). In the late 1970s and early 1980s this population was reported to be in decline. Based on data from observer programs operating in several commercial fisheries along the central California coast, it was determined that the level of incidental mortality of otters in the set gill-net fishery for halibut was not sustainable. Soon after this finding was reported, the state of California passed legislation that moved this fishery offshore, where otter entanglement was thought to be unlikely. Following this management action, the population started to recover.

In summary, it is possible in some cases to take actions that promote the recovery of listed populations. However, without knowledge as to what life history parameters are abnormal, as well as knowledge about the underlying cause of the problem, it is often impossible to know what CONSERVATION measures are appropriate. Unfortunately, the research necessary to determine rates of reproduction and survival in wild populations is both expensive and difficult. In addition, it often take several years of collecting such data to get estimates precise enough to allow scientists to evaluate different hypotheses about why the population is not recovering. Nonetheless, without such information, recovery efforts are severely hampered.

We should also point out that it is not always possible to determine what exactly is causing a listed population to decline (e.g., Steller sea lion) or preventing its recovery (e.g., northern fur seal). Scientists and conservationists can know a tremendous amount about the life history of an affected group, but this knowledge does not always help to direct management efforts. In such cases, the management agencies are required (although they may fall short) to manage in a way that "errs on the side of the animal." This means that managers are required to be cautious in authorizing human activities that are likely to adversely affect a listed species or the habitat upon which it depends. Finally, it should be noted that some populations listed under the U.S. ESA are recovering with little or no assistance from humans. This is typically the situation when a population was overharvested (e.g., many of the large whale populations), subsequently depleted, and then managed in such a way that additional harvest-related mortality was either eliminated or greatly reduced. When the affected population was not too severely reduced, when human-related mortality and serious injury remain low, and when the habitat is still healthy, recovery can occur. This has been observed for populations of gray, right, humpback, and blue whales in many of the world's oceans.

B. Need for Objective Classification Criteria

The U.S. ESA, as amended, requires the various management agencies to develop criteria for determining when a population has recovered to such an extent that it can be removed from the list of endangered and threatened wildlife. Unfortunately, this has not been done for any listed marine mammals. However, efforts are underway by several agencies (U.S. Fish and Wildlife Service, National Marine Fisheries Service, IUCN) to develop objective criteria that can be used to classify the degree to which a particular population is at risk of extinction. Such a task is not easy, in part because the information typically needed in population viability analysis is not available for most populations of marine mammals. For example, many of the available software packages that are used to estimate the likelihood of extinction require estimates of carrying capacity, home range size, and the degree to which environmental catastrophes affect a population. For marine mammals, these data are rarely available. Rather, the only data that can be reliably determined for most marine mammal populations include population size, trends in abundance, human-related removal levels, gross production, and stock structure. Therefore, it is critical that classification criteria be developed that utilize only this suite of information.

Gerber and DeMaster (1999) reported on a generic approach that could be applicable to large whales. In a separate paper (Gerber *et al.*, 1999), this approach was applied to a data set from the already delisted eastern North Pacific gray whale population. The results indicated that with about 10 years of data, collected at a cost of just over $650,000, a minimum data set could be developed that would be adequate for classifying this population under the U.S. ESA. The authors went on to argue that such an expenditure was well worth the cost because (1) U.S. ESA listings should mean something (i.e., when a population has truly recovered it should be delisted), and (2) the cost to society in terms of regulations and management for populations listed under the U.S. ESA can be expensive, especially for marine species. Therefore, where appropriate it is in society's interest to delist populations as soon as possible.

Other classification schemes have been proposed in the past by Mace and Lande (1991) and Mace *et al.* (1992) and more recently by the IUCN (1996). These approaches have considerable merit in that they use a series of "triggers" to classify the degree to which a population is threatened with extinction; any one of these "triggers" can lead to a more conservative classification. These criteria are also based on information that is possible to collect.

The management agencies need to move forward aggressively to adapt methods like those discussed earlier in classifying stocks under the U.S. ESA. It is hoped that by 2010, management agencies will have developed objective criteria that can be used to evaluate whether progress has been made in recovering each listed population and whether each population is still in need of the special protection afforded it under the U.S. ESA. It is worth noting that in its fourth iteration, the revised Florida manatee recovery plan (which is being developed but is incomplete as we write) is likely to include objective, measurable criteria for downlisting.

In the past, reclassification, or at least delisting, has met with considerable resistance from the environmental community. This can be unfortunate. It implies that the members of the environmental community do not trust the management agencies to properly evaluate the extent to which a particular

population is threatened with extinction; it may also suggest some distrust in the ability of managers to effectively address problems unless populations or species are listed as endangered or threatened. Resistance to delisting may also mean that the agencies are not doing enough to inform the general public about what it means to be listed under the U.S. ESA (e.g., what degree of threat is tolerable before a species or stock is listed). Finally, if objective criteria for classifying listed groups do not exist, then it is likely that important decisions will be made more often by engaging in emotional debate than by relying on scientific data. This situation needs to be addressed by Congress, which has passed excellent laws concerning protected species but which, unfortunately, has not always appropriated sufficient funds for the responsible agencies to carry out these laws. To some extent, this situation is the fault of the agencies for not being more aggressive and responsive in recognizing the value of developing objective classification criteria. Once objective criteria are developed for at least some of the listed populations and are used either to prioritize extremely limited funding relative to the job that needs to be done or to reclassify populations, there will be a general recognition of the value of this approach by the agencies, Congress, and the involved stakeholders.

Armed with better life history information and clearer, more objective criteria, conservationists may be able to work more effectively to help listed species or stocks recover. As noted earlier, however, lack of recovery in many cases is clearly associated with effects of diverse and intensive human activities. To reinforce an old adage used by Ken Norris (1978), effective management of wildlife ultimately involves effective management of people.

Acknowledgments

We are grateful to D. Laist, R. Mattlin, W. Perrin, J. Powell, R. Reeves, S. Rommel, and R. Wallace for constructive comments on the manuscript; to J. Leiby and J. Quinn for their careful editing; and to B. Brooks and S. Spangle for providing a definition of distinct population segment.

Endocrine Systems

DAVID J. ST. AUBIN
Mystic Aquarium, Connecticut

Endocrine systems function to control physiological and metabolic processes, and integrate these functions to meet specific environmental conditions or chronological needs. The effector substances are termed hormones and are typically produced and released into circulation by specialized cells that are usually localized in small glands. Because of their great potency and ability to broadly influence body functions, hormones are regulated by an exquisite set of negative and positive feedback loops that may link several glands (Fig. 1). For

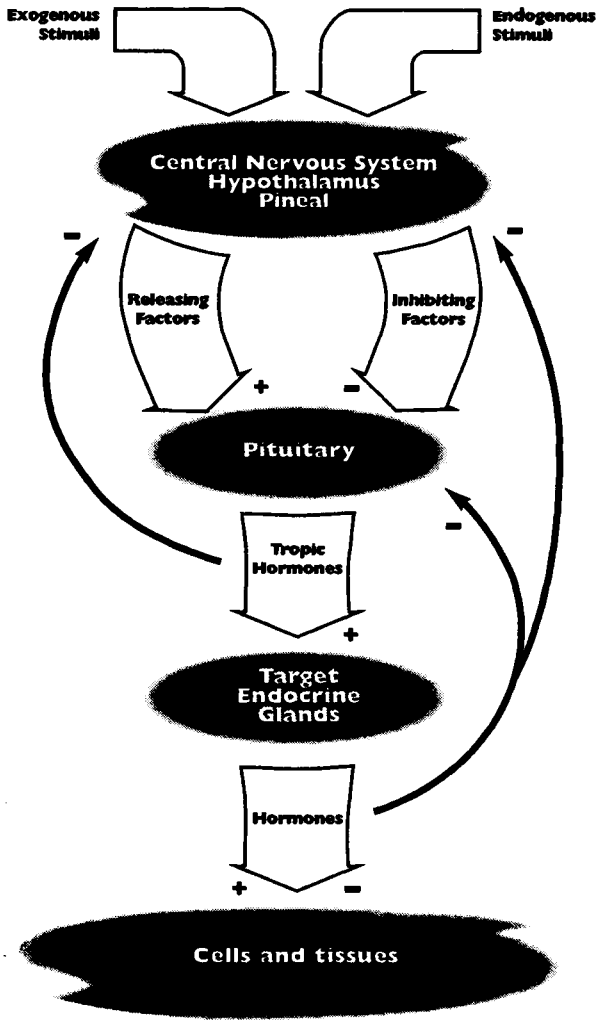

Figure 1 *Schematic representation of stimulatory (+) and inhibitory (−) relationships among principal components of mammalian endocrine systems. Figure by D. Scotti.*

the most part, endocrine systems in marine mammals follow the basic organization and chemical characteristics of other mammals. Nevertheless, it is intriguing to examine how these systems allow marine mammals to meet the peculiar challenges imposed by their environment.

I. Integration of Environmental Cues—Pineal–Hypothalamus–Pituitary

Many species of marine mammals inhabit environments that express drastic seasonal changes in air temperature and light or undergo migrations that produce the same effect. Mysticetes exploit productive cold waters at high latitudes during the long days of summer but retreat to tropical habitats in the fall to bear calves under more forgiving conditions. Day length appears to be an important cue that signals the time to abandon habitats that will soon become ice bound. Pinnipeds, particularly those in polar environments, seasonally partition activities such as breeding and molting to take advantage of favorable conditions that will increase the survival of offspring or allow recovery from fasts necessitated by long periods ashore.

Melatonin is the hormone most commonly associated with photoperiodism in mammals. It is produced primarily by the pineal gland (epiphysis) located above the third ventricle of the brain. Daylight suppresses the production of melatonin, which regulates the activity of the hypothalamus, pituitary, and, indirectly, the gonads and thyroid. Unfortunately, the hormone and its activity have received relatively little attention in the marine mammal literature. This deficit is ironic, as the pineal gland of the newborn southern elephant seal, *Mirounga leonina*, can weigh over 9 g, which is the size of the brain of a hamster, the subject of so much of the research on melatonin.

The exceedingly high plasma levels of melatonin in newborn seals draw attention to the important role of this hormone in the survival of animals born under harsh environmental conditions. Concentrations approach 300,000 pmol/l (69,000 pg/ml) in southern elephant seals at birth, but fall steadily during the ensuing 7–10 days. A similar pattern has been observed in harp, *Pagophilus groenlandicus*, gray, *Halichoerus grypus*, Weddell, *Leptonychotes weddellii*, and northern elephant seals, *M. angustirostris*. It has been postulated that the hormone promotes the generation of the active thyroid hormone triiodothyronine (T_3), which in turn accelerates metabolism and provides the heat necessary to withstand the extreme conditions experienced at the time of birth.

Marked seasonality is evident in the size of the pineal in southern elephant seals. The gland is largest in the winter dark period, and the high circulating levels of melatonin at that time presumably suppress gonadal function; hormone levels are uniformly low during the spring breeding season. A circadian rhythm in hormonal secretion is evident during the winter, but equivocal during the summer. In Weddell seals, at least, the cycle is abolished under continuous natural daylight.

The literature on melatonin in cetaceans is even more sparse. The very presence of a discernible pineal gland had been uncertain, but was eventually identified in a number of cetacean species. Extrapineal sources of melatonin, such as from the retina, likely augment the role of the small gland in integrating photoperiod with metabolic functions. One might expect that polar cetaceans such as belugas, *Delphinapterus leucas*, and narwhals, *Monodon monoceros*, need to entrain their endocrine physiology with seasonal changes marked by day length.

Some of the hypothalamic effects of melatonin are transferred to the pituitary gland or hypophysis, a small, compound structure located at the base of the brain. The glandular portion (adenohypophysis) produces a set of hormones that either directly elicit tissue responses (e.g., growth hormone, prolactin, and gonadotropins) or modulate the activity of other endocrine glands [e.g., adrenocorticotropic hormone (ACTH) and thyrotropin or thyroid-stimulating hormone (TSH)]. Early investigators on whaling vessels were impressed by the size of the pituitary in mysticetes (up to 53.5 g in a blue whale, *Balenoptera musculus*), although on a body weight basis, it is unremarkable. Nevertheless, the abundance of the tissue afforded the opportunity for extensive studies to extract and characterize the principal hypophyseal hormones. Fin whale, *B. physalus*, ACTH

was found to be identical to that of humans, whereas blue whale TSH more closely resembled that of nonprimates. Studies on beluga whales and bottlenose dolphins, *Tursiops truncatus*, have shown that synthetic ACTH and bovine TSH are capable of eliciting expected responses from the target glands, demonstrating at least some homology in the structure of these hormones among various groups of mammals.

II. Regulation of Metabolism—Thyroid

Early investigators were as impressed by the size of the cetacean thyroid as they were by the pituitary, to the degree that large whales were considered as a possible commercial source for thyroxin (T_4), the principal hormone synthesized by the gland. It was not only the size but the proportions of the thyroid that called attention to the importance of this gland in cetaceans; beluga whales have three times more thyroid tissue per unit body weight than a thoroughbred horse, and bottlenose dolphins have nearly twice as much thyroid as do humans (400 mg/kg vs 250 mg/kg). Because thyroid hormones regulate a wide variety of metabolic processes, particularly those associated with energy metabolism, the finding of relatively high circulating levels of thyroid hormones (TH) in some cetaceans compared with humans and other mammals reinforced long-standing notions of elevated metabolic rates in cetaceans. A more critical analysis of both cetacean metabolic rates and concentrations of free thyroid hormones, which are a better index of available hormone, has revised assumptions about hormonally stimulated metabolism as an adaptation to meet the thermal challenges of the marine environment. In pinnipeds, circulating TH levels and the basal metabolic rate are comparable to those in terrestrial mammals, but, surprisingly, their blood TH are lower than in West Indian manatees, *Trichechus manatus*, a species with a distinctly slower metabolism. Assumptions about the metabolic rate cannot be based solely on circulating TH levels.

Thyroid hormones do exhibit some important dynamics during the course of the development and life history of marine mammals. Circulating levels in neonatal phocid seals are understandably high in view of the need for metabolically derived heat until their lanugo coat gains insulating ability and blubber reserves are established. Thereafter, seasonal fluctuations in the blood levels of T_4 and T_3 have been correlated with changing metabolic needs. Marine mammals are well known for their ability to seasonally manage energy stores, enabling them to fast during migration or breeding. The hormonal modulation of energy consumption by tissues can allow for fat deposition, even when the energy intake is low, or mobilization of fat to sustain accelerated growth while feeding.

Thyroid hormones play a role in an important annual event for pinnipeds—the molt. As in other fur-bearing mammals, TH are seasonally elevated to promote hair growth. Controversy in the literature regarding the degree of association between visible molt and thyroid activity in pinnipeds may derive from the difficulty in recognizing when hair growth is actually stimulated by elevated TH. Hair loss, the overt sign of molting, may be enhanced by increased levels of cortisol at a time when T_4 and T_3 levels are low. Cortisol suppresses the secretion of TSH from the pituitary and inhibits the activation of T_4 to T_3. Fluctuating circulating levels of metabolically potent substances such as cortisol and TH during the molt draw attention to how intensely pinnipeds are physiologically affected at that stage of their annual cycle.

Among cetaceans, the seasonality of TH activity has been described for the beluga whale. The summer period of estuarine occupation is characterized by marked elevation in circulating levels of T_4 and T_3 and by histological evidence of intense cellular activity in the thyroid gland. Colloid reserves are depleted by columnar follicular cells, in contrast to the quiescent appearance of the gland in spring and fall when low cuboidal cells surround abundant stores of thyroid hormone. The implications of this burst of thyroid activity are broad, favoring mobilization of blubber and promoting the effects of other agents such as GH. It also coincides with a unique event in beluga epidermis. Cell production is enhanced, presumably under the influence of TH, and superficial turnover is accelerated by the relatively warm (10–15°C) freshwater environment. Taken together, these events constitute a true molt, lacking only the production of a hair coat to be fully analogous to the process in a pinniped. No comparable transformation has been described in any other cetacean; only the rubbing behavior of killer whales, *Orcinus orca*, on the cobbles of Telegraph Cove, British Columbia, hints of a seasonal pulse in epidermal growth. Studies on circulating levels of TH in Atlantic bottlenose dolphins have not revealed significant annual variation, even though the 15°C range of water temperatures experienced by these animals is equivalent to that encountered by belugas.

Reverse T_3 (rT_3) is a metabolically inactive product of T_4 monodeiodination and typically represents one-third to one-half the circulating concentration of T_3 in humans and other mammals. Cetaceans differ from this balance in T_4 metabolism, showing rT_3 levels that are equivalent or up to three times greater than those of T_3. The ratio is particularly skewed in belugas during the time of enhanced thyroid activity. Circulating levels of rT_3 up to 6.7 nmol/liter (440 ng/dl) are the highest observed in any mammal. Belugas may use this pathway to modulate the effects of markedly elevated levels of T_4, although other feedback mechanisms reducing the secretion of TSH would seem to be more efficient. The sensitivity of deiodinating pathways to increases in circulating levels of cortisol in belugas mimics that in laboratory mammals and is evidenced by coincidental elevation in plasma rT_3 and reduction in T_3.

III. Reproduction—Ovary and Testis

Like the molt, reproduction in most marine mammals is a highly seasonal activity. Most notable in this respect are high-latitude pinnipeds. For animals that are only periodically gregarious, synchrony of the reproductive state is critical. As in other mammals, gonadotropins released from the pituitary drive ovarian and testicular activity, resulting in ovulation and spermatogenesis, respectively, and the associated behaviors of receptivity in females and rut in males. In phocids and otariids, fetal development requires considerably less time than the interval that separates the annual congregation of animals for parturition and breeding. Delayed implantation of the blasto-

cyst therefore serves as a useful strategy to allow parturition to occur at the time of year most appropriate for successful pup rearing. Day length likely serves as a critical cue for implantation, although the sequence of hormonal events that trigger implantation has not yet been documented.

Reproductive cycles in cetaceans are highly variable, with some falling into relatively narrow time frames, such as in belugas, whereas others show very little seasonality. Bottlenose dolphins, which have been studied extensively in captivity, demonstrate some of the variability possible within a species. Some females may be seasonally polyestrous, with up to five cycles per year, whereas others may be anestrous for a year or more. The presence of males has an inconsistent effect, but there is the impression that ovulation may be induced. Testosterone levels in males tend to be higher in spring and fall, roughly coinciding with calving peaks (gestation is approximately 12 months), although individual males show varying patterns from year to year and are capable of impregnating females in almost any month. Seasonal constraints on breeding would appear to be less critical in tropical and subtemperate species than in those exploiting more polar habitats. An exception would be river dolphins exposed to drastic seasonal fluctuations in habitat associated with dry and rainy seasons. Synchrony of reproductive activity, and by inference reproductive hormones, is likely an important consideration.

IV. Fluid and Electrolyte Regulation—Pituitary and Adrenal

For a mammal, the marine environment represents a number of challenges, one of which is to obtain water while eliminating potentially life-threatening salt burdens. Renal adaptations and water balance are considered elsewhere in this volume; this discussion focuses on hormonal mechanisms for maintaining appropriate hydration and electrolyte concentrations. Marine mammals possess all the recognized endocrine systems for managing fluid and electrolytes. Antidiuretic hormone (ADH), also known in some species as arginine vasopressin (AVP) from the posterior pituitary (neurohypophysis), retains water, whereas aldosterone from the zona glomerulosa of the adrenal reclaims sodium. The former would seem to be highly desirable, whereas the latter is of questionable value considering the principal needs of these animals. It is paradoxical that studies on vasopressin have produced a conflicting picture of its role, whereas aldosterone is essential in preventing sometimes fatal hyponatremia in phocid seals.

In fasting northern elephant seal pups, AVP levels in blood decline over time, an unexpected finding in an animal needing to conserve water. Nevertheless, urinary output also falls despite the low circulating levels of AVP. Gray seals show a more typical response, with concurrently rising AVP and urinary osmolality. However, water loading in these animals does not produce the expected decrease in circulating AVP, even though urine volume rises and osmolality decreases. Early investigations in bottlenose dolphins failed to identify a significant role for AVP in this species. Manatees have higher vasopressin levels when in brackish water than in freshwater, presumably as an aid to conserving body water in the former environment.

Despite its apparent redundancy in the marine environment, aldosterone has been detected in all marine mammal species studied. The zona glomerulosa is particularly well developed in young seals, suggesting the need for a fully functional system for salt regulation at birth. Plasma levels in bottlenose dolphins and California sea lions, *Zalophus californianus*, are correlated with changes in renin activity, an important regulator of aldosterone secretion. Sodium restriction causes inconsistent changes in aldosterone in ringed seals, although levels are periodically elevated above those in controls. The freshwater-dwelling Baikal seal, *Pusa sibirica*, is more efficient in sodium conservation than its close marine relative, the ringed seal, *P. hispida*. Aldosterone levels in manatees vary according to their environment, with higher levels favoring sodium conservation when in freshwater. Some species of phocid seals are prone to hyponatremia, apparently when the zona glomerulosa has exhausted its ability to produce aldosterone. Hyponatremia can occur even when aldosterone levels are within the normal range, possibly as a result of a condition known as "aldosterone escape" in which tubular epithelial cells of the kidney lose their sensitivity to the hormone after prolonged stimulation.

Studies have identified atrial natriuretic peptide in several pinniped species. Produced within cardiomyocytes and secreted under the influence of blood volumetric expansion, this hormone results in natriuresis as a mechanism to enhance fluid loss and thereby restore normal blood volume. Its role in managing electrolyte burdens in marine mammals is still poorly understood, although its secretion in the harbor seal, *Phoca vitulina*, at least, appears to be less sensitive to volumetric stimuli than has been found in other mammals. The large intravascular capacity represented by distensible sinuses in these animals likely dampens the atrial stretch required to induce changes in circulating levels of the hormone.

V. Stress Response—Adrenal

Adrenal morphology in marine mammals follows the same pattern of cortical and medullary stratification as in terrestrial mammals, although the cetacean cortex is more highly lobulated. The importance of adrenal function in marine mammals is highlighted by the fact that it is one of the few tissues to which blood supply is maintained during a dive. Cortisol is the principal glucocorticoid in marine mammals; corticosterone is also secreted, but typically represents less than 10% of the circulating level of cortisol. Weddell seals are distinguished by excessively high circulating levels of cortisol, averaging 1600–2200 nmol/l (60–80 μg/dl), at least an order of magnitude greater than in humans and other terrestrial and marine mammals. The underlying cause of this variation is unclear, although it has been determined that concentrations of cortisol-binding proteins are proportionately high in this species, leaving only a small fraction of metabolically available hormone.

Glucocorticoid secretion is under the influence of ACTH from the adenohypophysis (Fig. 2) and has been evaluated using synthetic analogs of ACTH in a variety of marine mammal species. In pinnipeds, the cortical response represented by elevations in circulating levels of cortisol follows that of most terrestrial mammals, resulting in two- to fourfold increases within 15–30 min and persisting for up to 90 min. Cetaceans

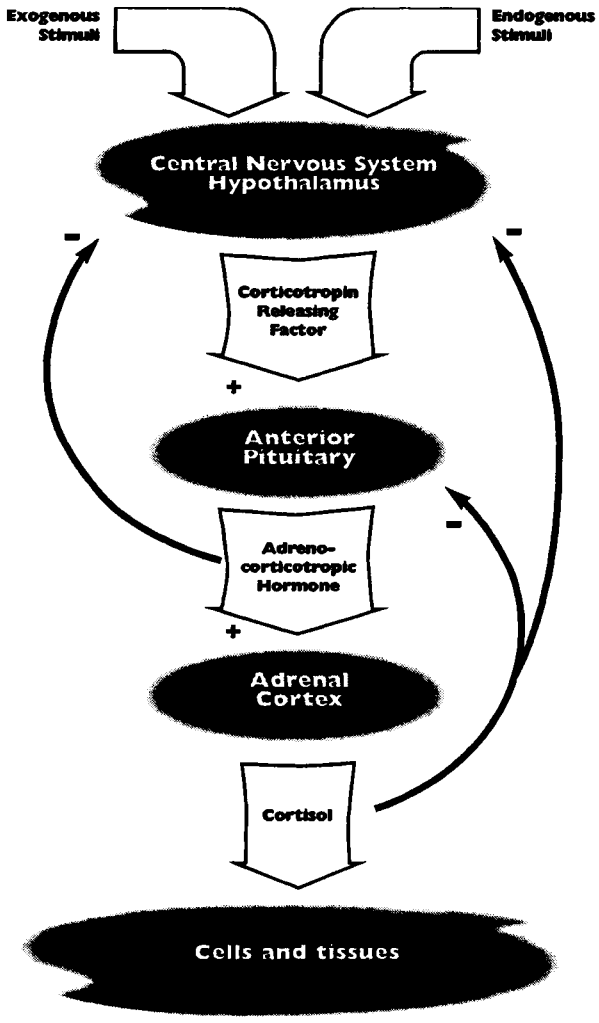

Figure 2 *The secretion of glucocorticoids (e.g., cortisol) from the adrenal cortex is initiated when a stimulated central nervous system produces corticotropin-releasing factor (CRF), which causes the secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary (adenohypophysis). Increased circulating levels of cortisol inhibit the further secretion of CRF and ACTH, as ACTH also inhibits the production of CRF, thus preventing excessive and prolonged elevation of cortisol in the blood. Figure by D. Scotti.*

show a different pattern. Resting levels of cortisol in belugas and bottlenose dolphins are relatively low, generally in the range of 50–100 nmol/l (2–4 μg/dl), and ACTH stimulation results in only modest elevations, usually less than twofold. Nevertheless, several glucocorticoid-mediated changes, such as alterations in circulating white blood cells (lymphopenia, eosinopenia, and neutrophilia), decreased T_4 and T_3, and elevated rT_3, are observed following ACTH stimulation, suggesting that only mild changes in cortisol are necessary to produce the physiologically appropriate effects. High cortisol availability in plasma or enhanced sensitivity of tissue receptors could account for this fundamental difference.

Adrenocortical stimulation in marine mammals produces an uncharacteristic response in aldosterone secretion. Cetaceans and phocid seals consistently show three- to fivefold increases in circulating levels of aldosterone following ACTH administration; terrestrial mammals, including humans, have less than half that response. One possible explanation lies in the development of hyponatremia in chronically stressed phocid seals. ACTH stimulation in these subjects fails to elicit an aldosterone response, presumably because of exhaustion of the chronically stimulated zona glomerulosa of the adrenal. Aldosterone's participation in the stress response in phocids suggests the need for sodium conservation at such times. The parallel finding of ACTH-stimulated aldosterone secretion in belugas and bottlenose dolphins draws attention to a common need and convergent adaptation to regulate electrolytes during stress. The advantage conferred by this mechanism is that sodium resorption should enhance water conservation, which would be important in an animal that might be deprived, in the short term at least, of dietary water.

The few studies on catecholamine physiology that have been undertaken in marine mammals have focused on the dive response. In hooded and Weddell seals, epinephrine induces splenic contraction, releasing a reservoir of stored erythrocytes and enhancing the aerobic dive capacity of the animal. Both epinephrine and norepinephrine increase during dives longer than a few minutes in Weddell seals and rapidly return to normal levels at the conclusion of the dive. These changes suggest that catecholamines play an integral role in the management of oxygen reserves during diving.

VI. Glucose Regulation—Endocrine Pancreas

Glucose homeostasis is managed as in terrestrial mammals by insulin and glucagon, secreted by pancreatic islet cells. Insulin promotes the uptake of glucose into cells, whereas glucagon has the opposite effect. The literature on these two hormones in marine mammals is sparse. The ratio of insulin to glucagon is typically low, consistent with a metabolism geared to producing glucose from a variety of precursors (gluconeogenesis) rather than deriving it from the small amount of carbohydrates typically found in their diet. During diving, glucose delivery to the brain is critical, and circulating levels of this energy source are maintained by the falling ratio of insulin to glucagon. This also contributes to hyperglycemia, or elevated blood sugar, at the end of the dive.

VII. Summary

As they have with a number of physiological systems, marine mammals have refined basic mammalian endocrine mechanisms to meet the demands imposed by their environment. Unusually high blood levels of melatonin in young seals, particularly elephant seals, act in conjunction with thyroid hormones to stimulate metabolism during the critical early stages of life in cold environments. Distinct seasonal cycles in thyroid, adrenal, and reproductive hormones entrain metabolism, molt, breeding, and parturition to optimize survival. Marine mammals have no unusually developed hormonal mechanisms for sodium excretion or water retention, which would be an asset in their hypertonic saline environment, but do show adaptive increases in aldosterone to conserve

sodium when in freshwater. The stress response of pinnipeds and cetaceans includes elevations in aldosterone, perhaps as a means of securing water and electrolyte balance during challenging times.

Energetics

DANIEL P. COSTA
University of California, Santa Cruz

Energetics provides a method to quantitatively assess the effort animals spend acquiring resources, as well as the relative way in which they allocate those resources. Energy flow models are analogous to cost-benefit models used in economics. Costs take the form of energy expended to acquire and process prey, and to maintain body functions. The energetic benefits are manifest as the food energy used for growth and reproduction. By measuring the various avenues of energy transfer, we can determine how animals organize their daily or seasonal activities and how they prioritize their behaviors. Thus, energy flow can be described as what goes into the animal as food and what comes out in the form of growth, waste, or metabolic work. Survival requires a positive balance between the costs of maintenance and the acquisition of food energy. If a marine mammal cannot compensate for decreases in energy acquisition, it must either reduce its overall rate of energy expenditure or utilize stored energy reserves. Conversely, in order to grow and reproduce, animals must obtain more energy than is just needed to survive. Marine mammals undergo profound variations in this dynamic equilibrium as they frequently go into prolonged negative energy balance while fasting during migration, reproduction or molt.
